When a mobile station enters a GSM network for the first time, the IMEI is transmitted for determination in which AUC/HLR subscriber data is stored. The MSC/VLR of the visited network asks for and stores a security triplet (a unique random number RAND, a signed response SRES, a ciphering key Kc) from the AUC/HLR. SRES and Kc are calculated from RAND with Ki.

Subscriber authentication:

- RAND is sent to the mobile station.
- SRES' and Kc' are calculated from RAND with Ki.
- SRES' is sent back to MSC/VLR.
- Authenticated if SRES=SRES'.

Kc=Kc' is used for radio link encryption/decryption.

After the initial registration, IMSI is stored in the VLR. A TMSI (temporary mobile subscriber identity) is generated, transmitted back to the mobile station, stored in the SIM card, and used for future subscriber identification in the visited network.

DECT is a cellular system and a common standard for cordless telephony, messaging, and data transmission standardized by ETSI (European Telecommunications Standards Institute). DECT is similar to GSM, but cell ranges are shorter (DECT, 2006).

DECT uses several advanced digital radio techniques for efficient radio spectrum utilization. It enables high speech quality and security with low radio interference risks and low-power technology. Mobility management, responsible for DECT communication security, consists of procedures for *identity, authentication, location, access rights, key allocation, parameter retrieval,* and *ciphering* (Umar, 2004).

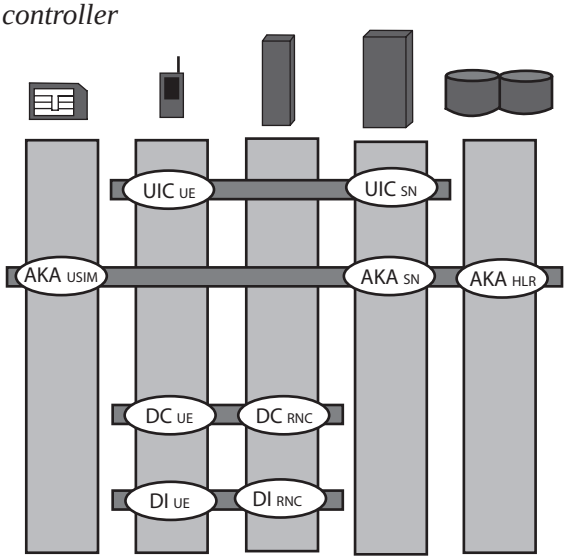
2.5 Generation

The GPRS (2.5G) infrastructure equals GSM. TSMI is replaced by P-TMSI (packet TMSI) and by P-TMSI signature as alternate identities. Mapping between IP addresses and IMSI is generated in the HLR GPRS Register. GPRS authentication is performed by SGSN (serving GPRS support node). As a consequence, user data and signaling are encrypted all the way from the mobile station to the SGSN. Tunneling, firewalls, and private IP techniques are used. IP addresses are assigned after authentication and encryption algorithm negotiations.

Third Generation

UMTS, Universal Mobile Telecommunications System, a standard for third-generation (3G) systems for mobile communication, referred to as International Mobile Telecommunications 2000 (IMT-2000) and initiated by the International Telecommunication Union (ITU), is presently being developed by the Third Generation Partnership Project (3GPP).

Figure 2. UMTS functional security architecture; UE is user equipment and RNC is radio network controller



The UMTS security architecture is based on 2G/2.5G security. Some GSM security features have been improved and some new features have been added. The UMTS security mechanisms are (see Figure 2): user identity confidentiality (UIC), authentication and key agreement (AKA), confidentiality of user and signaling data (DC), and integrity of signaling data (DI). See Lu (2002) for UMTS security details.

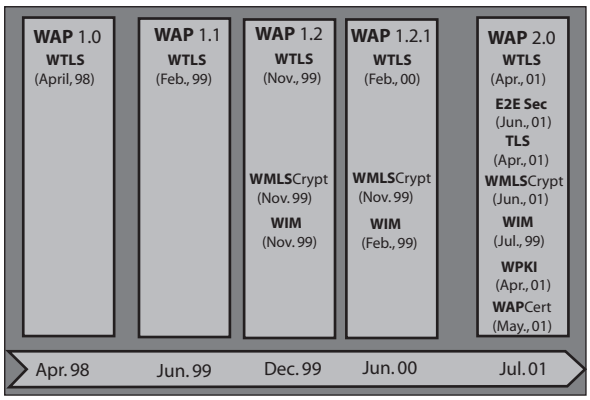
WAP

WAP (wireless application protocol) is an open mobile device application standard. WAP security protocols and specifications are being developed by the WAP Forum (Open Mobile Alliance, 2006). The evolution of WAP security specifications is shown in Figure 3.

WTLS/TLS/SSL

SSL/TLS are TCP-based security protocols for communication in client/server applications. WAP 2.0 adopts TLS as security protocol and supports the tunneling of SSL/TLS sessions through a WAP/WAP proxy. TLS/SSL in WAP 2.0 is a complement to the similar UDP-based WTLS protocol in earlier WAP versions. Server authentication and mutual authentication are options in WTLS/TLS/SSL-protected WAP applications.

Figure 3. The development of WAP security specifications



WMLScript Crypto Library, WIM, and WPKI

The lack of non-repudiation services and end-user authentication was addressed in WAP 1.2. The WMLScript (Wireless Markup Language Script) Crypto Library provides cryptographic functionality for WAP clients. WAP identity module (WIM) is used in WTLS and application-level security functions. A WIM stores and processes user authentication information, such as private keys. A WIM implementation example is a mobile phone S/WIM card (combined SIM and WIM). WPKI (wireless public key infrastructure) is a mobile environment PKI supported since WAP 2.0 (Open Mobile Alliance, 2006).

i-Mode

i-mode is a Japanese competitor to WAP for m-commerce. i-mode security features are:

- protection of the radio link between the i-mode handset and the base station,
- encryption/authentication of data transmitted between i-mode mobile devices and Web sites, and
- protection of private network links between the i-mode center and special service providers like banks.

The radio link is protected using SSL and other protocols, which are not public. Security of Web site connections and private network links are based on SSL. Mutual certificate authentication is supported (Umar, 2004).

Bluetooth

Bluetooth provides wireless short-distance transmission of data and voice signals between

Table 1. Bluetooth service levels

	Authorization	Authentication	Encryption
Trusted	Yes	Yes	Yes
Untrusted	No	Yes	Yes
Unknown	No	No	Yes

electronic devices. The specifications are defined by Bluetooth SIG (2006). The security is based on *authentication, authorization,* and *encryption.* The *security modes* are:

1. No security measures,
2. Security measures based on authorization, and
3. Authentication and encryption.

Authentication

Bluetooth device authentication is a unidirectional or mutual challenge/response process. Secret keys, called *link keys,* are generated either dynamically or by pairing. For dynamic link key generation, a passkey—the same passkey—must be entered in both connecting devices each time a connection is established. In pairing, a long-term stored link key is generated from a user-entered passkey, which can be automatically used in several connection sessions between the same devices.

Authorization

In authorization, a Bluetooth device determines whether or not another device is allowed access to a particular service. Levels of trust are *trusted*, *untrusted*, or *unknown*. Service levels are shown in Table 1.

Encryption

Bluetooth data transmission uses 128-bit encryption. Encrypted data can only be viewed by a device owning the proper decryption key. The encryption key is based on the link key.

ZigBee

ZigBee is a low-cost, low-power communications standard for wireless data communication in home and building automation. The ZigBee stack architecture is based on the standard OSI model. The IEEE 802.15.4-2003 standard defines the physical (PHY) layer and the medium access control (MAC) sub-layer. The ZigBee Alliance builds on this foundation by providing the network (NWK) layer and a framework for the application layer with: the application support sub-layer (APS), ZigBee device objects (ZDO), and manufacturer-defined application objects.

Security services are defined for key establishment, key transport, frame protection, and device management. The MAC, NWK, and APS layers are responsible for the secure transport of their respective frames. Data encryption uses the symmetric key 128-bit AES algorithm. Frame integrity is protected, since frames cannot be modified by parties without cryptographic keys. Replayed data frames are rejected by a frame freshness verification function of the NWK layer. Furthermore, the APS sub-layer establishes and maintains security relationships. ZDO manages the security policies and the security configuration of a device. Access control uses a list of trusted devices maintained by a ZDO (ZigBee Alliance, 2004).

WLAN

Broadband mobile communication is supported by a WLAN, which gives mobile users LAN connectivity through a high-speed radio link. Major WLAN security standards are (Pulkkis, Grahn, Karlsson, Martikainen, & Daniel, 2005): IEEE 802.11/WEP, WPA, and IEEE 802.11i.

WEP is not recommended due to security flaws. Data encryption is based on static encryption keys, and no user authentication mechanisms are speci-

fied. *WPA* addresses the WEP vulnerabilities and is based on IEEE 802.11i (see Figure 4).

The main features of WPA are:

- Temporal key integrity protocol (TKIP) to provide dynamical and automatically changed encryption keys, and
- IEEE 802.1X and EAP (extended authentication protocol) to provide strong user authentication.

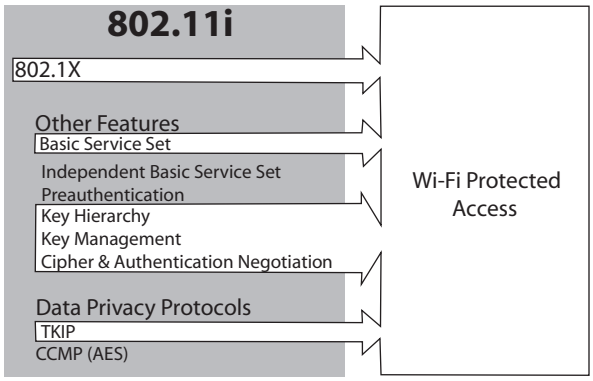
CCMP (cipher block chaining message authentication protocol) is an IEEE 802.11i protocol that uses the AES (advanced encryption standard) to provide stronger encryption than TKIP.

WiMax

WiMax is a new technology for wireless broadband Internet access. The MAC layer of the WiMax network stack has a security sub-layer with (Puthenkulam & Yin, 2005):

- A base station device and mobile user authentication capability based on the EAP protocol, X.509 certificates, and AAA servers (Radius, Diameter);
- Encryption key management using the privacy key management protocol (PKM) v2;
- AES-CCM authenticated encryption of all data communication—the Encryption Key Refresh Mechanism supports high data rates; and
- CMAC (cipher-based message authentication code) and HMAC (hash-based message authentication code), which handle control message integrity protection.

Figure 4. IEEE 802.11i features in WPA



Wireless USB

An USB wire provides two security services: (1) a wanted interconnection of two devices is created, and (2) all data in transit is protected from casual observation or malicious modification by external parties.

The goal of Wireless USB security is to provide analogous security services. Hosts and wirelessly connected devices are required to authenticate each other to avoid man-in-the-middle attacks. Data communication between a host and a wirelessly connected device is confidential and integrity-checked by AES-128/CCM encryption. Secret encryption keys are shared by mutually authenticated hosts and wirelessly connected devices (Wireless, 2005).

Satellite Communication Technology

A communication satellite permits two or more earth stations to send radio messages to each other over far distances. For satellite communication security it is necessary that earth stations have significant physical security, and RF (radio frequency) communication channels between satellites and earth stations are protected.

Satellite communications are normally secured by scrambling satellite signals using cryptography or transmitting same signals over several frequencies. The data bits are basically transmitted on different signals based on a secret scheme. The receiver of a signal must thus be aware of the secret scheme. Additional security protocols like IPSec can be used to encrypt radio messages. However, such protocols slow down

data transmission. The main challenge is thus to find a good balance between performance and security (Umar, 2004).

FUTURE TRENDS

Privacy, security, and trust issues are and will be of major importance. The growth of the Internet and m-commerce will dramatically increase the amount of personal and corporate information that can be captured or modified. In the near future ubiquitous computing systems will accentuate this trend. We can likewise expect an increase in privacy and security risks, not only with the emergence of mobile and wireless devices, but also with sensor-based systems, wireless networking, and embedded devices. Ubiquitous computing technologies will probably suffer from the same sorts of unforeseen vulnerabilities that met the Internet society.

CONCLUSION

Mobile terminals face security threats due to openness. Platforms are open for external software and content. Malicious software, like Trojan horses, viruses, and worms, has started to emerge. Fine-grained software authorization has been proposed. Downloaded software may then access particular resources only through user authorization. OS implementation vulnerability still remains a challenge because of difficulties in minimizing OS code running in privileged mode. Integrated hardware solutions may be the solution.

Wireless security architectures have many options, and many standards/protocols addressing wireless security are quite recent, especially standards/protocols based on public key cryptography. Therefore more practical experience from the use of these protocols/standards in mobile computing is needed for reliable estimation of the provided security.

Chapter 7.8
Security Architectures for B3G Mobile Networks

Christoforos Ntantogian
University of Athens, Greece

Christos Xenakis
University of Piraeus, Greece

ABSTRACT

The integration of heterogeneous mobile/wireless networks using an IP-based core network materializes the beyond third generation (B3G) mobile networks. Along with a variety of new perspectives, the new network model raises new security concerns, mainly, because of the complexity of the deployed architecture and the heterogeneity of the employed technologies. In this chapter, we examine and analyze the security architectures and the related security protocols, which are employed in B3G networks focusing on their functionality and the supported security services. The objectives of these protocols are to protect the involved parties and the data exchanged among them. To achieve these, they employ mechanisms that provide mutual authentication as well as ensure the confidentiality and integrity of the data transferred over the wireless interface and specific parts of the core network. Finally, based on the analysis of the security mechanisms, we present a comparison of them that aims at highlighting the deployment advantages of each one and classifies the latter in terms of: (1) security, (2) mobility, and (3) reliability.

INTRODUCTION

The evolution and successful deployment of wireless LANs (WLANs) worldwide has yielded a demand to integrate them with third generation (3G) mobile networks. The key goal of this integration is to develop heterogeneous mobile data networks, named as beyond 3G (B3G) networks, capable of supporting ubiquitous computing. Currently, the network architecture (3rd Generation Partnership Project [3GPP] TS 23.234, 2006) that integrates 3G and WLAN specifies two different access scenarios: (1) the *WLAN Direct IP Access* and (2) the *WLAN 3GPP IP Access.* The first scenario provides to a user an IP connection to the public Internet or to an intranet via the WLAN access network (WLAN-AN), while the second allows a user to connect to packet switch (PS) based services (such

as wireless application protocol [WAP], mobile multimedia services [MMS], location-based services [LBS] etc.) or to the public Internet, through the 3G public land mobile network (PLMN).

Along with a variety of new perspectives, the new network model (3G-WLAN) raises new security concerns, mainly, because of the complexity of the deployed architecture and the heterogeneity of the employed technologies. In addition, new security vulnerabilities are emerging, which might be exploited by adversaries to perform malicious actions that result in fraud attacks, inappropriate resource management, and loss of revenue. Thus, the proper design and a comprehensive evaluation of the security mechanisms used in the 3G-WLAN network architecture is of vital importance for the effective integration of the different technologies in a secure manner.

In this chapter we examine and analyze the security architectures and the related security protocols, which are employed in B3G, focusing on their functionality and the supported security services for both WLAN Direct IP Access and 3GPP IP Access scenarios. Each access scenario (i.e., WLAN Direct Access and WLAN 3GPP IP Access) in B3G networks incorporates a specific security architecture, which aims at protecting the involved parties (i.e., the mobile users, the WLAN, and the 3G network) and the data exchanged among them. We elaborate on the various security protocols of the B3G security architectures that provide mutual authentication (i.e., user and network authentication) as well as confidentiality and integrity services to the data transferred over the air interface of the deployed WLANs and specific parts of the core network. Finally, based on the analysis of the two access scenarios and the security architecture that each one employs, we present a comparison of them. This comparison aims at highlighting the deployment advantages of each scenario and classifying them in terms of: (1) security, (2) mobility, and (3) reliability.

The rest of this chapter is organized as follows. The next section outlines the B3G network architectures and presents the WLAN Direct IP Access and the 3GPP IP Access scenarios. The third section elaborates on the B3G security architectures analyzing the related security protocols for each scenario. The fourth section compares the security architectures and consequently, the two access scenarios. Finally, the fifth section contains the conclusions.

BACKGROUND

The B3G Network Architecture

As shown in Figure 1, the B3G network architecture includes three individual networks: (I) the WLAN-AN, (II) the visited 3G PLMN, and (III) the home 3G PLMN. Note that Figure 1 illustrates the architecture for a general case where the WLAN is not directly connected to the user's home 3G PLMN. The WLAN-AN includes the wireless access points (APs), the network access servers (NAS), the authentication, authorization, accounting (AAA) proxy (Laat, Gross, Gommans, Vollbrecht, & Spence, 2000), and the WLAN-access gateway (WLAN-AG). The wireless APs provide connectivity to mobile users and act like AAA clients, which communicate with an AAA proxy via the Diameter (Calhoun, Loughney, Guttman, Zorn, & Arkko, 2003) or the Radius (Rigney, Rubens, Simpson, & Willens, 1997) protocol to convey user subscription and authentication information. The AAA proxy relays AAA information between the WLAN and the home 3G PLMN. The NAS allows only legitimate users to have access to the public Internet, and finally, the WLAN-AG is a gateway to 3G PLMN networks. It is assumed that WLAN is based on the IEEE 802.11 standard (IEEE std 802.11, 1999).

On the other hand, the visited 3G PLMN includes an AAA proxy that forwards AAA information to the AAA server (located in the home 3G PLMN), and a wireless access gateway (WAG), which is a data gateway that routes users' data to

the home 3G PLMN. On the other hand, the home 3G PLMN includes the AAA server, the packed data gateway (PDG) and the core network elements of the universal mobile telecommunications system (UMTS), such as the home subscriber service (HSS) or the home location register (HLR), the Gateway GPRS support node (GGSN) and the Serving GPRS support node (SGSN). The AAA server retrieves authentication information from the HSS/HLR and validates authentication credentials provided by users. The PDG routes user data traffic between a user and an external packet data network, which is selected based on the 3G PS-services requested by the user. The latter identifies these services by means of a WLAN-access point name (W-APN), which represents a reference point to the external IP network that supports the PS services to be accessed by the user.

As mentioned previously, the integrated architecture of B3G networks specifies two different network access scenarios: (1) the WLAN direct IP access and (2) the WLAN 3GPP IP Access. The first scenario provides to a user connection to the public Internet or to an intranet via the WLAN-AN. In this scenario both the user and the network are authenticated to each other using the extensible authentication protocol method for GSM subscriber identity modules (EAP-SIM) (Haverinen & Saloway, 2006) or the Extensible Authentication Protocol-Authentication and Key Agreement (EAP-AKA) (Arkko & Haverinen, 2006) protocol. Moreover, in this scenario, the confidentiality and

Figure 1. The B3G network architecture

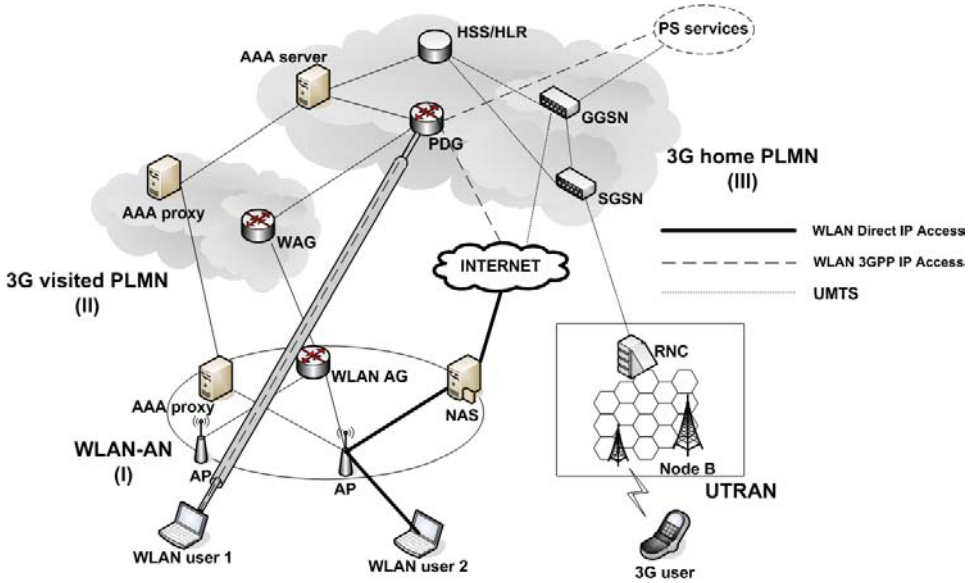

Table 1. 3G-WLAN interworking security mechanisms

Security	*WLAN Direct IP Access*	*3GPP IP Access*
Authentication	EAP-SIM or EAP-AKA	IKEv2 with EAP-SIM or EAP-AKA
Data protection	CCMP or TKIP protocol	IPsec based VPN tunnel using the ESP protocol

CCMP = Counter-Mode/CBC-Mac Protocol TKIP = Temporal Key Integrity Protocol

integrity of users data transferred over the air interface is ensured by the 802.11i security framework (IEEE std 802.11i, 2004). On the other hand, the WLAN 3GPP IP Access scenario allows a WLAN user to connect to the PS services (like WAP, MMS, LBS, etc.) or to the public Internet through the 3G PLMN. In this scenario, the user is authenticated to the 3G PLMN using the EAP-SIM or alternatively the EAP-AKA protocol encapsulated within IKEv2 (Kaufman, 2005) messages. The execution of IKEv2 is also used for the establishment of an IP security (Ipsec)-based virtual private network (VPN) (Kent & Atkinson, 1998a) tunnel between the user and the PDG that provides confidentiality and integrity services to the data exchanged between them (see Figure 1). Table 1 summarizes the security protocols employed in each access scenario.

SECURITY ARCHITECTURES FOR B3G NETWORKS

Each network access scenario (i.e., WLAN direct access and WLAN 3GPP IP access) in B3G networks incorporates a specific security architecture, which aims at protecting the involved parties (i.e., the mobile users, the WLAN, and the 3G network) and the data exchanged among them. These architectures (3GPP TS 23.234, 2006) consist of various security protocols that provide mutual authentication (i.e., user and network authentication) as well as confidentiality and integrity services to the data sent over the air interface of the deployed WLANs and specific parts of the core network. In the following, the security architectures and the involved security protocols, which are employed in B3G networks, are presented and analyzed focusing on their functionality and the supported security services.

WLAN Direct IP Access Scenario

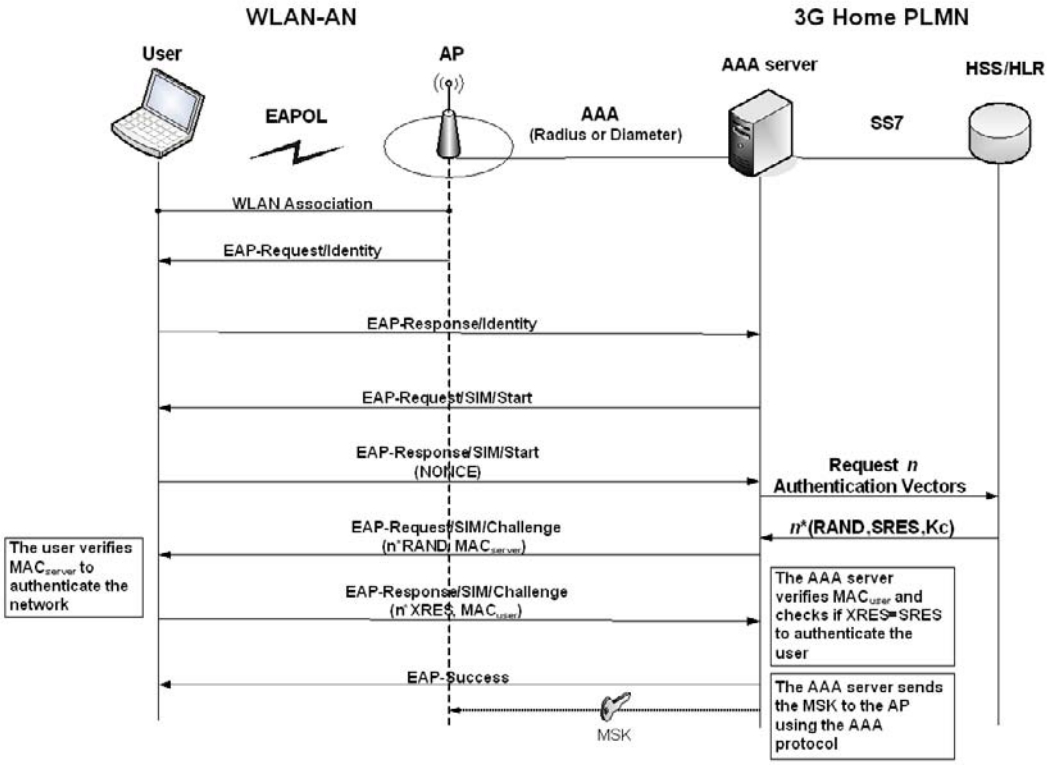
In the WLAN Direct IP Access scenario, both the user and the network are authenticated to each other using EAP-SIM or EAP-AKA, which are based on the 802.1X port access control (IEEE std 802.1X, 2001). After a successful authentication, the user obtains an IP address from the WLAN-AN and then, he/she gets access to the public Internet or an intranet, depending on the requested service. In this scenario, the confidentiality and integrity of user's data conveyed over the air interface of WLAN (IEEE std 802.11, 1999) are ensured by 802.11i (IEEE std 802.11i, 2004), which is analyzed next.

Authentication in WLAN Direct IP Access

The specific security protocol (i.e., EAP-AKA or EAP-SIM) that will be used for mutual authentication between the user and the network depends on the user's subscription. If the user possesses a UMTS subscribers identity module (USIM) card (3GPP TS 22.100, 2001), then, the EAP-AKA protocol is employed. Otherwise, EAP-SIM is used in cases that the user has a SIM-card (European Telecommunications Standards Institute [ETSI] TS 100 922, 1999) of global system for mobile communications (GSM)/general packet radio service (GPRS) (3GPP TS 0.3.6, 2002). When the AAA server receives the user's identity, it fetches from the HSS/HLR the user's profile in order to determine the employed authentication protocol that will be employed (i.e., EAP-SIM or EAP-AKA). In the following, we analyze the functionality of these two protocols focusing on the security services that each one provides.

EAP-SIM. EAP-SIM (Haverinen & Saloway, 2006) provides mutual authentication in a network environment that integrates 3G and WLANs using the credentials included in a SIM-card of a GSM/GPRS subscription. It involves a user, an AAA client (which is actually a wireless AP), and an AAA server that obtains authentication information (i.e., authentication triplets) from the HSS/HLR of the

Figure 2. The EAP-SIM authentication and session key agreement procedure



network where the user is subscribed (see Figure 2). EAP-SIM incorporates two basic enhancements that eliminate known security weaknesses of the authentication and key agreement procedure of GSM/GPRS (Haverinen & Saloway, 2006). First, the keys used in EAP-SIM are enhanced to have 128-bits security, in contrast to the 64-bit security of the original GSM/GPRS keys. Second, EAP-SIM supports mutual authentication, in contrast to the GSM/GPRS authentication, which performs only user to network authentication.

For the generation of stronger keys, the EAP-SIM protocol combines *n* (*n*=2 or *n*=3) individual random challenge (RANDs) that result in the derivation of *n* session keys, Kc. These keys are combined with a random number (NONCE payload), the user identity and other context-related information in order to generate the master key (*MK*) of the EAP-SIM protocol, as shown in the following formula:

$$MK = SHA1(Identity | n*Kc | NONCE | Version\ List | Selected\ Version)^{1}, \quad (1)$$

where SHA1 is a hash function (Eastlake & Jones, 2001). In the sequel, the produced key *MK* is fed into a pseudo random function (prf) that generates other keys used in EAP-SIM. From these keys the most important are: (1) the master session key (*MSK*), which is used in 802.11i to generate the encryption keys, as described later on, and (2) the *K_auth* key, which is used in EAP-SIM for the generation of keyed message authentication codes (MACs) for authentication purposes.

Figure 2 shows the message exchange of EAP-SIM between the user and the AAA server, which

is analyzed next. Note that the user communicates with the wireless AP via the EAP over LAN (EAPOL) protocol (IEEE std 802.1X, 2004).

- First, the user associates with the wireless AP and the latter sends an EAP-Request/Identity message to the user asking for his/her identity.
- The user responds with a message (EAP-Response/Identity) that includes his/her identity in the format of network access identifier (NAI) (Aboba & Beadles, 1999). This identity can be either the International Mobile Subscriber Identity (IMSI), or a temporary identity (i.e., pseudonym).
- Knowing the user's identity, the AAA server issues an EAP-Request/SIM/Start message, which actually starts the authentication procedure.
- The user sends back an EAP-Response/SIM/Start message that includes a nonce parameter (NONCE), which is the user's challenge to the network.
- Upon receiving this message, the AAA server communicates with HSS/HLR and obtains *n* (*n*=2 or *n*=3) authentication triplets (RAND, SRES, Kc) for the specific user (the holder of the SIM-card). The generation of the GSM authentication triplets is based on a permanent, pre-shared (between the user and the network) secret key, *Ki*, which is assigned to the user when the latter is subscribed to the GSM/GPRS network.
- Then, the AAA server sends to the user an EAP-Request/SIM/Challenge message, which contains the *n* RANDs and the MAC_{server} of the message payload, which is calculated using the *K_auth* key as follows:

$$MAC_{server}=HMAC\_SHA1_{K\_auth}(EAP\text{-}Request/SIM/Challenge(n*RAND)|\ NONCE)^{2}, \quad (2)$$

where *NONCE* is the nonce sent by the user to the AAA server, and HMAC-SHA1 (Krawczyk, Bellare, & Canetti, 1997) is the MAC algorithm that generates the keyed hash value. Before the calculation of the MAC_{server} value, the AAA server must first generate the *MK* key (see Eq. 1), and, subsequently, the *K_auth* and *MSK* keys.

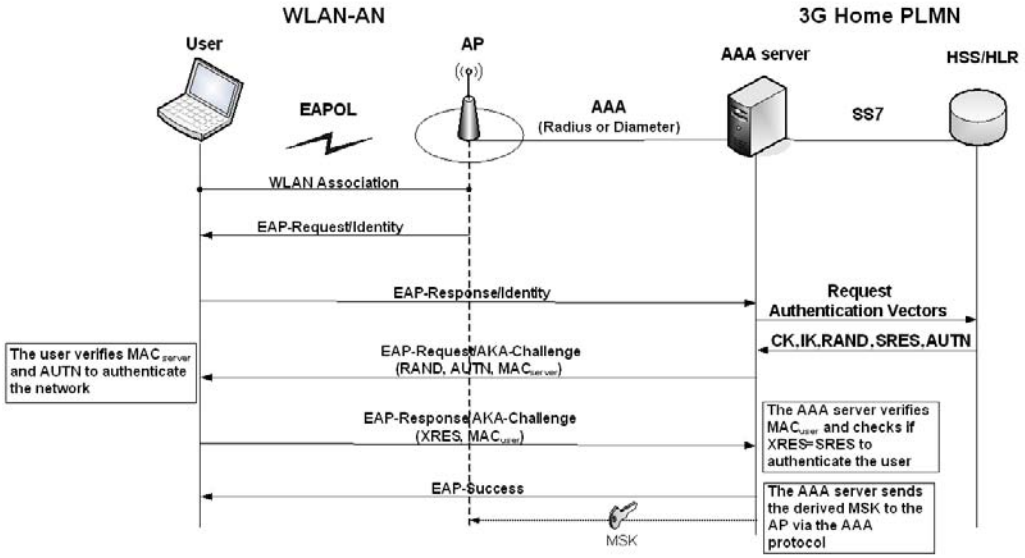
- Upon receiving the EAP-Request/SIM/Challenge, the user executes the GSM/GPRS authentication algorithms *n* times (one for each received RAND), in order to produce the *n* Kc keys and the *n* expected response (XRES) values. In the sequel, using the produced *n* *Kc* keys he/she generates the *MK* (see Eq. 1), and, consequently, the *K_auth* and the *MSK* keys, similarly, to the AAA server.
- Next, the user verifies the MAC_{server} using the *K_auth* key, and if this check is successful, then, the network is authenticated to the user, and the latter conveys to the AAA server the generated *n* XRES values within a EAP-Response/SIM/Challenge message. This message also includes the MAC_{user} value generated as follows:

$$MAC_{user}=HMAC\text{-}SHA1_{K\_auth}(EAP\text{-}Response/SIM/Challenge(n*XRES)\ |\ n*XRES)^{3}, \quad (3)$$

- Upon receiving this message, the AAA server examines whether the produced MAC_{user} is valid and if the *n* XRES values are equal to the *n* SRES values received from HSS/HLR for authentication. If these checks are successful, the AAA server sends an EAP-Success message to the user indicating the successful completion of the authentication procedure. In addition, the AAA server sends to the wireless AP the session key *MSK* within an AAA message (e.g., Radius or Diameter).

At this point, both the user and the network are mutually authenticated, and the user and the wireless AP share the key *MSK*, which is used for encryption purposes in the employed 802.11i security framework (see the *Data protection-802.11i*

Figure 3. The EAP-AKA authentication procedure and session key agreement



standard section).

EAP-AKA.EAP-AKA (Arkko & Haverinen, 2006) is an alternative to the EAP-SIM authentication protocol that uses a USIM-card and the UMTS AKA procedure. It involves the same network components with EAP-SIM (i.e., a user, an AAA client and an AAA server) and uses the same protocols for communication between them (i.e., EAPOL, Radius, Diameter, etc.). In the following, the EAP-AKA message exchange is analyzed:

- Likewise EAP-SIM, in the first two messages in the EAP-AKA negotiation (see Figure 3) the wireless AP requests for the user's identity (EAP request/identity message), and the latter replies by sending an EAP response/identity message, which contains his/her permanent IMSI or a temporary identity in an NAI format.
- After obtaining the user's identity, the AAA-server checks whether it possesses a 3G authentication vector, stored from a previous authentication with the specific user. If not, the AAA server sends the users IMSI to the HSS/HLR. The latter generates *n* 3G authentication vectors for the specific user by using the UMTS permanent secret key, *K*, which is assigned to the user when he/she is subscribed to the network, and sends it to the AAA-server. Note that an authentication vector includes a RAND, the authentication token (AUTN), the XRES, the encryption key (*CK*), and the integrity key (*IK*) (Xenakis & Merakos, 2004).
- In the sequel, the AAA server selects one out of *n* obtained authentication vectors to proceed with the EAP-AKA authentication procedure and stores the remaining *n*-1 for future use. From the selected authentication vector, the AAA server uses the keys *CK* and *IK* and the identity of the user to compute the *MK* of EAP-AKA as shown in the following formula:

$$MK = SHA1(Identity|IK|CK), \quad (4)$$

MK is used as a keying material to generate the *MSK* and the *K_auth* key. The AAA server uses

the *K_auth* key to calculate a keyed MAC_{server} (see Eq. 5), which verifies the integrity of the next EAP-AKA message (EAP-Request/AKA-Challenge).

$$MAC_{server}=HMAC\text{-}SHA1_{K\_auth}(EAP\text{-}Request/AKA/Challenge(RAND,AUTN)), \quad (5)$$

- The AAA server sends this message (EAP-Request/AKA-Challenge) to the user that contains the RAND, AUTN, and MAC_{server} payload. After receiving this information message, the user executes the UMTS-AKA algorithms and verifies the AUTN payload (Xenakis & Merakos, 2004). In the sequel, he/she generates the *IK* and *CK* keys and uses these two keys, as shown in Equation 4, to calculate the key *MK*. Subsequently, he/she uses *MK* to calculate the key *MSK* and the key *K_auth*, in order to verify the received MAC_{server} value.
- If these verifications (i.e., AUTN, MAC_{server}) are successful, the user computes the user's response to the challenge, noted as XRES payload, and sends an EAP-Response/AKA-Challenge message to the AAA server that includes the XRES and a new MAC_{user} value, which covers the whole EAP message and it is calculated using the *K_auth* key as follows:

$$MAC_{user}=HMAC\text{-}SHA1_{K\_auth}(EAP\text{-}Response/AKA/Challenge(n*XRES)), \quad (6)$$

- Upon receiving the EAP-Response/AKA-Challenge message the AAA server verifies the received MAC_{user} value and checks if the received user's response to the challenge (XRES) matches with the response (i.e., SRES) received from the HLR/HSS.
- If all these checks are successful, the AAA server sends an EAP-Success message along with the key *MSK* to the wireless AP. The latter stores the key and forwards the EAP-Success message to the user.

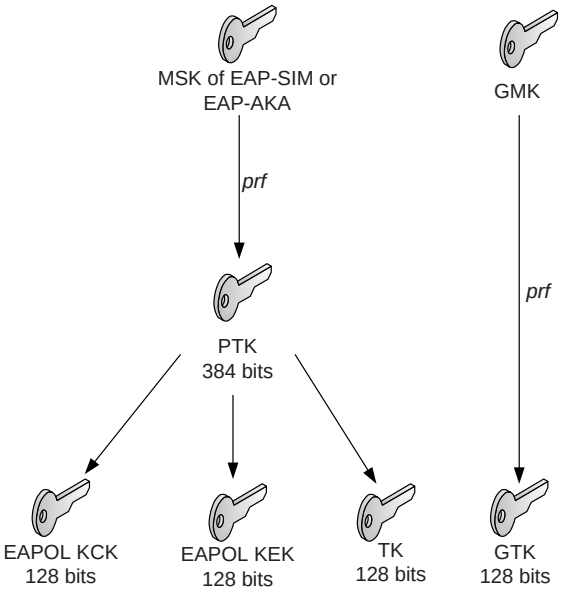
Finalizing the EAP-AKA protocol, both the user and the network have been authenticated to each other, and the user and the wireless AP share the key *MSK*, which is used in the security framework of 802.11i for generating the session encryption keys, as described in the next section.

Data Protection-802.11i Standard

As mentioned previously, 802.11i is employed to provide confidentiality and integrity services to users' data conveyed over the radio interface of the deployed WLAN in the WLAN Direct IP Access scenario. The 802.11i standard was developed to enhance the security services provided in WLANs. Its design was motivated by the fact that the wired equivalent privacy (WEP) protocol, due to its security flaws, could not fulfil the security requirements of WLANs (Borisov, Goldberg, & Wagner, 2001). The design goal of 802.11i is twofold: (1) to provide session key management by specifying a four-way handshake and group key handshake procedures, and (2) to enhance the confidentiality and integrity services provided to users' data by incorporating two security protocols (1) the counter-mode/CBC-MAC protocol (CCMP), which employs the advanced encryption standard (AES), and (2) the temporal key integrity protocol (TKIP), which uses the same encryption (RC4) with the WEP protocol. In the following, we analyze the four-way and group key handshake procedures of 802.11i and we present the functional details of the CCMP protocol. Since the TKIP protocol is considered to be a short term solution and it is merely a software enhancement of WEP, we do not elaborate further on it.

Four-way and group key handshakes. After a successful completion of the authentication procedure of EAP-SIM or EAP-AKA, the user and the AP perform the four-way and group key handshakes of 802.11i (IEEE std 802.11i, 2004) in order to generate the session keys. In the four-way handshake, both the user and the AP derive the

Figure 4. The CCMP protocol key hierarchy



pairwise transient key (*PTK*) from the *MSK* key that was generated in EAP-SIM or EAP-AKA to protect the four-way handshake messages and the unicast messages. In addition, the AP delivers to the user a group temporal key (*GTK*), which is used to protect broadcast/multicast messages. The *GTK* key is generated from the group master key (*GMK*), which is stored and maintained in the AP. The group key handshake is executed whenever the AP wants to deliver a new *GTK* key to the connected users. Note that all the messages exchanged during the four-way and the group key handshakes comply with the EAPOL-Key message format (IEEE std 802.1X, 2004).

As its name implies, the 802.11i four-way handshake consists of a total of four EAPOL-Key messages, which are analyzed next. Each of these messages includes key information (key_info payload), such as key identity, key replay counter, and so forth.

- At the beginning of the four-way handshake, the AP sends an EAPOL-Key message to the user that includes the A_{nonce}, which is a random number used as input for the generation of the *PTK* key, as described later on.
- Upon receiving the first EAPOL-Key message, the user generates a new random number called S_{nonce}. Then, he/she calculates the 384-bits *PTK* key using the first 265 bits of the *MSK* key (*MSK* was generated during the authentication procedure of EAP-SIM or EAP-AKA as described in the *Authentication in the WLAN Direct AP Access* section), the user's address, the AP's address, the S_{nonce} value, and the A_{nonce} value, as follows:

$$PTK = prf(MSK, \text{“}Pairwise\ key\ expansion\text{”}, Min(AP\ address, user's\ address) \mid Max(AP\ address, user's\ address) \mid Min(A_{nonce}, S_{nonce}) \mid Max(A_{nonce}, S_{nonce})), \quad (7)$$

where *prf* is a pseudo random function, “*Pairwise key expansion*” is a set of characters, and, finally, the Min and Max functions provide the minimum and maximum value, respectively, between two inputs. In the sequel, the generated *PTK* key is partitioned to derive three other keys: (1) a

128-bits key confirmation key (*KCK*) that provides integrity services to EAPOL-Key messages, (2) a 128-bits key encryption key (*KEK*) used to encrypt the *GTK* key as described next, and, (3) a 128-bits temporal key (*TK*) used for user's data encryption (see Figure 4).

- After the calculation of these keys, the user forwards to the AP the second EAPOL-Key message (step 2-Figure 5) that includes the S_{nonce}, the user's Robust Security Network Information Element (RSN IE) payload, which denotes the set of authentication and cipher algorithms that the user supports, and a message integrity code (MIC), which is a cryptographic digest used to provide integrity services to the messages of the four-way handshake and it is computed as follows:

$$MIC = HASH_{KCK}(EAPOL\text{-}Key\ message), \quad (8)$$

where $HASH_{KCK}$ denotes a hash function (i.e., HMAC-MD5 or HMAC-SHA-128) that uses the *KCK* key to generate the cryptographic hash value over the second EAPOL-Key message.

- Upon receiving this message, the AP calculates the key *PTK* and the related keys (i.e., *KCK*, *KEK*, and *TK* keys), (the same with the user), and, then, verifies the integrity of the message (producing the MIC value). Next, it generates the 128-bits *GTK* key from the *GMK* key as follows:

$$GTK = prf(GMK, \text{"Group key expansion"} \mid AP\ address \mid G_{nonce}), \quad (9)$$

where G_{nonce} is a random number generated from the AP to derive the *GTK* key

- In the sequel, the AP replies to the user by sending the third EAPOL-Key message (step 3), which includes the A_{nonce} value (the same

Figure 5. The four-way and group key handshakes of 802.11i

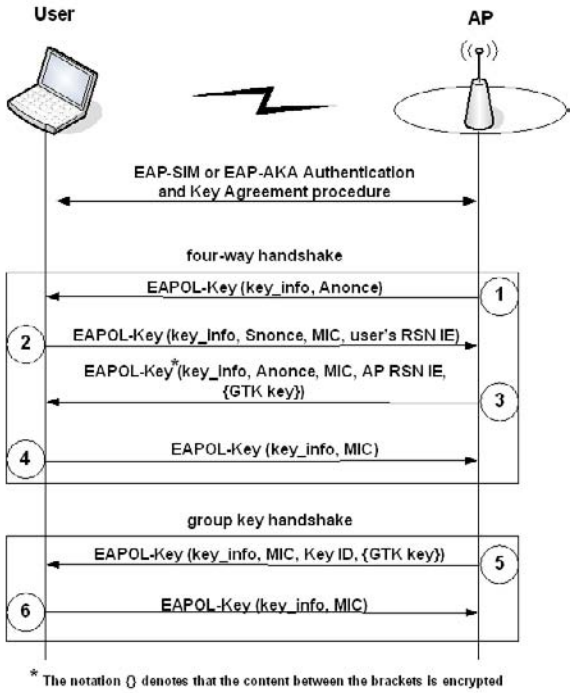


Figure 6. The CCMP protocol

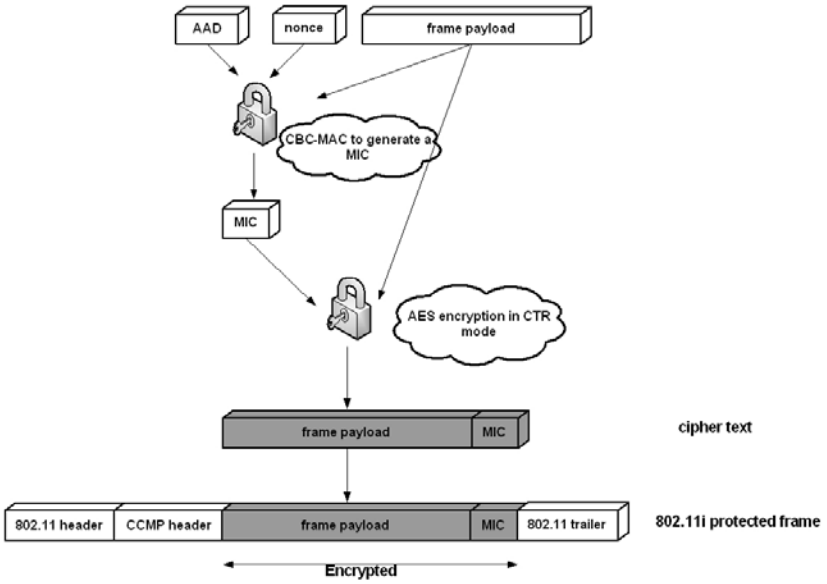

with the first EAPOL-Key message), an MIC over the third EAPOL-Key message, the AP's RSN IE, and the *GTK* key, which is used to protect the broadcast/multicast messages and it is conveyed encrypted using the *KEK* key, as follows:

$$Encrypted\ GTK = ENC_{KEK}(GTK), \quad (10)$$

where ENC_{KEK} denotes the encryption algorithm (i.e., AES or RC4), which uses the *KEK* key to encrypt the *GTK* key.

- By receiving this message, the user checks whether the MIC is valid and compares his/her RSN IE with the AP's RSN IE ensuring that they support the same cryptographic algorithms. If all these checks are correct, the user decrypts the *GTK* key using the *KEK* key and sends to the AP the last message of the four-way handshake (step 4), which includes an MIC payload over the fourth EAPOL-Key message, to acknowledge to the AP that he/she has installed the *PTK* key and the related keys (i.e., *KEK*, *KCK*, and *TK* keys), as well as the *GTK* key.
- Once the AP receives the fourth EAPOL-Key message, it verifies the MIC as previously. If this final check is successful, the four-way handshake is completed successfully, and both the user and the AP share: (1) the *TK* key to encrypt/decrypt unicast messages, and (2) the *GTK* key to encrypt/decrypt broadcast/multicast messages.

In case that the AP wants to provide a new *GTK* key to the connected users, it executes the group key handshake, as shown in Figure 5.

- The AP first generates a fresh *GTK* key from the *GMK* key and sends an EAPOL-Key message that includes an MIC value and the new *GTK* key to the users. Note that MIC is computed over the body of this EAPOL-Key message using the *KCK* key, and the *GTK* key is conveyed encrypted using the *KEK* key. Recall that both the user and the AP

share the *KEK* and *KCK* keys, which were generated in the four-way handshake.

- Upon receiving the previous message, the user employs the *KCK* key to verify whether the MIC is valid and then, he/she decrypts the *GTK* key using the *KEK* key. Finally, he/she replies to the AP with an EAPOL-Key message, which includes an MIC that acknowledges to the AP that he/she has installed the *GTK* key.
- Once the AP receives this message, it verifies the MIC. If this final verification is successful, then, the group key handshake is completed successfully and the user can encrypt broadcast/multicast messages using the new *GTK* key.

CCMP Protocol. 802.11i incorporates the CCMP protocol to provide confidentiality and integrity services to users' data conveyed over the radio interface of WLANs. The CCMP protocol combines the AES encryption algorithm in CounTeR mode (CTR-AES) to provide data confidentiality and the Cipher Block Chaining Message Authentication Code (CBC-MAC) protocol to compute an MIC over the transmitted user's data that provides message integrity (Whiting, Housley, & Ferguson, 2003).

The operation of the CCMP protocol can be divided into three distinct phases. In phase 1, the CCMP protocol constructs an additional authentication data (AAD) value from constant fields of the 802.11 frame header (IEEE std 802.11, 1999). In addition, it creates a nonce value from the priority field of the 802.11 frame header and from the packet number (PN) parameter, which is a 48-bit counter incremented for each 802.11i protected frame. In phase 2, the CCMP protocol computes an MIC value over the 802.11 frame header, the AAD, the nonce, and the 802.11 frame

Figure 7. 3GPP IP access authentication procedure

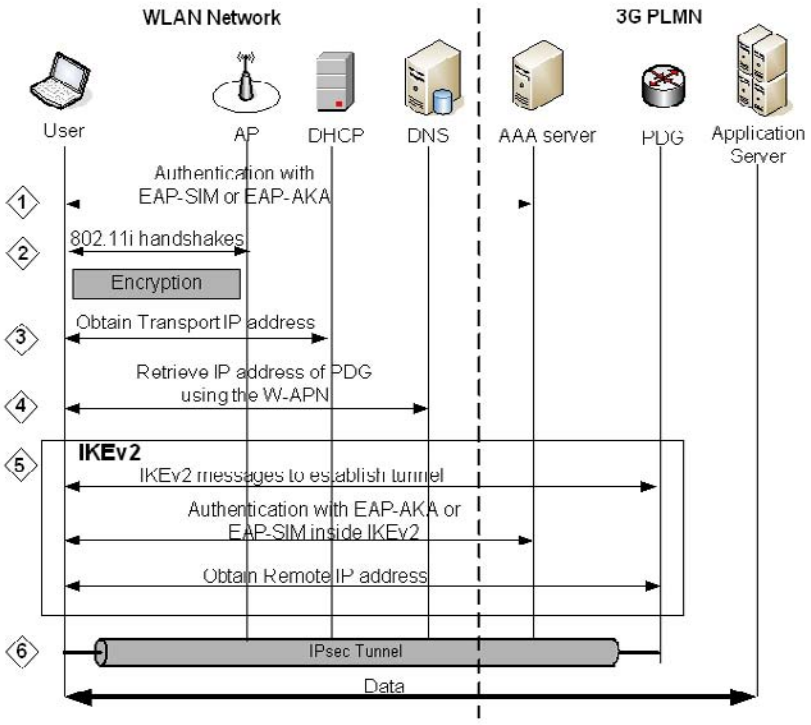

Figure 8. 3GPP IP access authentication protocol stack

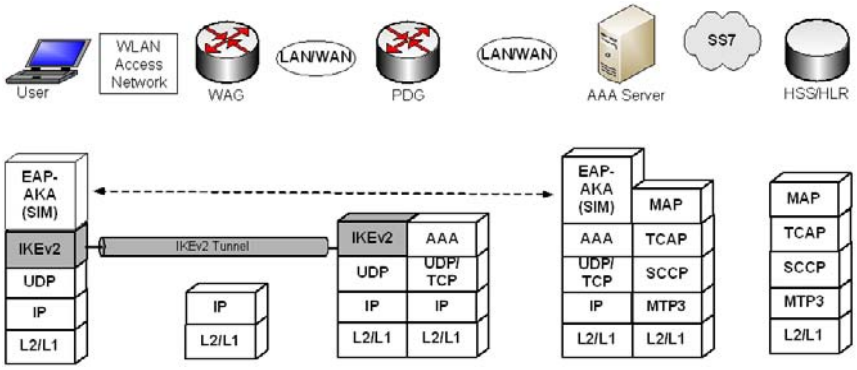


payload using the CBC-MAC algorithm and the *TK* key (or the *GTK* key for broadcast/mulitcast communication). Recall that the *TK* key is part of the *PTK* key that is generated in the four-way handshake. In the sequel, CCMP forms the cipher text of the 802.11 frame payload and the produced MIC, using the CTR-AES encryption algorithm and the *TK* key (or the *GTK* key). Finally, in phase 3, the CCMP protocol constructs the 802.11i frame from the concatenation of: (1) the 802.11 header, (2) the CCMP header, which is created from the PN parameter and the identity of the encryption key, (3) the cipher text, and (4) the 802.11 trailer, which is the frame check sequence (FCS) (see Figure 6). The receiver of the 802.11i frame must verify that the PN parameter is fresh and the MIC value is valid. If these checks are successful, then, the receiver decrypts the 802.11i frame payload using the *TK* key (or the *GTK* key).

WLAN 3GPP IP Access

In contrast to the WLAN Direct IP Access scenario, in which a user gets access to the public Internet, directly, through the WLAN-AN, the WLAN 3GPP IP Access scenario provides to the WLAN user access to the PS services or the Internet through the 3G PLMN. Before getting access to them, the user must perform the six (6) discrete steps, presented in Figure 7 and described as follows:

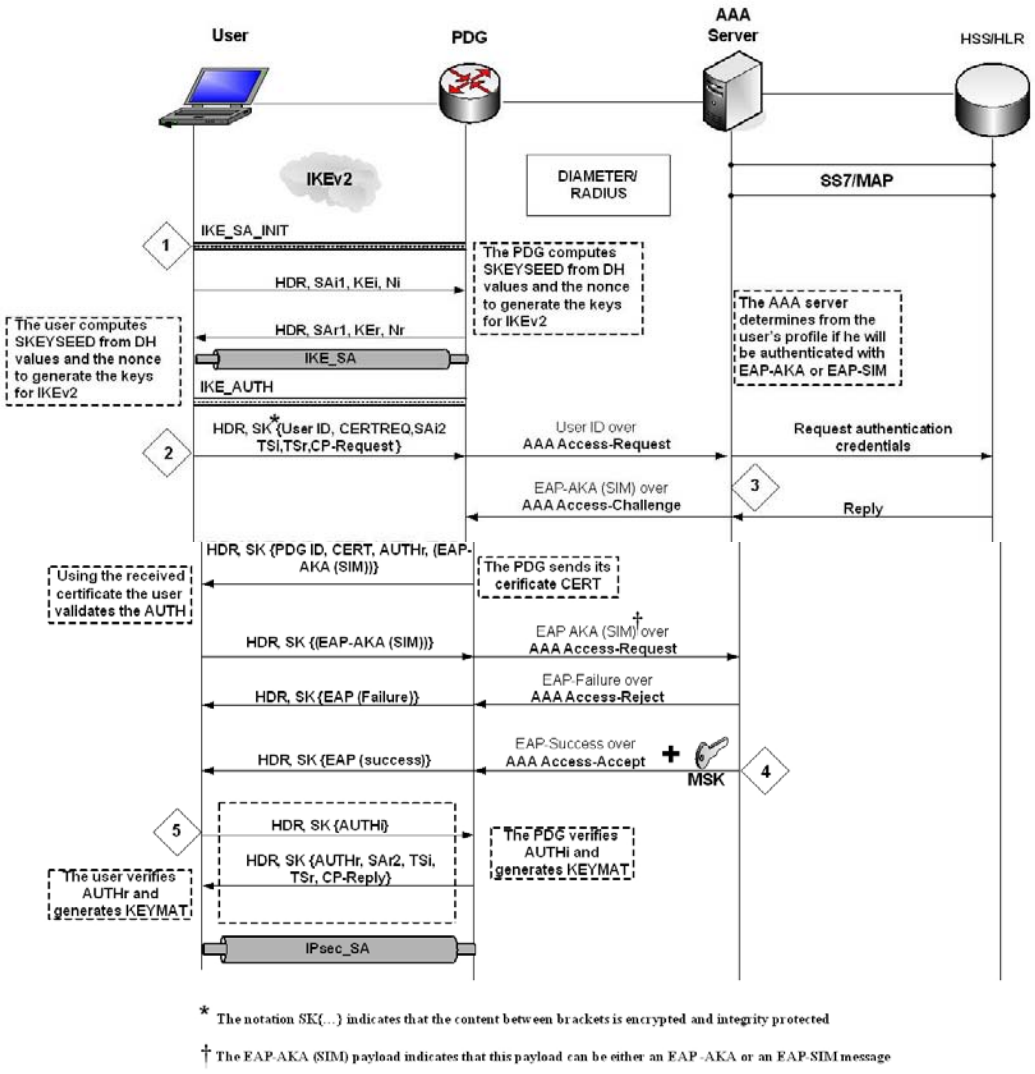
1. **Initial authentication.** The user and the network are authenticated to each other using either the EAP-SIM or EAP-AKA protocol. This authentication step enables the user to obtain a local IP address, called transport IP address, which is used for access to the WLAN environment and the PDG. Note that this initial authentication can be omitted, if the PDG trusts the WLAN network and its users.
2. After the EAP-SIM or EAP-AKA execution, the four-way handshake and optionally the group key handshake follow to provide the 802.11i session keys. Then, the communication between the user and the wireless AP is encrypted using the CCMP or alternatively the TKIP protocol.
3. After the completion of the initial authentication step and the 802.11i handshakes, the user communicates with the Dynamic Host Configuration Protocol (DHCP) server to obtain the transport IP address. This local address is used by the user to execute the IKEv2 in step 4.
4. The user retrieves the IP address of the PDG using the W-APN identity and the domain name system (DNS) protocol. Thus, both the user and the PDG participate in a second

authentication step that combines IKEv2 and EAP-SIM or EAP-AKA.

5. **Second authentication.** The user and the PDG execute the IKEv2 negotiation protocol, which encapsulates either EAP-SIM or EAP-AKA for authentication of the negotiating peers. After authentication completion, the user obtains a global IP address, called remote IP address, which is used for access to the PS services and the public Internet via the 3G PLMN. In addition, the execution of IKEv2 results in the establishment of a pair of IPsec security associations (SAs) between the user and the PDG, which are used for the deployment of an IPsec-based VPN.
6. The deployed IPsec based VPN protects user's data exchanged between the user and the PDG (in both directions) ensuring data origin authentication, data confidentiality and message integrity.

Figure 8 presents the protocol stack used in

Figure 9. The execution of IKEv2 based on EAP-SIM or EAP-AKA



* The notation SK{...} indicates that the content between brackets is encrypted and integrity protected

† The EAP-AKA (SIM) payload indicates that this payload can be either an EAP-AKA or an EAP-SIM message

the 3GPP IP Access scenario for each entity that participates in the authentication procedure. The main authentication protocol is EAP-SIM or EAP-AKA, which is executed between the user and the AAA server. The user encapsulates EAP-SIM or EAP-AKA messages within IKEv2 and conveys them to the PDG. The latter acting as an AAA client transfers the EAP-SIM or EAP-AKA messages to the AAA server using an AAA protocol. Note that the AAA protocol can be either RADIUS, which runs over the user datagram protocol (UDP) or Diameter, which runs typically over the TCP protocol. The AAA server also includes the mobile application part (MAP) protocol stack to be able to communicate with the HSS/HLR and obtain authentication triplets and authorization information.

From the previous steps that a user has to perform to get access to the PS services or the public Internet in the WLAN 3GPP IP Access scenario, the initial authentication using either EAP-SIM or EAP-AKA (step 1) and the 802.11i handshakes (step 2) are the same with these of the WLAN Direct IP Access scenario, which has been analyzed in the *Authentication in the WLAN Direct IP Access* and *Data protection-802.11i standard* sections. Moreover, the acquisition of a local IP address (step 3) and the retrieval of the PDG address (step 4) do not present any significant interest from a security point of view. Thus, in the following sections we analyze the second authentication step (step 5), which includes a combined execution of IKEv2 with EAP-SIM or EAP-AKA, and the deployment of a bidirectional VPN that protects data exchanged.

Authentication in WLAN 3GPP IP Access

IKEv2 (Kaufman, 2005) is a simplified redesign of IKE (Harkins & Carrel, 1998) that allows two peers to authenticate each other (i.e., mutual authentication) and derive keys for secure communication with IPsec. The exchanged messages within IKEv2 are protected ensuring confidentiality and integrity, while the peers are authenticated using certificates, pre-shared keys, or the EAP protocol. In the context of WLAN 3GPP IP Access scenario, the user and the PDG execute IKEv2. The authentication of the user is based on EAP-SIM or EAP-AKA, while the authentication of the PDG is based on certificates.

The IKEv2 protocol is executed in two sequential phases (i.e., phase 1 and phase 2). In phase 1, the user and the PDG establish two distinct SAs: (1) a bidirectional IKE_SA that protects the messages of phase 2, and (2) an one-way IPsec_SA that protects user's data. During phase 2, the user and the PDG using the established IKE_SA can securely negotiate a second IPsec_SA that is employed for the establishment of a bidirectional IPsec based VPN tunnel between them.

The IKEv2 phase 1 negotiation between the user and the PDG is executed in two sub-phases: (1) the IKE_SA_INIT, and (2) the IKE_AUTH exchange, as shown in Figure 9. The IKE_SA_INIT exchange (noted as step 1 in Figure 9) consists of a single request and reply messages, which negotiate cryptographic algorithms, exchange nonces, and do a Diffie-Hellman exchange. In the context of this sub-phase, four cryptographic algorithms are negotiated: (1) an encryption algorithm, (2) an integrity protection algorithm, (3) a Diffie-Hellman group, and (4) a prf. The latter prf is employed for the construction of keying material for all of the cryptographic algorithms used. After the execution of the IKE_SA_INIT, an IKE_SA is established that protects the IKE_AUTH exchange. The second sub-phase (i.e., IKE_AUTH) authenticates the previous messages; exchanges identities and certificates; encapsulates EAP-SIM or alternatively EAP-AKA messages; and establishes an IPsec_SA (step 2-5 in Figure 9). All the messages of IKEv2 include a header payload (HDR), which contains a security parameter index (SPI), a version number, and security-related flags. The SPI is a value chosen by the user and the PDG to identify a unique SA. In the following, the IKEv2 negotiation is

analyzed:

- At the beginning of the IKEv2 negotiation (step 1 in Figure 9), the user sends to the PDG the SAi1, which denotes the set of cryptographic algorithms for the IKE_SA that he/she supports, the KEi that is the Diffie-Hellman value, and an Ni value that represents the nonce. The nonce (i.e., a random number at least 128 bits) is used as input to the cryptographic functions employed by IKEv2 to ensure liveliness of the keying material and protect against replay attacks.
- The PDG answers with a message that contains its choice from the set of cryptographic algorithms for the IKE SA (SAr1), its value to complete the Diffie-Hellman exchange (KEr) and its nonce (Nr). At this point, both the user and the PDG can calculate the SKEYSEED value as follows:

$$SKEYSEED = prf((Ni \mid Nr), g \wedge ir)^4, \tag{11}$$

  where prf is the pseudo random function negotiated in the previous messages, and g^ir is the shared secret key that derives from the Diffie-Hellman exchange. The SKEYSEED value is used to calculate various secret keys. The most important are: the *SK_d* used for providing the keying material for the IPsec SA; *SK_ei* and *SK_ai* used for encrypting and providing integrity services, respectively, to the IKEv2 messages from the user to the PDG (IKE_SA); and, finally, *SK_er* and *SK_ar* that provide security services in the opposite direction (IKE_SA).

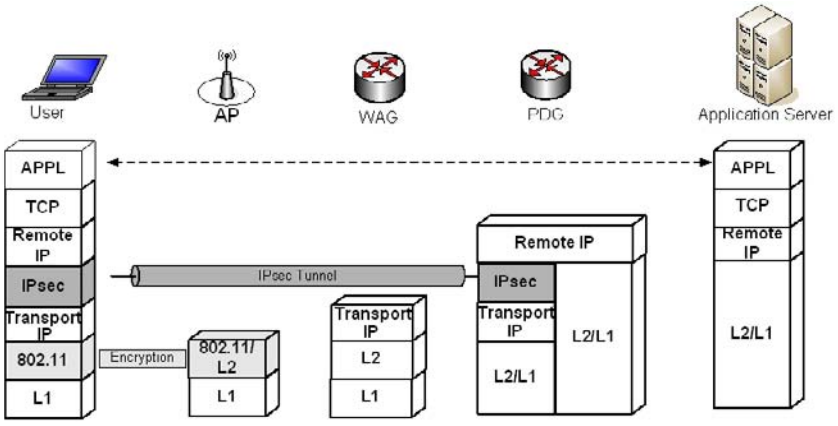
Finalizing the IKE_SA_INIT exchange, the IKE_AUTH exchange can start. It is worth noting that from this point all the payloads of the following IKEv2 messages, excluding the message header (HDR payload), are encrypted and integrity protected using the IKE_SA (see step 2 in Figure 9).

- The IKE_AUTH exchange of messages starts when the user sends to the PDG a message that includes his/her identity (IDi), which could be in an NAI format, the CERTREQ payload (optionally), which is a list of the certificate authorities (CA) whose public keys the user trusts, and the traffic selectors (TSi and TSr), which allow the peers to identify the packet flows that require processing by IPsec. In addition, in the same message the user must include the Configuration Payload Request (CP-Request), which is used to obtain a remote IP address from the PDG and get access to the 3G-PLMN.
- After receiving this information, the PDG forwards to the AAA server the user identity (IDi) including a parameter, which indicates that the authentication is being performed for VPN (tunnel) establishment. This will facilitate the AAA server to distinguish between authentications for WLAN access and authentications for VPN setup.
- Upon receiving the IDi, the AAA server fetches the user's profile and authentication credentials (GSM triplets if authentication is based on EAP-SIM, or 3G authentication vectors if authentication is based on EAP-AKA) from HSS/HLR (if these are not available in the AAA server in advance).
- Based on the user's profile, the AAA server initiates an EAP-AKA (if the user possesses a USIM card) or an EAP-SIM authentication (if the user possesses a GSM/GPRS SIM card) by sending to the PDG the first message of the related procedure (i.e., EAP-SIM or EAP-AKA) included in a AAA protocol (i.e., Radius or Diameter) (step 3 in Figure 9). Note that since there is no functional difference between the EAP-SIM and the EAP-AKA authentication when these protocols are encapsulated in IKEv2, we present them in a generic way. Thus, we introduce

the EAP-AKA (SIM) payload notation (see Figure 9) to indicate that this payload can be an EAP-SIM or an EAP-AKA message.

- Upon receiving the first EAP-AKA (SIM) message, the PDG encapsulate it within an IKEv2 message and forwards the encapsulated message to the user. Except for the EAP-AKA (SIM) payload, this message also includes the PDG's identity, which identifies the provided 3G services (W-APN) (see the *Background* section), the PDG's certificate (CERT), and the AUTHr field. The latter contains signed data used by the user to authenticate the PDG. Similarly to the previous messages, the payload of this IKEv2 message, except for the message header, is encrypted using the IKE_SA.
- Upon receiving the EAP-AKA (SIM) payload, the user verifies the AUTHr field by using the public key of the PDG included in the certificate field (CERT), and answers by sending an EAP-AKA (SIM) response message encapsulated again within an IKEv2 message. From this point, the IKEv2 messages contain only EAP-AKA (SIM) payloads, which are encrypted and integrity protected as described previously.
- The EAP-SIM or EAP-AKA exchange continues, normally, until an EAP-SUCCESS message (or an EAP-FAILURE in case of a failure) is sent from the AAA server to the PDG, which ends the EAP-AKA or the EAP-SIM dialogue. Together with the EAP-SUCCESS message, the key *MSK* is sent from the AAA server to the PDG via the AAA protocol, as shown in Figure 9 (step 4).
- After finishing the EAP-AKA or EAP-SIM dialogue, the last step (step 5) of IKEv2 reauthenticates the peers, in order to establish an IPsec_SA. This authentication step is necessary in order defeat man-in-the-middle attacks, which might take place because the authentication protocol (e.g., EAP-SIM or EAP-AKA) runs inside the secure protocol (e.g., IKEv2). This combination creates a security hole since the initiator and the responder have no way to verify that their peer in the authentication procedure is the entity at the other end of the outer protocol (Asokan, Niemi, & Nyberg, 2002). Thus, in order to prevent possible attacks against IKEv2 (i.e., man-in-the-middle attacks), both the user and the PDG have to calculate the AUTHi and the AUTHr payloads, respectively, using the *MSK* key that was generated from the EAP-SIM or EAP-AKA protocol. Then, both the user and the PDG send each other the AUTHi and AUTHr payloads to achieve a security bind-

Figure 10. 3GPP IP access data plane



ing between the inner protocol (EAP-SIM or EAP-AKA) and the outer protocol (IKEv2). Note that the PDG together with the AUTHr payload sends also its traffic selector payloads (TSi and TSr), the SAr2 payload, which contains the chosen cryptographic suit for the IPsec_SA and the assigned user's remote IP address in the Configuration Payload Reply (CP-REPLY) payload.

After the establishment of the IPsec_SA the keying material (*KEYMAT*) for this SA is calculated as follows:

$$KEYMAT = prf(SK\_d, Ni \mid Nr), \quad (12)$$

where Ni and Nr are the nonces from the IKE_SA_INIT exchange, and *SK_d* is the key that is calculated from the SKEYSEED value (see eq. 11). The *KEYMAT* is used to extract the keys that the IPsec protocol uses for security purposes. Note that the deployed IPsec_SA protects the one-way communication between the user and the PDG. For bidirectional secure communication, one more SA needs to be established between them (the user and the PDG) by executing the IKEv2 phase 2 over the established IKE_SA.

Data Protection

After the completion of the authentication procedure and the execution of IKEv2 between the PDG and the user, a pair of IPsec_SAs has been established between these two nodes. This pair deploys a bidirectional VPN between them that allows for secure data exchange over the underlying network path. At the same time, the user has been subscribed to the 3G PLMN network for charging and billing purposes using either the EAP-AKA or EAP-SIM protocol.

The deployed VPN runs on top of the wireless link and extends from the user's computer to the PDG, which is located in the user's home 3G PLMN (see Figure 1 and 10). It is based on IPsec (Kent & Atkinson, 1998a), which is a developing standard for providing security at the network layer. IPsec provides two choices of security service through two distinct security protocols: the Authentication Header (AH) protocol (Kent & Atkinson, 1998c), and the encapsulating security payload (ESP) protocol (Kent & Atkinson, 1998b). The AH protocol provides support for connectionless integrity, data origin authentication, and protection against replays, but it does not support confidentiality. The ESP protocol supports confidentiality, connectionless integrity, anti-replay protection, and optional data origin authentication. Both AH and ESP support two modes of operation: transport and tunnel. The transport mode of operation provides end-to-end protection between the communicating end points by encrypting the IP packet payload. The tunnel mode encrypts the entire IP packet (both IP header and payload) and encapsulates the encrypted original IP packet in the payload of a new IP packet.

In the deployed VPN of the WLAN 3GPP IP Access scenario, IPsec employs the ESP protocol and is configured to operate in the tunnel mode. Thus, VPN provides confidentiality, integrity, data origin authentication, and anti-reply protection services protecting the payload and the header of the exchanged IP packets. From the two IP addresses (i.e., transport and remote IP address) of each authenticated user, the remote IP address serves as the inner IP address, which is protected by IPsec, and the transport IP address serves as the IP address of the new packets, which encapsulate the original IP packets and carry them between the user and the PDG (see Figure 10). Thus, an adversary can not disclose, fabricate unnoticed, or perform traffic analysis to the data exchanged between the user and the PDG. Finally, IPsec can use different cryptographic algorithms (i.e., DES, 3DES, AES, etc.) depending on the level of security required by the two peers and the data that they exchange.

COMPARISON OF THE SCENARIOS

Based on the presentation of the two access scenarios (i.e., WLAN Direct IP Access and 3GPP IP Access) that integrate B3G networks and the analysis of the security measures that each one employs, this section provides a brief comparison of them. The comparison aims at highlighting the deployment advantages of each scenario and classifies them in terms of: (1) security, (2) mobility, and (3) reliability.

Regarding the provided security services, both scenarios support mutual authentication. In the WLAN Direct IP Access scenario, the authentication procedure employs either EAP-SIM or EAP-AKA, depending on the user's subscription. However, both protocols present the same security weaknesses, which can be exploited by adversaries to perform several attacks such as identity spoofing, denial of service (DoS) attacks, replay attacks, and so forth (Arkko & Haverinen, 2006; Haverinen & Saloway, 2006). On the other hand, the authentication procedure of the 3GPP IP Access scenario is more secured, since it combines the aforementioned protocols (i.e., EAP-SIM and EAP-AKA) with IKEv2. Specifically, the PDG is authenticated using its certificate, and the user is authenticated using EAP-SIM or EAP-AKA. It is worth noting that since the EAP-SIM and EAP-AKA messages are encapsulated in protected IKEv2 messages, the identified security weaknesses associated with them are eliminated.

Regarding confidentiality and data integrity services, both scenarios protect sensitive data conveyed over the air interface. More specifically, in the WLAN Direct IP Access scenario, high level security services are provided only in cases that the CCMP security protocol is applied, since it incorporates the strong AES encryption algorithm. A downside of applying CCMP is that it requires hardware changes to the wireless APs, which might be replaced. In the WLAN 3GPP IP Access scenario, data encryption is applied at the layer 2 (using WEP, TKIP, or CCMP) and layer 3 (using IPsec), simultaneously (see Figure 10). This duplicate encryption provides advanced security services to the data conveyed over the WLAN radio interface, but at the same time it may cause bandwidth consumption, longer delays, and energy consumption issues at the level of mobile devices.

Another deployment feature, which can be used for comparing the two scenarios, has to do with mobility. The WLAN Direct IP Access scenario may support user mobility by employing one of the mobility protocols, proposed for seamless mobility in wireless networks (Saha, Mukherjee, Misra, & Chakraborty, 2004). On the other hand, in the WLAN 3GPP IP Access scenario, the established VPN between a user and the PDG adds an extra layer of complexity to the associated mobility management protocols of this scenario. This complexity arises from the fact that as the mobile user moves from one access network to another and his/her IP address changes, the mobility protocols must incorporate mechanisms that maintain, dynamically, the established VPN, enabling the notion of mobile VPN. An attempt to address this problem can be found in Dutta et al., 2004) that designs and implements a secure universal mobility architecture, which incorporates standard mobility management protocols, such as mobile IP for achieving mobile VPN deployment.

Finally, the deployed IPsec-based VPNs between the users and the PDG in the 3GPP IP Access scenario may raise reliability issues. Reliability is perceived as the ability to use VPN services at all times, and it is highly related to the network connectivity and the capacity of the underlying technology to provide VPN services. In the 3GPP IP Access scenario, all data traffic passes through the VPN tunnels that are extend from the users to the PDG. The number of the deployed VPNs can grow significantly, due to the fact that each user can establish multiple VPNs at the same time to access different services. Thus, the PDG must be able to

support a large number of simultaneous VPNs in order to provide reliable security services.

CONCLUSION

This chapter has analyzed the security architectures employed in the interworking model that integrates 3G and WLANs, materializing B3G networks. The integrated architecture of B3G networks specifies two different network access scenarios: (1) the WLAN Direct IP Access, and (2) the WLAN 3GPP IP Access. The first scenario provides to a user connection to the public Internet or to an intranet via the WLAN-AN. In this scenario both the user and the network are authenticated to each other using EAP-SIM or EAP-AKA, depending on the user's subscription. Moreover, the confidentiality and integrity of the user's data transferred over the air interface are ensured by the 802.11i security framework. On the other hand, the WLAN 3GPP IP Access scenario allows a user to connect to the PS services (like WAP, MMS, LBS, etc.) or to the public Internet through the 3G PLMN. In this scenario, the user is authenticated to the 3G PLMN using EAP-SIM or alternatively EAP-AKA encapsulated within IKEv2, while the network is authenticated to the user using its certificate. In addition, the execution of IKEv2 is used for the establishment of an IPsec-based VPN between the user and the network that provides extra confidentiality and integrity services to the data exchanged between them.

KEY TERMS

Authentication, Authorization, and Accounting (AAA): AAA is a security framework which provides authentication, authorization, and accounting services. The two most prominent AAA protocols are Radius and Diameter.

Beyond Third Generation (B3G): B3G is the integration of heterogeneous mobile networks

through an IP-based common core network.

Counter-Mode/CBC-MAC Protocol (CCMP): CCMP is a security protocol defined in 802.11i, which employs the AES encryption to provide confidentiality and data integrity services.

Extensible Authentication Protocol (EAP): EAP is a security framework used to provide a plethora of authentications options, called EAP methods.

Extensible Authentication Protocol-Authentication and Key Agreement (EAP-AKA): EAP-AKA is an EAP method based on UMTS authentication of USIM cards.

Extensible Authentication Protocol method for GSM Subscriber Identity Modules (EAP-SIM): EAP-SIM is an EAP method based on GSM authentication of SIM cards.

802.11i: 802.11i is a security framework that incorporates the four-way handshake and group-key handshake for session key management and specifies the TKIP and CCMP security protocols to provide confidentiality and integrity services in 802.11 WLAN.

IKEv2: IKEv2 is a security association (SA) negotiation protocol used to establish an IPsec-based VPN tunnel between two entities.

IP security (IPsec): IPsec is a security protocol used to provide VPN services.

Chapter 7.9
Privacy and Anonymity in Mobile Ad Hoc Networks

ABSTRACT

Providing privacy is often considered a keystone factor for the ultimate take up and success of mobile ad hoc networking. Privacy can best be protected by enabling anonymous communication and, therefore, this chapter surveys existing anonymous communication mechanisms for mobile ad hoc networks. On the basis of the survey, we conclude that many open research challenges remain regarding anonymity provisioning in mobile ad hoc networks. Finally, we also discuss the notorious Sybil attack in the context of anonymous communication and mobile ad hoc networks.

INTRODUCTION

The quest for privacy in today's increasingly pervasive information society remains a fundamental research challenge. In the traditional (wired) Internet, one essential means for protecting privacy is *anonymous communication*. Being anonymous usually implies that a user remains unlinkable to a set of items of interest (e.g., communication partners, messages) from an attacker's perspective (Pfitzmann & Hansen, 2006). The capabilities of the attacker are usually modeled by an *attacker model*, which can, for instance, include a rogue communication partner or an observer tapping the communication lines. Further, more advanced

applications can be deployed on top of anonymous communication mechanisms, to, for instance, enable pseudonymous applications.

This chapter investigates how anonymous communication can be enabled in *mobile ad hoc networks* (Corson & Macker, 1999); networks constituted by mobile platforms that establish on-the-fly wireless connections among themselves and ephemera networks without central entities to control it. They are of great importance as they constitute a basic core functionality needed for deploying *ubiquitous computing.* In short, ubiquitous computing would allow for computational environments providing information instantaneously through "invisible interfaces," thus allowing unlimited spreading and sharing of information. If realized, ubiquitous computing could offer an invaluable support for many aspects of our society and its institutions. However, if privacy aspects are neglected, there is a great likelihood that the end product will resemble an Orwellian nightmare.

In this chapter, we study how privacy and anonymity issues are tackled today in mobile ad hoc networks by surveying existing anonymous communication mechanisms adapted for mobile ad hoc networks[1]. Only recently, a number of such proposals have been suggested. In the survey, we evaluate some of these approaches against a set of general requirements (Andersson, Martucci, & Fischer-Hübner, 2005), which assess to which degree these approaches are suitable for mobile ad hoc networks. We also discuss Sybil attacks (Douceur, 2002) in the context of anonymous communication and mobile ad hoc networks.

This chapter is structured as follows. First, an introduction to privacy, anonymity, and anonymity metrics is provided in "Background." Then, existing approaches for enabling anonymity in ad hoc networks are described in "Anonymous Communication in Mobile Ad Hoc Networks." In "Survey of Anonymous Communication Mechanisms for Ad Hoc Networks" these approaches are evaluated against the aforementioned requirements. Then, Sybil attacks in the context of anonymous communication and mobile ad hoc networks are discussed in "Future Trends." Finally, conclusions are drawn in "Conclusions."

BACKGROUND

In this section, the concepts of privacy and anonymity and their relation are introduced. Methods for quantifying anonymity are also discussed.

Definitions of Anonymity and Related Concepts

Pfitzmann and Hansen (2006) define *anonymity* as "the state of being not identifiable within a set of subjects, the *anonymity set*" (p. 6). The

Figure 1. Unlinkability between a user in the anonymity set and an item of interest

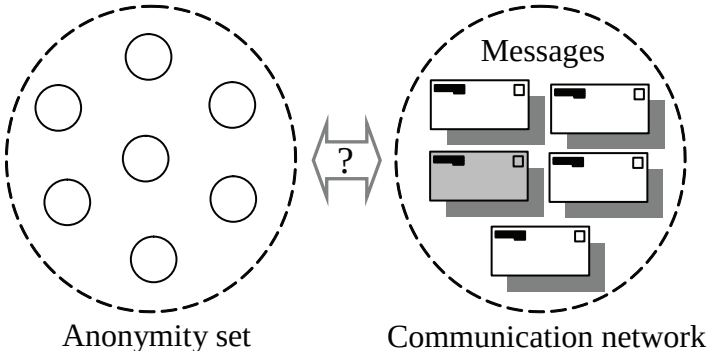

Figure 2. Setting a path between A and D (through B and C) using layered encryption; PK_B and PK_C are the public keys of B and C. K_{AB} and K_{AC} are shared symmetric keys. D is an external receiver

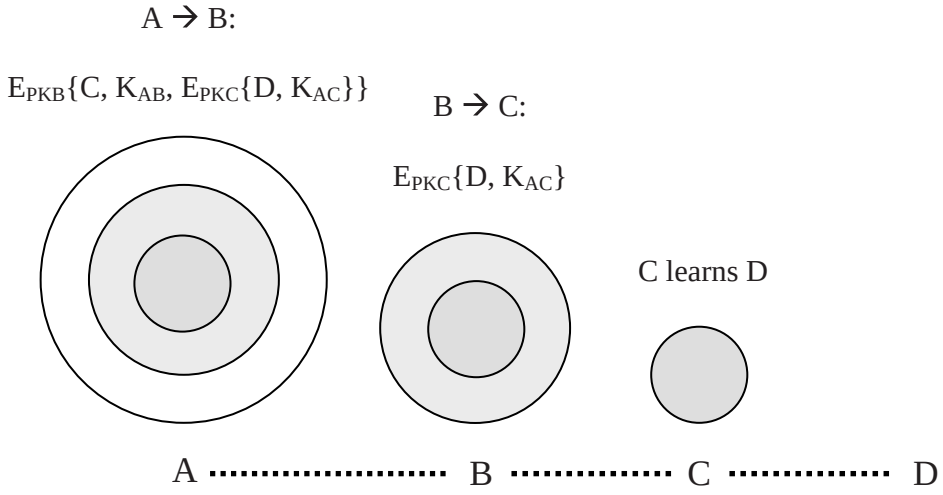


anonymity set includes all possible subjects in a given scenario, such as possible senders of a message.

Related to anonymity is *unlinkability*, where unlinkability of two or more items of interest (IOIs, e.g., subjects, messages, events, actions, etc.) means that within the system (comprising these and possibly other items), from the attacker's perspective, these items of interest are no more and no less related after his observation than they are related concerning his a-priori knowledge. (Pfitzmann & Hansen, 2006, p. 8)

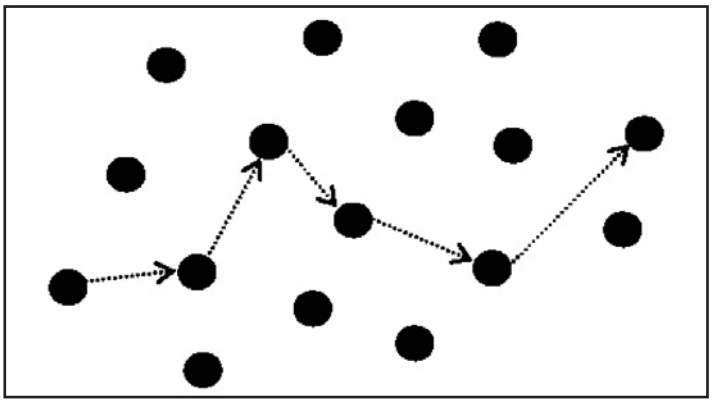
Anonymity can be defined in terms of unlinkability: *sender anonymity* entails that a message cannot be linked to the sender, while *receiver anonymity* implies that a message cannot be linked to the receiver (see Figure 1).

In traditional networks, such as the Internet, anonymous communication is often realized by *anonymous overlay networks*, which establish *virtual paths* consisting of one or more intermediary nodes, along which packets are transmitted. Using methods described below, the anonymous overlay network constructs the paths in such a manner that the correlation between the sender and receiver, and possibly also the identity of the sender and/or the receiver, is hidden.

A classic method enabling anonymity, where the sender determines the full path, is *layered encryption*[2]: a message is wrapped into several encryption layers. As the message propagates the network, these layers are sequentially decrypted by each successive node in the path, until the receiver decrypts the final layer. Each layer usually includes the identity of the next node in the path and a symmetric key shared with the initiating node (see Figure 2). In this way, expensive public key encryption is only used for constructing the path; for data delivery symmetric encryption is used. Messages encrypted in layers are often denoted *message onions*. Layered encryption enables anonymity as intermediary nodes do not know whether their predecessor and successor nodes are the sender or receiver, respectively.

An alternative approach, first applied in Crowds (Reiter & Rubin, 1997), is to let the sender select its successor randomly, which in turn flips a biased coin to decide whether it should end the path and connect to the receiver, or extend the path to a random node. The flipping of the biased coin is repeated until a node decides to connect to the receiver (see Figure 3). In this approach, link-to-link encryption between intermediary hops

Figure 3. "Crowds-like" path setting between the sender and receiver



in the path is usually combined with end-to-end encryption. This approach enables sender anonymity towards network nodes and the receiver, as neither of these nodes can deduce if the previous node in the path is the sender.

Another method specifically tailored for providing receiver anonymity is *invisible implicit addressing* (Pfitzmann & Waidner, 1987). Invisible implicit addressing hides the identity of the receiver by first encrypting a message (or a part of it) with the receiver's public key (or a shared symmetric key). Instead of sending the message directly to the receiver, the message is then *broadcasted* to all nodes in the network, which all must try to decrypt the message. However, only the intended receiver will be able to successfully decrypt the message.

On the Relation between Privacy and Anonymity

Privacy is recognized either explicitly or implicitly as a fundamental human right by most constitutions of democratic societies. Privacy can be defined as the right to *informational self-determination*, that is, individuals must be able to determine for themselves when, how, to what extent, and for what purpose personal information about them is communicated to others.

In Europe, the right for privacy of individuals is protected by the by a legal framework mainly consisting of the EU Data Protection Directive 95/46/EC, which defines general privacy requirements, and the E-Communications Privacy Directive 2002/58/EC, which specifically applies for personal data processing within the electronic communication sector.

An important privacy principle is *data minimization*, stating that the collection and processing of personal data should be minimized. Clearly, the less personal data are collected or processed, the less the right to informational self-determination is affected. Art. 6 (1) of the EU Data Protection Directive 95/46/EC embodies the principle of data minimization by stating that personal data should be limited to data that are adequate, relevant, and not excessive, and by requiring that data should only be kept in a form that permits identification of data subjects for no longer than it is necessary for the purpose for which the data were collected or for which they are further processed. Consequently, technical tools such as privacy-enhancing technologies should be available to contribute to the effective implementation of these requirements by providing anonymity and/or pseudonymity for the users and other concerned individuals.

More specific legal requirements for anonymization can also be found in the E-Communi-

cations Privacy Directive 2002/58/EC: Pursuant to Art.9 of the Directive: location data may only be processed when they are made anonymous, or with the consent of the user or subscriber to the extent and for the duration necessary for the provision of a value-added service.

On Measuring Anonymity

This section discusses *anonymity metrics*, which quantify the degree of anonymity in a given scenario in the following manner. First, the given attacker model, together with the properties of the anonymous communication mechanism, are passed as input to the anonymity metric. Then, the metric determines the degree of anonymity based using for example, analysis or by simulation, depending on the metric at hand. In Table 1, we summarize the most common anonymity metrics.

Although the metrics listed above differs in many respects, the main parameters contributing to the degree of anonymity in all metrics are *size of anonymity set* (anonymity set size and *k*-anonymity), *probability distributions* (entropy-based metric by Diaz et al.), and both (entropy-based metric by Serjantov and Danezis and the Crowds-based metric).

Anonymous Communication in Mobile Ad Hoc Networks

In *proactive* routing protocols (Perkins, 2001), each node always maintains routes to all other nodes, including nodes to which no packets are being sent. Standard proactive protocols do not enable anonymity as all nodes know significant amounts of information about other nodes.

In *reactive* routing protocols (Perkins, 2001), routes between nodes are established on demand, meaning that less packets are circulated in the network, for example, for status sensing. Also standard reactive routing protocols fail to enable anonymity. As a proof of concept, consider the reactive protocols dynamic source routing (DSR) (Johnson & Maltz, 1996) and ad hoc on-demand

Table 1. A summary of anonymity metrics

Anonymity set size
A classic indicator of anonymity is the size of the anonymity set. This metric is appropriate for mechanisms in which all users are equally likely to be the sender of a particular message, as in the DC-networks (Chaum, 1988) or Crowds, regarding the Web server (Reiter & Rubin, 1997).
K-anonymity
If a mechanism provides *k*-anonymity (Sweeney, 2002), *k* constitutes a lower bound of the anonymity set size *n*. For example, $k = 3$ implies that an attacker cannot exclude more than $(n - 3)$ users from the anonymity set.
Crowds-based metric
In the Crowds-based metric[3] (Reiter & Rubin, 1997), anonymity is measured on a continuum, including the points *possible innocence* (the probability that a user is not the sender is not negligible), *probable innocence* (the probability that a user is a sender $\geq 1/2$), and *beyond suspicion* (the user is not more likely than any other user to be the sender). The analysis is based on the communication patterns in Crowds, and the result is a probability depending on the anonymity set size and the number of corrupted users.
Entropy-based metrics
In entropy-based metrics (Diaz, Seys, Claessens, & Preneel, 2002; Serjantov & Danezis, 2002), each user is first assigned with a probability of being the sender of a message. The entropy regarding which user sent the message is then calculated using Shannon's theories (Shannon, 1948). The resulting degree is system-wide and may change depending on, for example, changes in the attacker's knowledge. Diaz et al. solely bases their analysis on the probability distributions (equally distributed probabilities → max degree of anonymity), while in Serjantov and Danezis metric, a large anonymity set contribute positively to the degree of anonymity.

distance vector routing (AODV) (Perkins & Royer, 1999).

- In DSR, during route discovery[4] the route request (RREQ) includes the IP addresses of the sender and receiver in plain. The IPs are also disclosed by the route reply (RREP) message. During data transfer, the path between the sender and receiver is included in plain in the packet headers.
- Also in AODV, the RREQ and RREP messages disclose the sender and receiver IP addresses. Also, routing data at each node in an active path discloses the receiver IP.

This situation applies for virtually any standard routing protocol. So far, two methods for enabling anonymous communication in mobile ad hoc networks have been proposed: *anonymous routing protocols* and *anonymous overlay networks.* They are explained in the next sections.

Anonymous Routing Protocols

An anonymous routing protocol replaces the standard routing protocol with a protocol preserving anonymity (see Figure 4). Anonymous routing protocols normally include building blocks for *anonymous neighborhood authentication, anonymous route discovery,* and *anonymous data transfer.* The first phase is not always included; instead many approaches assume that other mechanisms offer this service.

During anonymous neighborhood authentication, nodes establish trust relationships with their *neighbors* (i.e., nodes within one-hop distance). "Trust" implies that the nodes prove mutual possession of some valid identifiers, such as certificates, pseudonyms, public/private key-pairs, or combinations thereof.

The task of anonymous route discovery is to establish an anonymous path between the sender and receiver. Sender anonymity is often achieved through layered encryption. Sometimes, receiver anonymity is enabled by invisible implicit addressing, meaning in this context that a challenge is included in the RREQ that only the receiver can decrypt[5].

The main disadvantage with invisible implicit addressing is that all nodes receiving the RREQ must try to decrypt the challenge, resulting in considerable overhead (especially as the RREQ reaches all nodes). When the RREP is propagated back to the sender on the path created by the corresponding RREQ message, *visible implicit addressing* (Pfitzmann & Waidner, 1987) is often used to hinder nodes other than the sender from

Figure 4. Anonymous routing protocol

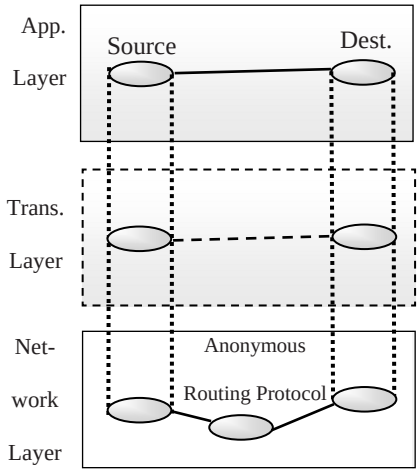


Figure 5. Anonymous overlay network

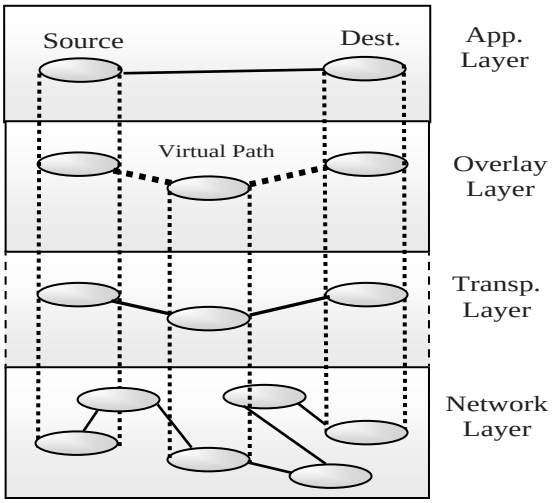

matching RREP messages with corresponding RREQ messages. This is often enabled by including sequence numbers in the RREP and RREQ so that only the sender can conclude that the sequence number of a given RREP corresponds to an earlier sent out RREQ.

During anonymous data transfer, data messages are sent along the paths created during route discovery. Only protocols that use *source routing* can apply layered encryption, as the sender in this case needs to decide the full path. Else, link-to-link encryption, possibly combined with end-to-end encryption, is normally used.

Anonymous Overlay Networks

In mobile ad hoc networks, anonymous overlay networks are normally deployed above the routing or transport layer (see Figure 5), where they can use services from the standard routing protocol (e.g., finding a route to the next node in the path) or the transport layer (e.g., reliable data delivery).

Anonymous overlay networks can be divided into the following phases: *group buildup, path construction,* and *data transfer.*

During group buildup, the user base of the overlay network is populated. One strategy for group buildup is to assign this task to one or more *directory servers,* where a set of nodes (or at least one node) must act as a directory server (Martucci, Andersson, & Fischer-Hübner, 2006). Similarly as in anonymous routing protocols, virtual path setting and data transfer are either based on layered encryption, or link-to-link encryption combined with end-to-end encryption.

Comparison between Anonymous Routing Protocols and Anonymous Overlay Networks

In Table 2 we summarize the respective pros and cons with anonymous routing protocols and anonymous overlay networks.

Survey of Anonymous Communication Mechanisms for Ad Hoc Networks

The survey is divided into two parts: one part for anonymous routing protocols and one for anonymous overlay networks[6]. Before the survey,

Table 2. Pros and cons with anonymous routing protocols and anonymous overlay networks

Advantages with Anonymous Routing Protocols
They make it possible to control already on the routing level what information is being disclosed during routing. Yet, this does not exclude the possibility that additional efforts may be needed in upper layers. Also, most approaches use the shortest path between the sender and receiver.
Disadvantages with Anonymous Routing Protocols
The replacement of the standard routing protocol; this will likely decrease the user base, which degrades anonymity according to many metrics. Besides, nodes may be exposed if a connection-oriented transport layer is used above the anonymous routing protocol, as they establish direct connections between nodes.
Advantages with Anonymous Overlay Networks
Flexibility; an anonymous overlay network is independent of the routing protocol and, further, compatible with applications expecting services from for example, a reliable transport layer.
Disadvantages with Anonymous Overlay Networks
The performance can be expected to be slightly worse as messages are detoured through a set of overlay nodes, instead of being transmitted on the shortest route between the sender and recipient.

however, we list the evaluation criteria against which the mechanisms included in the survey are evaluated.

Evaluation Criteria

Six requirements were defined by Andersson et al. (2005) that an anonymous overlay network should meet to be suitable for mobile ad hoc networks. These requirements are general enough to be suitable for providing the criteria against which the mechanisms surveyed in this chapter are evaluated. They are listed below:

R1. The anonymous communication mechanism must scale well. It should perform well also with a large number of participants.

R2. The anonymous communication mechanism must provide strong anonymity properties. We examine how the studied approaches resist an attacker model including a global observer[7], path insiders, other network nodes, and the receiver.

R3. The anonymous communication mechanism must be fair regarding the distribution of workload among the nodes. The workload should be equally distributed (and nodes should not be forced to spend a lot of resources on behalf of others). Else, incentives should be given for accepting a higher workload.

R4. The anonymous communication mechanism must provide acceptable performance. It should be lightweight (e.g., generate few messages and avoid public key operations). We evaluate whether the studied approaches presents arguments indicating a good performance. We also evaluate whether there are strong assumptions that could hamper performance.

R5. The anonymous communication mechanism must employ a peer-to-peer paradigm (P2P) model. There should be no dependence on central hardware/services, or at least, it should be minimized. We also study whether there are some implicit requirements for centralized services that are hidden by strong assumptions.

R6. The anonymous communication mechanism must handle a dynamic topology. It must tolerate that nodes are frequently entering or leaving the network.

In the survey, we grade the approaches according to which degree they satisfy these requirements: ●●● = the requirement is satisfied to a high degree; ●● = … is satisfied to a medium degree; ● = … is satisfied to a low degree; and ○ = … is violated. Regarding the grading of R2, the approaches are graded according to which degree they provide anonymity against each item in the assumed attacker model (see R2).

Survey of Anonymous Routing Protocols

In this section, we survey a variety of prominent anonymous routing protocols proposed in recent years. The ratings of the mechanisms are listed in table-form in the next section.

Anonymous Dynamic Source Routing Protocol (AnonDSR)

AnonDSR (Song, Korba, & Yee, 2005) is a source routing protocol using invisible implicit addressing for route discovery. The RREP is created as a message onion. Both the sender and recipient know the intermediary nodes in the path. Data messages are sent as message onions on bidirectional paths. AnonDSR includes a security parameter establishment (SPE) protocol for exchanging security parameters prior to route discovery, which contains a major flaw (see R2).

R1. As the SPE protocol is used to establish shared secrets between sender and receivers, the issues regarding it (see R2) may hamper scalability.

R2. The SPE protocol broadcasts the IDs of the senders and receivers in plain. If used, AnonDSR provides merely confidentiality. If not used, AnonDSR provides sender and receiver anonymity against observers, path insiders, and network nodes.
AnonDSR changes the message appearance at intermediary hops. Yet, a global observer may correlate the RREQ sizes or trace data flows in the network.

R3. During route discovery, nodes spend energy to assess whether they are the intended receiver. Intermediary nodes must perform public key encryptions.

R4. The range of the nodes and the network size is not specified in the performance simulation of AnonDSR, and only route discovery is evaluated while data transfer and node mobility are not considered. Also, as implicit addressing with public key cryptography is used, AnonDSR cannot be expected to provide high performance.

R5. No special nodes needed, and thus AnonDSR adheres well to the P2P paradigm.

R6. AnonDSR does not support rebuilding of broken paths. Also, the insecurities in the SPE protocol may cause problems for new nodes joining the network that wish to establish security parameters with existing nodes.

Secure Distributed Anonymous Routing Protocol (SDAR)

SDAR (Boukerche, El-Khatib, Xu, & Korba, 2004) is a source routing protocol enabling a system for managing trust: nodes associate their neighbors with a trust level based on past behavior. Invisible implicit addressing is used to hide the receiver identity in the RREQ. The RREP and data messages are sent as message onions.

R1. SDAR can be expected to scale badly as every node in the network must perform three public key operations per received RREQ message.

R2. SDAR offers sender and receiver anonymity against observers and other network nodes.
SDAR alters messages appearance and applied padding to thwart global observers. Still, only nodes assumed to forward RREQ/RREP packets do so, others drop them.

R3. It is not specified whether the certificate authority (CA) is a central service or distributed among the nodes. When processing RREQ packets, all nodes must perform one public key encryption, one public key decryption, and one signature generation.

R4. There are serious performance issues in SDAR. For instance, every node must perform must perform three public key operations for each RREQ it forwards.

R5. The existence of a CA (or similar) is assumed for distributing public keys. It is not specified how it would be implemented.

R6. We predict that the trust management system in SDAR would suffer in a dynamic topology; it would be difficult for nodes to be highly trusted as they would be ● punished for leaving the network in the midst of a communication. Also, path rebuilding in case of broken paths is not considered.

MASK

MASK (Zhang, Liu, & Lou, 2005) does not use source routing. Prior to route discovery, MASK performs anonymous neighborhood authentication, and nodes know each other by temporal pseudonyms. For performance reasons, MASK avoids invisible implicit addressing during route discovery; instead, the receiver identity is disclosed in the RREQ. After route discovery,

a sender may have multiple active paths to the receiver. End-to-end and/or link-to-link encryption is employed during data transfer, depending on the application at hand.

R1. MASK can be expected to scale well as it avoids the usage of implicit addressing. Yet, an increased node density (i.e., more neighbor nodes) may degrade performance during anonymous neighborhood authentication.
R2. MASK offer sender anonymity against path insiders, network nodes, and observers, but no receiver anonymity. MASK uses altered message appearance, random choice of paths, and per-hop message delay to harden traffic analysis during low traffic. No node forwards RREQ/RREP messages more than once.
R3 The avoidance of implicit addressing bears a positive impact on fairness.
R4. Simulation results indicate that MASK provides good performance. However, the mutual authentication between neighboring nodes was shown to be the most costly operation and in scenarios where the transmission range is small compared to the network size,
this may affect performance negatively.
R5. A trusted authority (TA) is used during the bootstrapping phase of the network.
R6. Broken paths are handled by broadcasting error packets in case of a broken path. Still, the tight synchronization scheme between neighboring nodes may lead to problems in some situations where neighboring nodes leave and join often.

Anonymous On-Demand Routing (ANODR)

ANODR (Kong, Hong, Sanadidi, & Gerla, 2005) is a source routing protocol aiming to protect privacy by avoiding persistent identifiers. Invisible implicit addressing based on symmetric encryption is used to hide the receiver identity during route discovery. The RREP is created as a message onion. During data transfer, it is not specified whether or not the data payload is encrypted.

R1. It is unclear how senders and receivers share symmetric keys. Given that they share a key, to solve the challenge in the RREQ, the receiver
may have to try all keys shared with other nodes (see R4). Further, other network nodes must try all their shared keys to conclude that they are not the intended receiver.
R2. ANODR offers sender and receiver anonymity against observers, path insiders, and networks nodes. Senders and receivers are not mutually anonymous. ANODR uses traffic mixing to thwart observers, where messages are independently and randomly delayed. Yet, traffic patters are leaked as only nodes assumed to forward the RREP does so. Further, as the payload of data messages is not altered at intermediary hops, it is trivial for a global observer to trace data traffic.
R3. Each node must spend considerable resources when forwarding RREQ packets.
R4. There are serious performance issues in ANODR (see R1).
Although ANODR has performed reasonably well in a simulation scenario, problems can be expected in a real world scenario.
R5. No special nodes are needed, and thus ANODR adheres well to the P2P paradigm.
R6. ANODR supports path rebuilding in case of broken paths. However, it is unclear how new nodes should share symmetric keys with old nodes

Discount Anonymous On-Demand Routing (Discount ANODR)

Discount ANODR (Yang, Jakobsson, & Wetzel, 2006) is a low-latency source routing protocol that

avoids invisible implicit addressing. A random time to live counter is used for RREQ/RREP messages to confuse observers (implemented by flipping a biased coin). Data are sent as message onions along unidirectional paths (i.e., a new path must be build for the reply).

R1. Discount ANODR can be expected to scale well. However, the bias of the coin flipping may have to be adapted if the geographical size of the network increases.

R2. Discount ANODR provides sender anonymity against local observers, as the coin flipping and random padding during route discovery confuse observers to a certain degree. No receiver anonymity.
Data messages are padded with random bits.

R3. There are no special nodes and no public encryption on behalf of other nodes.

R4. Discount ANODR avoids public key encryption and invisible implicating addressing.
The coin flipping may degrade performance as nodes on the shortest path may drop the RREQ, resulting in nonoptimal paths. Also, RREP packets can be lost for the same reason. Unidirectional paths also hamper performance.

R5. The nodes have to collectively administrate two values determining the bias of the coins deciding whether a node should forward a RREQ and a RREP, respectively.

R6. Discount ANODR rebuilds broken paths, but does not discuss how to collectively adapt the bias of the coin flipping when the network characteristics change.

Anonymous Routing Protocol for Mobile Ad Hoc Networks (ARM)

ARM (Seys & Preneel, 2006) aims to foil global observers by using random time-to-live values and padding for all messages. Senders and receivers share one-time pseudonyms. Invisible implicit addressing hides the receiver by including the secret pseudonym in the RREQ. The RREP is created as a message onion. Link-to-link encryption is used for data transfer.

R1. As a tight synchronization scheme is used between sender and recipients, it is assumed that senders shares keys and pseudonyms with a limited set of receivers.

R2. ARM offers sender and receiver anonymity against networks nodes, path insiders, and observers. Senders and receivers have an a-priori relationship. In ARM, data messages have a uniform size, RREQ/RREP messages are randomly padded, and RREQ/RREP/ data messages are propagated using random time-to-live values. The effectiveness of this limited dummy traffic is not formally proven.

R3. While no nodes perform public key operations, the amount of nodes forwarding RREQ/ RREP and data messages increases due to the random time-to-life values.

R4. If assuming a static environment, there are no conclusive arguments orthogonal to performance. However, all nodes in ARM generate overhead traffic.
ARM has not yet been simulated to assess the performance.

R5. There are no special nodes in ARM. In a real world scenario, central infrastructure may be required to realize the assumption that each node should possess a unique identifier; it is unclear how this would clash with the P2P paradigm.

R6. The assumption that each node establishes a broadcast key with its neighbors is problematic when considering dynamic topologies. Further, ARM does not consider path rebuilding in case of broken paths.

Distributed Anonymous Secure Routing Protocol (ASRP)

ASRP (Cheng & Agrawal, 2006) is a routing protocol not based on source routing where nodes are known by dynamic random pseudonyms. Invisible implicit addressing (based on public encryption) is used for both RREQ and RREP packets. Data messages are link-to-link and end-to-end encrypted. It is not specified whether the paths are bidirectional or unidirectional.

R1. All nodes in the network must perform two public key operations per RREQ (one private key decryption and one public key generation). This hampers scalability as the more nodes in the network, the more generated RREQ packets.

R2. Senders and receivers are not mutually anonymous as they have an a-priori relationship. Anonymity is offered against path insiders and network nodes, and ASRP alters message appearance and maintains a uniform message size to confuse attackers.

R3. All nodes spend significant resources when forwarding RREQ and RREP packets. For the RREQ, see R1. For propagation of RREP packets, all nodes on the path must perform three public key operations (one private key decryption and two public key encryptions).

R4. The performance of ASRP has not been simulated. Route discovery can be expected to offer a low performance, as public key encryption is extensively used.

R5. No special nodes are needed, and thus ASRP adheres to the P2P paradigm.

R6. Path rebuilding in case of broken paths is not considered. This means that the expensive route discovery process has to be initiated for each case of path failure.

Privacy Preserving Routing (PPR)

PPR (Capkun, Hubaux, & Jakobsson, 2004) is a proactive protocol for communication between ad hoc networks interconnected by fixed access points (AP). Nodes know each other by temporal pseudonyms. In the sender network, nodes maintain the shortest path to the AP. In the receiver's network, the AP maintain the shortest paths to the nodes. Routing consists of three parts: *uplink* (distance vector protocol), *inter-station*, and *downlink* (source routing). In uplink, a sender sends a message that reaches the AP as a message onion. In downlink, the receiver's AP send an onion to the receiver.

R1. The AP and the CA are the major points of workload aggregation in PPR, but as these are centrally offered services, PPR can be expected to scale well.

R2. PPR offers sender and receiver anonymity against observers, network nodes, and path insiders. There are no countermeasures against global observers in the senders or receivers networks, except message alteration at intermediary hops. Anonymity is quantified using the entropy-based anonymity metric (see section "On Measuring Anonymity"). There is no anonymity against the AP.

R3. Nodes do not perform special roles or execute public key operations on behalf of others.

R4. Public key encryption is only used for establishing trust relationships among neighboring nodes. The performance of PPR has not yet been simulated.

R5. PPR violates the P2P model as the existence of a CA and several AP is assumed.

R6. The existence of the AP facilitate the handling of trust and security issues in a dynamic topology. The uplink protocol is the most vulnerable part regarding routing, but it can be expected to handle dynamic topologies well.

Summary of Survey Results for Anonymous Routing Protocols

The survey results for all requirements (except R2) are summarized in Table 3. The survey results for R2 are summarized in Table 4.

SURVEY OF ANONYMOUS OVERLAY NETWORKS

In this section, we study two anonymous overlay networks for ad hoc networks: Chameleon (Martucci et al., 2006) and MRA (Jiang, Vaidya, & Zhao, 2004).

Chameleon

Chameleon can be described as a variant of Crowds adapted for mobile ad hoc networks. In Chameleon, the nodes share the responsibility of being directory servers during group buildup. Node authentication is based on certificates (the existence of a TCP (transmission control protocol)/SSL (secure socket layer) layer is assumed). Data messages are end-to-end and link-to-link encrypted or only link-to-link encrypted.

R1. The load on each node is approximately constant as the size of the network grows. However, if too few directory servers are used, this may put a limit on scalability.

R2. Chameleon offers sender anonymity against receivers and sender and receiver anonymity against local observers and malicious nodes.
The degree of anonymity is quantified by the Crowds-based metric (see "On Measuring Anonymity").

R3. A small subset of the nodes must act as directory servers. It is suggested that nodes take turns in acting as the directory servers.

R4. Chameleon is based on light-weight encryption.
However, the performance of Chameleon has not yet been assessed through simulation.

R5. Chameleon generally follows the P2P paradigm. However, nodes are assumed to possess certificates obtained in advance and the global probability deciding the expected path length has to be administrated collectively by the nodes

R6. Chameleon repairs broken paths at the point of breach, rather that rebuilding the whole path. Without redundancy, vanishing directory servers may be a problem.

Mix Route Algorithm (MRA)

MRA applies traffic mixing[9] (Chaum, 1981) in a mobile ad hoc scenario. A subset of the nodes acts as mixes, which constitute the virtual paths. Each node assigns a mix as its *dominator mix*. A RREQ is sent to the receiver via the sender's dominator mix, triggering the receiver to register at its dominator mix with a DREG (dominator registration) message. Each mix periodically broadcasts RUPD (route update) messages containing its registered receivers and a path field, which is updated as the RUPD propagates through the network. When it reaches the sender, it contains the path to the receiver.

R1. Scalability may be hampered if the mix set is static in a growing network.

R2. As the min path length is one, a mix may learn the identity of both the sender and receiver. The first mix always learns the sender ID.
Receiver anonymity is in doubt as all mixes broadcast information in the network about which receivers it is currently providing services for (i.e., the RUPD messages).

R3. Incentives for the costly operating of mixes are left as a future research problem.

R4. MRA is based on pubic-key cryptography. Basing MRA on symmetric cryptography is left as future research. Results from a performance simulation are presented, but only different mix settings are compared.

R5. No central services are needed. Still, establishing trust between mixes and other nodes are left as future research. This may require aid from external trusted nodes.

R6. If the sender or dominator mix move, the sender may have to switch dominator mix. If the mix set is small, problems may arise regarding the mix advertisement as nodes only retransmit advertisement messages from their dominator mixes.

Summary of Survey Results for Anonymous Overlay Networks

The results from the survey are summarized in Table 5.

DISCUSSION

From the survey, we can make the following observations:

1. **It is difficult to protect against a global eavesdropper.** None of the studied approaches implement powerful and proven countermeasures against global observers. We believe that it is an open research problem regarding how to enable such countermeasures while at the same time offering an acceptable level of performance in mobile ad hoc networks[12].
2. **It is difficult to implement invisible implicit addressing efficiently.** There is a clear trade-off between on the one hand enabling receiver anonymity by using invisible implicit addressing and on the other hand satisfying the fairness, dynamic, and scalability requirements. The proposals using invisible implicit addressing either use costly public key cryptography (e.g., AnonDSR, SDAR, ASRP) or avoid public key operations at the cost of including strong assumptions regarding in beforehand mutual distribution of secrets (e.g., ARM, ANODR).

3. **It is straightforward to hide the identity of the sender from other network nodes.** This is probably because most of the approaches use classical techniques for hiding the identity of the sender, such as layered encryption, that have been used before in other contexts.
4. **No anonymous routing protocol implements sender anonymity towards the receiver.** Hiding the sender identity during route discovery would require a mechanism for hiding the propagation of the RREP messages similar (and equally costly as) to the invisible implicit addressing schemes used for hiding the propagation of the RREQ messages.

FUTURE TRENDS

A *Sybil attack* (Douceur, 2002) implies one attacker forging multiple identifiers in the network to control an unbalanced portion of the network. Sybil attacks can undermine security in, for instance, mobile ad hoc networks based on reputation schemes or threshold cryptography (Piro, Shields, & Levine, 2006). Douceur has showed that *preventing* Sybil attacks is practically impossible as it requires a TTP (trusted third party) to manually assert that each identity corresponds to only one logical entity in the network. Yet, during the years, and recently also for mobile ad hoc networks, many approaches for *detecting* Sybil attacks have been proposed. In this section, we discuss why Sybil attacks threaten anonymity in ad hoc networks, and discuss some proposed countermeasures.

The Sybil Attack in Mobile Ad Hoc Networks

Mobile ad hoc networks are highly susceptible to Sybil attacks because of, for instance, the lack of reliable network or data link identifiers, and the absence of a trusted entity capable of vouching for the one-to-one binding between physical devices and logical network identifiers. This may give the impression that ad hoc nodes are naturally anonymous as nodes could confuse observers by regularly changing their {IP, MAC} pairs. Although this may prevent long-term tracking, other problems may arise. For instance, when there is a need to identify a node offering a specific service, a rouge node could easily impersonate this service. The absence of reliable network identifiers may also disrupt routing, as a rouge user could announce false information using multiple {IP, MAC} pairs. Also, as senders and receivers establish direct connections, they are still vulnerable to traffic analysis and physical layer oriented attacks (Capkun et al., 2004).

However, the Sybil attack also poses a threat against anonymous routing protocols and anonymous overlay networks. For both approaches, the anonymity set denotes the user base. There are some differences though. In an anonymous overlay network, the anonymity set is used as a pool of nodes serving as an input parameter to the path

Table 5. Summary of survey results (left) and summary of anonymity requirement R2 (right)

Requirement	*Chameleon*	*MRA*

creation algorithm. Polluting the anonymity set with many Sybil identities might yield a path only containing Sybil identities. If this happens, the attacker can easily break anonymity by linking the sender to the receiver. In an anonymous routing protocol, however, each node only stepwise extends the path to another node within a single-hop distance, until the receiver is reached. Thus, the locations of the nodes play a more important role here, and as all Sybil identities share the same location, it is difficult for the attacker to force the creation of paths in which it controls all nodes.

Thus, the Sybil attack poses a greater threat to anonymity in anonymous overlay networks compared to anonymous routing, although it still poses a great threat to other security properties for anonymous routing.

Mechanisms for Detecting the Sybil Attack in mobile Ad Hoc Networks

In this section, we describe two recent proposals for thwarting Sybil attacks in mobile ad hoc networks.

- The fact that Sybil nodes in mobile ad hoc networks naturally travel together in clusters can be used for detecting Sybil attacks (Piro et al., 2006). Piro et al. propose a detection mechanism in which each node records all encountered {IP, MAC} pairs. If a user repeatedly observes a set of {IP, MAC} pairs sharing the same location, there is an increased likelihood that these {IP, MAC} pairs represent Sybil nodes. One drawback with this strategy is that it is unclear how to prevent a detected attacker from generating new {IP, MAC} pairs and relaunch a new attack later, as there is no underlying long-term identity that can be blocked from the system.
- Another strategy is to cryptographically guarantee a one-to-one mapping between all temporal network identifiers seen in a particular network and corresponding certified long-term identifiers (Martucci et al., 2008). To tailor this approach for ad hoc networks, the nodes must be able to assert the validity of the temporal identifiers without having to interact with the TTP. Further, to protect privacy, only the TTP should be able to link a temporal identifier to the corresponding long-term identifier and there should be unlinkability between temporal identifiers used in different contexts. The fact that you need reliable identifiers to protect against the Sybil attack and to provide reliable anonymous communication has been labeled as the *identity-anonymity paradox* (Martucci et al., 2006).

CONCLUSION

In mobile ad hoc networks, anonymous communication can either be enabled by anonymous routing protocols or anonymous overlay networks. Currently, anonymous routing is the most popular approach, although future requirements, such as flexibility regarding the applications, may raise the need for anonymous overlay networks.

We evaluated commonly proposed anonymous routing protocols and anonymous overlay networks for mobile ad hoc networks against a set of evaluation criteria and showed that a number of research challenges remain. For instance, it is difficult to offer receiver anonymity without using a complex and performance-hampering invisible implicit addressing scheme, and it is further difficult to protect against global observers.

Finally, we introduced Sybil attacks, a notorious threat to all computer networks, including mobile ad hoc networks. We expect that the area of enabling reliable identifiers in a privacy-friendly manner is an interesting future research area.

KEY TERMS

Anonymity: The state of being not identifiable within a set of subjects.

Anonymity Metrics: Metrics for quantifying the degree of anonymity in a scenario.

Mobile Ad Hoc Network: Networks constituted of mobile devise which may function without the help of central infrastructure or services.

Privacy: The right to informational self-determination, that is, individuals must be able to determine for themselves when, how, to what extent, and for what purpose personal information about them is communicated to others.

Receiver Anonymity: Implies that a message cannot be linked to the receiver.

Sender Anonymity: Means that a message cannot be linked to the sender.

Unlinkability: If two items are unlinkable, they are no more or less related after an attacker's observation than they are related concerning the attacker's a-priori knowledge.

END NOTES

[1] As devices in ad hoc networks are responsible for their own services, including security and routing, protocols for anonymous communication for wired networks are not suitable for ad hoc networks, not even those based on the peer-to-peer paradigm (P2P) (Andersson et al., 2005).

[2] This method is sometimes also called telescope encryption. A public key based version of the method was initially introduced by Chaum (1981). Onion Routing, which only uses public key encryption for setting the path, and then relies on symmetric encryption, was later proposed by Goldschlag, Reed, and Syverson (1996).

[3] The Crowds-based metric was developed for Crowds, but has since been used in other contexts.

[4] This denotes the process of setting a path between the sender and a receiver. First, the sender floods a route request (RREQ) into the network, which triggers the sending of a route reply (RREP) from the receiver to the sender. During the propagation of the RREQ and RREP, respectively, the path is interactively formed.

[5] In the context of mobile ad hoc networks, this method is often referred to as a global trapdoor.

[6] In the survey, we omit approaches relying on the existence of either a positioning device (e.g., GPS) in the mobile devices or a location server in the mobile ad hoc network.

[7] A global observer is an observer that is capable of observing all networks traffic in the whole network.

[8] Note that no anonymity is provided against the access points (not included in attacker model).

[9] Batching and reordering traffic to hide the correlation between incoming and outgoing traffic.

[10] No sender anonymity if path length is one.

[11] No receiver anonymity against last mix on the path.

[12] It is commonly believed that omnipresent protection against a global observer can only be achieved if all nodes transmit a constant flow of traffic, requiring massive usage of dummy traffic.

Chapter 7.10
Integrity Protection of Mobile Agent Data

Sheng-Uei Guan
Brunel University, UK

INTRODUCTION

One hindrance to the widespread adoption of mobile-agent technology is the lack of security. Security will be the issue that has to be addressed carefully if mobile agents are to be used in the field of electronic commerce. SAFER (secure agent fabrication, evolution and roaming) is a mobile-agent framework that is specially designed for the purpose of electronic commerce (Guan & Hua, 2003; Guan, Zhu, & Maung, 2004; Zhu, Guan, Yang, & Ko, 2000). Security has been a prime concern from the first day of our research (Guan & Yang, 2002; Yang & Guan, 2000). By building strong and efficient security mechanisms, SAFER aims to provide a trustworthy framework for mobile agents to assist users in conducting mobile or electronic-commerce transactions.

Agent integrity is one such area crucial to the success of agent technology (Wang, Guan, & Chan, 2002). Despite the various attempts in the literature, there is no satisfactory solution to the problem of data integrity so far. Some of the common weaknesses of the current schemes are vulnerabilities to revisit attacks, when an agent visits two or more collaborating malicious hosts during one roaming session, and illegal modification (deletion or insertion) of agent data. The agent monitoring protocol (AMP; Chionh, Guan, & Yang, 2001), an earlier proposal under SAFER to address agent data integrity, does address some of the weaknesses in the current literature. Unfortunately, the extensive use of PKI (public-key infrastructure) technology introduces too much overhead to the protocol. Also, AMP requires the agent to deposit its data collected to the agent owner or butler before it roams to another host. While this is a viable and secure approach, the proposed approach, Secure Agent Data Integrity Shield (SADIS), will provide an alternative by allowing the agent to carry the data by itself without depositing them (or the data hash) onto the butler.

Besides addressing the common vulnerabilities of current literature (revisit attacks and data-modification attacks), SADIS also strives to achieve maximum efficiency without compromising security. It minimizes the use of PKI technol-

ogy and relies on symmetric key encryption as much as possible. Moreover, the data encryption key and the communication session key are both derivable from a key seed that is unique to the agent's roaming session in the current host. As a result, the butler can derive the communication session key and data encryption key directly. Another feature in SADIS is strong security.

Most of the existing research works focus on detecting integrity compromise (Esparza, Muñoz, Soriano, & Fomé, 2006) or bypassing integrity attacks by requiring the existence of a cooperating agent that is carried out within a trusted platform (Ouardani, Pierre, & Boucheneb, 2006). However, these works neglect the need to identify the malicious host. With SADIS, the agent butler will not only be able to detect any compromise to data integrity, but will identify the malicious host effectively.

BACKGROUND

Agent data integrity has been a topic of active research in the literature for a while. SADIS addresses the problem of data integrity protection via a combination of techniques discussed by Borselius (2002): execution tracing, encrypted payload, environmental key generation, and undetachable signature.

One of the recent active research works is the security architecture by Borselius, Hur, Kaprynski, and Mitchell (2002). Their architecture aims at defining a complete security architecture designed for mobile-agent systems. It categorizes security services into the following: agent management and control, agent communications service, agent security service, agent mobility service, and agent logging service. SADIS addresses the agent communication service as well as agent security services (integrity protection), while previous research on SAFER addresses agent mobility service.

While many of the security services are still under active research, the security mechanisms for protecting agents against malicious hosts were described by Borselius, Mitchell, and Wilson (2001). The paper proposes a threshold scheme to protect mobile agents. Under the mechanism, a group of agents is dispatched to carry out the task, with each agent carrying a vote. Each agent is allowed to contact a merchant independently and gathers a bid based on the given criteria. Each agent votes for the best bid (under a trading scenario) independently. If more than n out of m ($m > n$) agents vote for the transaction, the agent owner will agree to the transaction.

Such a mode of agent execution effectively simplifies agent roaming by allowing one agent to visit one merchant only. While the approach avoids the potential danger of having the agent compromised by the subsequent host, it does not employ a mechanism to protect the agent against the current host. Most important of all, the threshold mechanism's security is based on the probability that no more than n hosts out of m are malicious. In another words, the security is established based on probability. Different from this approach, SADIS's security is completely based on its own merits without making any assumption about probability of hosts being benign or malicious. This is because the author believes that in an e-commerce environment, security should not have any dependency on probability.

Other than the research by Borselius (2002), Borselius et al. (2002), and Borselius et al. (2001), there are related research works in the area. One such research work on agent protection is SOMA (Secure and Open Mobile Agent) developed by Corradi, Cremonini, Montanari, and Stefanelli (1999). It is a Java-based mobile-agent framework that provides for scalability, openness, and security on the Internet. One of the research focuses of SOMA is to protect the mobile agent's data integrity. To achieve this, SOMA makes use of two mechanisms: the multihop (MH) protocol and trusted third party (TTP) protocol. The MH

protocol works as follows. At each intermediate site the mobile agent collects some data and appends them to the previous ones collected. Each site must provide a short proof of the agent computation, which is stored in the agent. Each proof is cryptographically linked with the ones computed at the previous sites. There is a chaining relation between proofs. When the agent moves back to the sender, the integrity of the chained cryptographic proofs is verified, allowing the sender to detect any integrity violation.

The advantage of the MH protocol is that it does not require any trusted third party or even the agent butler for its operation. This is a highly desirable feature for an agent integrity protection protocol. Unfortunately, the MH protocol does not hold well against revisit attacks when the agent visits two or more collaborating malicious hosts during one roaming session (Chionh et al., 2001). Roth (2001) provides more detailed descriptions on potential flaws of the MH protocol.

Another agent system that addresses data integrity is Ajanta (Tripathi, 2002). Ajanta is a platform for agent-based application on the Internet developed in the University of Minnesota. It makes use of an append-only container for agent data integrity protection. The main objective is to allow a host to append new data to the container but prevents anyone from modifying the previous data without being detected. Similar to the MH protocol, such an append-only container suffers from revisit attacks.

From these attacks in existing research, the importance of protecting agent itinerary is obvious. In SADIS, the agent's itinerary is implicitly updated in the agent butler during key seed negotiation. This prevents any party from modifying the itinerary recorded on the butler and guards against all itinerary-related attacks.

There is one recent research work on agent data integrity protection called the One-Time Key Generation System (OKGS) being studied in Kwang-Ju Institute of Science and Technology, South Korea (Park, Lee, & Lee, 2002). OKGS does protect the agent data against a number of attack scenarios under revisit attacks, such as data-insertion attacks and data-modification attacks, to a certain extent. However, it does not protect the agent against deletion attacks as two collaborating malicious hosts can easily remove roaming records in between them.

Inspired by OKGS's innovative one-time encryption key concept, SADIS will extend this property to the communication between agent and butler as well. Not only the data encryption key is one-time, but the communication session key as well. Using efficient hash calculations, the dynamic communication session key can be derived separately by the agent butler and the agent with minimum overhead. Despite the fact that all keys are derived from the same session-based key seed, SADIS also ensures that there is little correlation between these keys. As a result, even if some of the keys are compromised, the key seed will still remain secret.

PROTECTION OF AGENT DATA INTEGRITY

SADIS is designed based on the SAFER framework. The proposal itself is based on a number of assumptions that were implemented under SAFER. First, entities in SAFER, including agents, butlers, and hosts, should have globally unique identification number (IDs). These IDs will be used to uniquely identify each entity. Second, each agent butler and host should have a digital certificate that is issued by a trusted certificate authority (CA) under SAFER. Each entity with a digital certificate will be able to use the private key of its certificate to perform digital signatures and, if necessary, encryption. Third, while the host may be malicious, the execution environment of mobile agents should be secure and the execution integrity of the agent should be maintained. This assumption is made because protecting the agent's execution environment is

a completely separate area of research that is independent of this chapter. Without a secure execution environment and execution integrity, none of the agent data protection scheme will be effective. The last assumption is that entities involved are respecting and cooperating with the SADIS protocol. Finally, SADIS does not require the agent to have a predetermined itinerary. The agent is able to decide which host is the next destination independently.

Key Seed Negotiation Protocol

When an agent first leaves the butler, the butler will generate a random initial key seed, encrypt it with the destination host's public key, and deposit it into the agent before sending the agent to the destination host. It should be noted that agent transmission is protected by the supervised agent transport protocol (Guan & Yang, 2002). Otherwise, a malicious host ("man in the middle") can perform an attack by replacing the encrypted key seed with a new key seed and encrypt it with the destination's public key. In this case, the agent and the destination host will not know the key seed has been manipulated. When the agent starts to communicate with the butler using the wrong key seed, the malicious host can intercept all the messages and reencrypt them with the correct key derived from the correct key seed and forward them to the agent butler. In this way, a malicious host can compromise the whole protocol.

The key seed carried by the agent is session based; it is valid until the agent leaves the current host. When the agent decides to leave the current host, it must determine the destination host and start the key seed negotiation process with the agent butler.

The key seed negotiation process is based on the Diffie-Hellman (DH) key exchange protocol (Diffie & Hellman, 1976) with a variation. The agent will first generate a private DH parameter *a* and its corresponding public parameter *x*. The value *x*, together with the ID of the destination host, will be encrypted using a communication session key and sent to the agent butler.

The agent butler will decrypt the message using the same communication session key (derivation of communication session key will be discussed later in the section). It, too, will generate its own DH private parameter *b* and its corresponding public parameter *y*. With the private parameter *b* and the public parameter *x* from the agent, the butler can derive the new key seed and use it for communications with the agent in the new host. Instead of sending the public parameter *y* to the agent as in normal DH key exchange, the agent butler will encrypt the value *y*, host ID, agent ID, and current time stamp with the destination host's public key to get message *M*. Message *M* will be sent to the agent after encrypting with the communication session key.

$$M = E(y + \text{host ID} + \text{agent ID} + \text{time stamp}, H_{pubKey})$$

At the same time, the agent butler updates the agent's itinerary and sends it to the agent. When the agent receives the double-encrypted DH public parameter *y*, it can decrypt with the communication session key.

Subsequently, the agent will store *M* into its data segment and requests the current host to send itself to the destination host using the agent transport protocol (Guan & Yang, 2002).

On arriving at the destination host, the agent will be activated. Before it resumes normal operation, the agent will request the new host to decrypt message *M*. If the host is the right destination host, it will be able to use the private key to decrypt message *M* and thus obtain the DH public parameter *y*. As a result, the decryption of message *M* not only completes the key seed negotiation process, but also serves as a means to authenticate the destination host. Once the message *M* is decrypted, the host will verify that the agent ID in the decrypted message matches the incoming agent, and the host ID in the decrypted message matches that of the current host.

With the plain value of *y*, the agent can derive the key seed by using its previously generated private parameter *a*. With the new key seed derived, the key seed negotiation process is completed. The agent can resume normal operation in the new host.

Whenever the agent and the butler need to communicate with each other, the sender will first derive a communication session key using the key seed and use this communication session key to encrypt the message. The receiver can make use of the same formula to derive the communication session key from the same key seed to decrypt the message.

The communication session key K_{CSK} is derived using the formula below.

K_{CSK} = Hash(key_seed + host ID + seqNo)

The sequence number is a running number that starts with 1 for each agent roaming session. Whenever the agent reaches a new host, the sequence number will be reset to 1. Given the varying communication session keys, if one of the messages is somehow lost without being detected, the butler and agent will not be able to communicate afterward. As a result, SADIS makes use of TCP/IP (transmission-control protocol/Internet protocol) as a communication mechanism so that any loss of messages can be immediately detected by the sender. In the case of an unsuccessful message, the sender will send ping messages to the recipient in plain format until the recipient or the communication channel recovers. Once the communication is reestablished, the sender will resend the previous message (encrypted using the same communication session key).

When the host provides information to the agent, the agent will encrypt the information with a data encryption key K_{DEK}. The data encryption key is derived as follows.

K_{DEK} = Hash(key_seed + host ID)

Data Integrity Protection Protocol

The key seed negotiation protocol lays the necessary foundation for integrity protection by establishing a session-based key seed between the agent and its butler. Agent data integrity is protected through the use of this key seed and the digital certificates of the hosts. Our data integrity protection protocol is comprised of two parts: chained signature generation and data integrity verification. Chained signature generation is performed before the agent leaves the current host. The agent gathers data provided by the current host d_i and construct D_i as follows.

$$D_i = E(d_i + ID_{host} + ID_{agent} + time\ stamp, k_{DEK})$$

or

$$D_i = d_i + ID_{host} + ID_{agent} + time\ stamp$$

The inclusion of the host ID, agent ID, and time stamp is to protect the data from possible replay attacks, especially when the information is not encrypted with the data encryption key. For example, if the agent ID is not included in the message, a malicious host can potentially replace the data provided for one agent with that provided for a bogus agent. Similarly, if the time stamp is not included in the message, earlier data provided to the same agent can be used at a later time to replace current data provided to the agent from the same host. The inclusion of the IDs of the parties involved and a time stamp essentially creates an unambiguous memorandum between the agent and the host.

After constructing D_i, the agent will request the host to perform a signature on the following:

ci = Sig(Di + ci-1 + IDhost + IDagent + time stamp, kpriv),

where c_0 is the digital signature on the agent code by its butler.

There are some advantages with the use of chained digital signature compared to the conventional signature approach. In the scenario where a malicious host attempts to modify the data from an innocent host *i* and somehow manages to produce a valid digital signature c_i, the data integrity would have been broken if the digital signatures were independent and not chained to each other. The independent digital signature also opens the window for host *i* to modify data provided to the agent at a later time (one such scenario is the agent visits one of the host's collaborating partners later). Regardless of the message format used, so long as the messages are independent of each other, host *i* will have no problem reproducing a valid signature for the modified message. In this way, data integrity can be compromised. With chained digital signature, even if the malicious host (or host *i* itself) produces a valid digital signature after modifying the data, the new signature c_i' is unlikely to be the same as c_i. If the new signature is different from the original signature, as the previous signature is provided as input to the next signature, the subsequent signature verification will fail, thus detecting compromise to data integrity. The inclusion of the host ID, agent ID, and time stamp prevents anyone from performing a replay attack.

When the agent reaches a new destination, the host must perform an integrity check on the incoming agent. In the design of SADIS, even if the new destination host does not perform an immediate integrity check on the incoming agent, any compromise to the data integrity can still be detected when the agent returns to the butler. The drawback, however, is that the identity of the malicious host may not be established. One design focus of SADIS is not only to detect data integrity compromise, but more importantly, to identify malicious hosts. To achieve malicious-host identification, it is an obligation for all hosts to verify the incoming agent's data integrity before activating the agent for execution. In the event of data integrity verification failure, the previous host will be identified as the malicious host.

FUTURE TRENDS

Besides agent data integrity and agent transport security, there are other security concerns to be addressed in SAFER. One such concern is a mechanism to assess the agent's accumulated risk level as it roams. There have been some considerations for using the agent battery concept to address this during the earlier stages of research. Furthermore, in order to establish the identity of different agents from different agent communities, a certain level of certification by trusted third parties or agent passports are required (Guan, Wang, & Ong, 2003). More research can be conducted in these areas.

CONCLUSION

In this chapter, a new data integrity protection protocol, SADIS, is proposed under the SAFER research initiative. Besides being secure against a variety of attacks and robust against vulnerabilities pointed out in related work in the literature, the research objectives of SADIS include efficiency. This is reflected in the minimized use of PKI operations and reduced message exchanges between the agent and the butler. The introduction of a variation to DH key exchange and evolving communication session keys further strengthened the security of the design. Unlike solutions suggested in some existing literature, the data integrity protection protocol aims not only to detect data integrity compromise, but more importantly, to identify the malicious host.

With security, efficiency, and effectiveness as its main design focus, SADIS works with other security mechanisms under SAFER (e.g., agent transport protocol) to provide mobile agents with a secure platform.

FUTURE RESEARCH DIRECTIONS

Recently there have been active research activities on the use of intelligent agents to mine user preferences: so-called personalization agents. Such agents, when equipped with inference engines, would be able to derive personal interests when observing Web or mobile-user interactions or click streams during online transactions. They would carry sensitive, personal data that should not be disclosed to outsiders. The protection of data in such agents is crucial. The migration of such agents or personalized data may be necessary when the service platform consists of multiple servers. For now, such agents usually reside on the server side, where strict security may already be in place. In the near future, such agents could be deployed on the client side, with a different name such as personal secretary, personal agent, and so forth. Such an agent may be dispatched by the user to run errands such as product brokering, information collection, or even transaction negotiation. An agent that carries user preference data is therefore vulnerable to attacks due to the fact that it has sensitive data inside. Protection of data in such type of agents would then be necessary.

TERMS AND DEFINITIONS

Agent: An agent is a piece of software that acts to accomplish tasks on behalf of its user.

Cryptography: Cryptography is the art of protecting information by transforming it (encrypting it) into an unreadable format, called cipher text. Only those who possess a secret key can decipher (or decrypt) the message into plain text.

Flexibility: Flexibility is the ease with which a system or component can be modified for use in applications or environments other than those for which it was specifically designed.

Integrity: Integrity regards the protection of data or program code from being modified by unauthorized parties.

Mobile Agent: Also called a roaming agent, it is an agent that can move from machine to machine for the purpose of data collection or code execution.

Protocol: A protocol is a convention or standard that controls or enables the connection, communication, and data transfer between two computing endpoints. Protocols may be implemented by hardware, software, or a combination of the two. At the lowest level, a protocol defines a hardware connection.

Security: Security involves the effort to create a secure computing platform designed so that agents (users or programs) can only perform actions that have been allowed.

Chapter 7.11
Key Distribution and Management for Mobile Applications

György Kálmán
University Graduate Center – UniK, Norway

Josef Noll
University Graduate Center – UniK, Norway

ABSTRACT

This chapter deals with challenges raised by securing transport, service access, user privacy, and accounting in wireless environments. Key generation, delivery, and revocation possibilities are discussed and recent solutions are shown. Special focus is on efficiency and adaptation to the mobile environment. Device domains in personal area networks and home networks are introduced to provide personal digital rights management (DRM) solutions. The value of smart cards and other security tokens are shown and a secure and convenient transmission method is recommended based on the mobile phone and near-field communication technology.

A PROBLEM OF MEDIA ACCESS

On the dawn of ubiquitous network access, data protection is becoming more and more important. While in the past network connectivity was mainly provided by wired connections, which is still considered the most secure access method, current and future users are moving towards wireless access and only the backbone stays connected by wires. In a wired environment, eavesdropping is existent, but not as spread and also not easy to implement. While methods exist to receive electromagnetic radiation from unshielded twisted pair (UTP) cables, a quite good protection can be achieved already by transport layer encryption or deploying shielded twisted pair (STP) or even fibre.

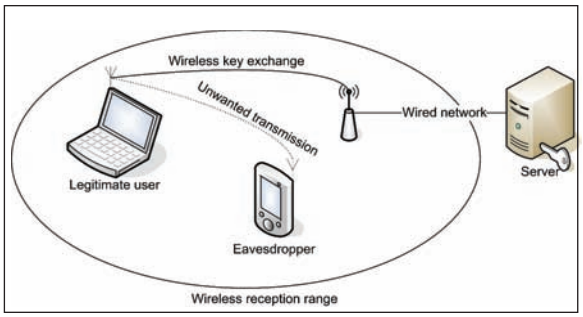
New technologies emerged in the wireless world, and especially the IEEE 802.11 family has drastically changed the way users connect to networks. The most basic requirements for new devices are the capability of supporting wireless service access. The mobile world introduced general packet radio service (GPRS) and third generation (3G) mobile systems provide permanent IP connectivity and provide together with Wi-Fi access points continuous wireless connec-

tivity. Besides communications devices such as laptops, phones, also cars, machines, and home appliances nowadays come with wireless/mobile connectivity.

Protecting user data is of key importance for all communications, and especially for wireless communications, where eavesdropping, man-in-the-middle, and other attacks are much easier. With a simple wireless LAN (WLAN) card and corresponding software it is possible to catch, analyse, and potentially decrypt wireless traffic. The implementation of the first WLAN encryption standard wired equivalent privacy (WEP) had serious weaknesses. Encryption keys can be obtained through a laptop in promiscuous mode in less than a minute, and this can happen through a hidden attacker somewhere in the surrounding. Data protection is even worse in places with public access and on factory default WLAN access points without activated encryption. Standard Internet protocols as simple mail transport protocol (SMTP) messages are not encoded, thus all user data are transmitted in plaintext. Thus, sending an e-mail over an open access point has the same effect as broadcasting the content. With default firewall settings an intruder has access to local files, since the local subnet is usually placed inside the trusted zone. These examples emphasise that wireless links need some kind of traffic encryption.

When the first widespread digital cellular network was developed around 1985, standardisation of the global system for mobile communication (GSM) introduced the A5 cryptographic algorithms, which can nowadays be cracked in real-time (A5/2) or near real-time (A5/1). A further security threat is the lack of mutual authentication between the terminal and the network. Only the terminal is authenticated, the user has to trust the network unconditionally. In universal mobile telecommunications system (UMTS), strong encryption is applied on the radio part of the transmission and provides adequate security for current demands, but does not secure the transmission over the backbone. UTMS provides mutual authentication through an advanced mechanism for authentication and session key distribution, named authentication and key agreement (AKA).

Figure 1. A basic problem of broadcast environment



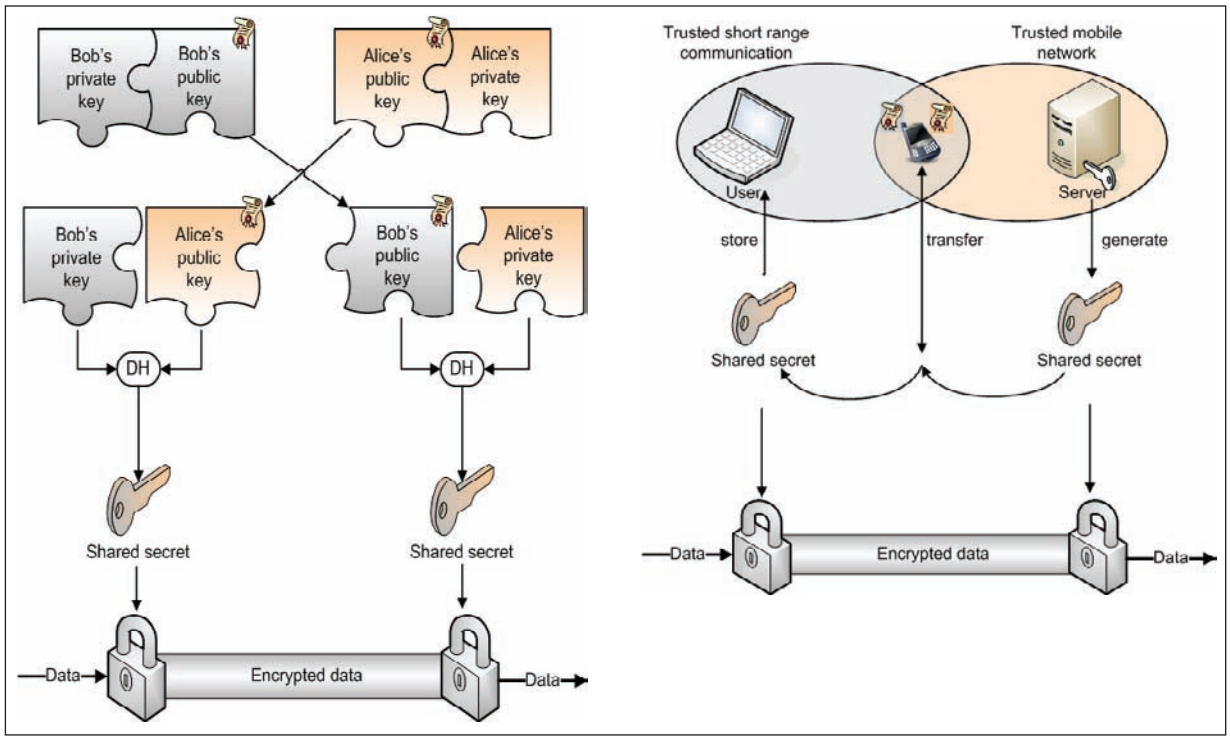
A LONG WAY TO SECURE COMMUNICATION

Applying some kind of cryptography does not imply a secured access. Communicating parties must negotiate the key used for encrypting the data. It should be obvious that the encryption key used for the communication session (session key) cannot be sent over the air in plaintext (see Figure 1).

In order to enable encryption even for the first message, several solutions exist. The simplest one, as used in cellular networks is a preshared key supplied to the mobile terminal on forehand. This key can be used later for initialising of the security infrastructure and can act as a master key in future authentications.

In more dynamic systems the use of preshared keys can be cumbersome. Most of WLAN encryption methods support this kind of key distribution. The key is taken to the new unit with some kind of out of band method, for example with an external unit, as indicated in Figure 2. Practically all private and many corporate WLANs use static keys, allowing an eavesdropper to catch huge amounts

Figure 2. (a) Diffie-Hellmann key exchange and (b) out-of-band key delivery



of traffic and thus enable easy decryption of the content. This implies that a system with just a secured access medium can be easily compromised. Non-aging keys can compromise even the strongest encryption, thus it is recommended to renew the keys from time to time.

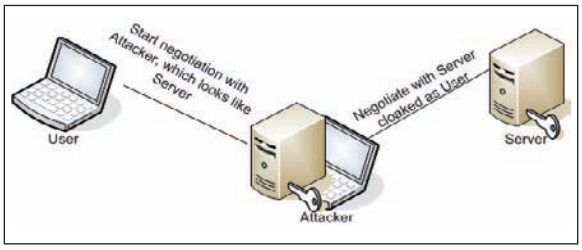
Outside the telecom world it is harder to distribute keys on forehand, so key exchange protocols emerged, which offer protection from the first message and do not need any preshared secret. The most widespread protocol is the Diffie-Hellman (DH) key exchange of Figure 2, which allows two parties that have no prior knowledge of each other to jointly establish a shared secret key over an insecure communications channel.

This protocol does not authenticate the nodes to each other, but enables the exchange data, which can be decoded only by the two parties. Malicious attackers may start a man-in-the-middle attack (see Figure 4). Since this problem is well-known, several modifications enable identity based DH, for example Boneh, Goh, and Boyen (2005) showed a hierarchical identity based encryption method, which is operating in fact as a public key system, where the public key is a used chosen string.

Public key infrastructure (PKI) can help defending corresponding parties against man-in-the-middle attacks. Public key cryptography is based on the non polynomial (NP) time problems, for example of factorisation or elliptic curves.

Two keys, a public and a private are generated. The public key can be sent in plaintext, because messages encrypted with the public key can only be decoded by the private key and vice versa. The two way nature of public keys makes it possible to authenticate users to each other, since signatures generated with the public key can be checked with the public key. Message authenticity can be guaranteed. Still, the identity of the node is not proven. The signature proves only that the message was encoded by the node,

Figure 3. Principle of a man-in-the-middle attack



which has a public key of the entity we may want to communicate with.

Identity can be ensured by using certificates. Certificate authorities (CA) store public keys and after checking the owner's identity out of band, prove their identity by signing the public key and user information with their own keys. This method is required for financial transactions and business and government operations. Without a CA, the public keys can be gathered into a PKI, which provides an exchange service. Here, most commonly, a method called web of trust is used. A number of nodes, who think that the key is authentic, submit their opinion by creating a signature. The solution enables community or personal key management, with a considerable level of authenticity protection.

While public keys can be sent, private keys must be kept secret. Although they are protected usually with an additional password, this is the weakest point in the system. If the user saves a key in a program in order to enter the key automatically, security provided by the system is equal to the security of the program's agent application. Private firewalls and operating system policies usually will not stop a good equipped intruder.

Another security issue for terminals is the lack of tamper resistant storage. Usage of smart cards is a solution to this issue, but introduces additional hardware requirements. The lack of secure storage is getting much attention in DRM schemes. Most DRM schemes use a software-based method, but also hardware-assisted ones have lately been introduced.

All these authentication methods, secure storage and rights management support secure data exchange, but they do not protect the privacy of user credentials, preferences, and profiles. Ad hoc networks, like personal area networks (PANs), which move around and are dynamically configured open for intrusion attacks on the privacy.

Thus, protection of user credentials in wireless environments is one of the focal points of current research. Before addressing privacy, we will first summarise issues in key management protocols.

FROM KEY EXCHANGE TO ACCESS CONTROL INFRASTRUCTURE

Mobility and wireless access introduced new problems in network and user management, as compared to fixed network installations with, for example, port-based access restrictions. The network operators want to protect the network against malicious intruders, charge the correct user for the use, and provide easy and open access to their valued services.

The first step to get access to an encrypted network is to negotiate the first session key. This has been solved in coordinated networks like mobile networks through pre-shared keys. Authentication and access control is provided by central entities to ensure operations.

In computer networks, which are not controlled in such way and usually not backed-up by a central authorisation, authentication, and accounting (AAA), different methods have been created for connection control. The basic method is still to negotiate encryption keys based on a preshared secret. Typical preshared keys are a password for hash calculation, one time password sent via cell phone or keys given on an USB stick.

There are several solutions to protect the data transmitted over a wireless link. In private networks, security based on preshared keys is a

Figure 4. TLS key negotiation

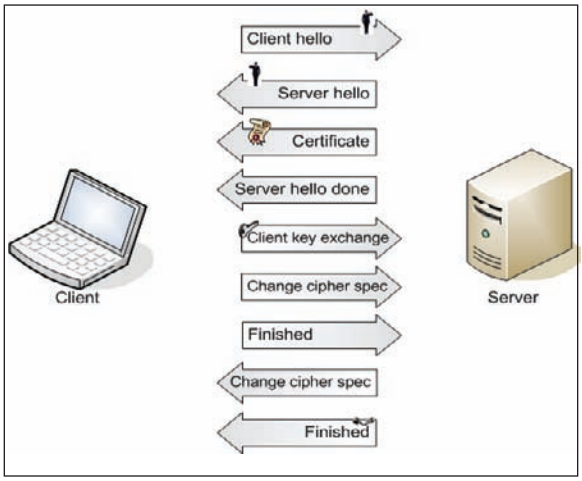


Figure 5. TLS-KEM key negotiation

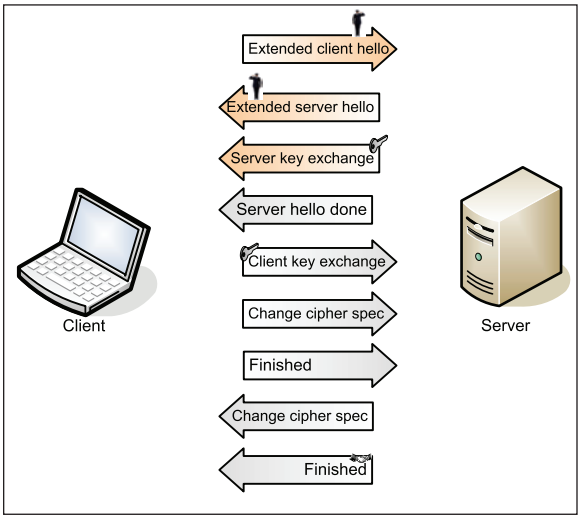


working solution. In corporate or public networks, a more robust solution is needed. The most promising way is to integrate session key negotiation into the AAA process. Since providers or companies have to identify the connected user, they rely on an AAA infrastructure and have an encryption of user credentials as compulsory policy. A certificate-based medium access control and AAA system is advised, where AAA messages can carry also the certificates needed to secure the message exchange.

As public key operations induce a lot of network traffic, the negotiated session keys have to be used in the most efficient way. Encryption protocols designed for wired environments, like transport layer security (TLS) do not consider problems associated with the broadcast transmissions and limitations of mobile devices. In a wired, or at least fixed environment, computational cost of key negotiations is usually neglected. For example TLS is using several public key operations to negotiate a session key. This can be a problem for mobile devices, since computational cost is much higher in asymmetric encryption. The standard TLS suite uses lots of cryptographic operations and generates a too large message load on wireless links (see Figure 5).

If a mobile device wants to execute mutual authentication with a service provider, with certificate exchanges, it can lead to big amounts of data transferred over the radio interface beside the high computing power needs.

In environments with limited resources, authentication and identity management based on preshared keys is still the most effective solution. Badra and Hajjeh (2006) propose an extension to TLS, which enables the use of preshared secrets instead the use of asymmetric encryption. This is in line with the efforts to keep resource needs at the required minimum level in mobile devices. A preshared key solution was also proposed by the 3rd Generation Partnership Projects (3GPP, 2004) and (3GPP2, 2007) as an authentication method for wireless LAN interworking. The problem with the proposed solution is preshared keys does not provide adequate secrecy nor identity protection in Internet connections. To deal with this problem, the TLS-key exchange method (TLS-KEM) provides identity protection, minimal resource need, and full compatibility with the original protocol suite as seen in Figure 6.

In direct comparison, the public key based TLS needs a lot more computing, data traffic, and deployment effort.

In UMTS networks, an array of authentication keys is sent to the mobile in authentication vectors. In the computer world a good solution would be using hash functions to calculate new session keys, as these consume low power and require little computing.

A moving terminal can experience a communication problem, as the overhead caused by key negotiation might extend the connection time to a network node. A preserved session key for use in the new network is a potential solution in a mobile environment, as it speeds up the node's authentication. Lee and Chung (2006) recommend a scheme, which enables to reuse of session keys. Based on the AAA infrastructure, it is possible to forward the key to the new corresponding AAA server on a protected network and use it for authentication without compromising system security. This can reduce the delay for connecting, and also reduces the possibility of authentication failure. Since the old session key can be used for authenticating the node towards the new AAA server, connection to the home AAA is not needed any more. The messages are exchanged as follows (Lee & Chung, 2006): when sending the authorisation request to the new network, the node also includes the old network address it had. The foreign agent connects to the new local AAA server and sends an authentication request. The new AAA server connects to the old one sending a message to identify the user. The old AAA authenticates the message by checking the hash value included, and generates a nonce for the terminal and the foreign agent. The server composes an AAA-terminal answer, which is composed from a plain nonce, an encrypted nonce using the key shared between the old foreign agent and the terminal. Then the whole message is signed and encrypted with the key used between the two AAA servers. When the new AAA receives it, decrypts and sends the message to the new foreign agent. Based on the plain nonce, the agent generates the key and sends down the reply, which includes also the nonce encrypted by the old AAA. After the authentication of the user towards the network, the user can start using services.

Key distribution and efficiency in e-commerce applications is another important aspect. The network's AAA usually does not exchange information with third parties or can not use the authentication data of the network access because of privacy issues. Current security demands require mutual identification of communicating parties in an e-commerce application. This can easily lead to compromising the customer to companies (for example in a GSM network, the user has to trust the network unconditionally). If the user can also check the identity of the service provider, at least man-in-the-middle attacks are locked out.

When a user starts a new session with a service provider, this session should be based on a new key set. The session key has to be independent from the previous one in means of traceability and user identity should not be deductible from the session key, thus ensuring user privacy. For mutual identification, a key exchange method is proposed by Kwak, Oh, and Won (2006), which uses hash values to reduce resource need. The key calculation is based on random values generated by the parties, which ensures key freshness.

The use of hash functions is recommended in mobile environments, providing better performances for public key based mechanisms (Lim, Lim, & Chung, 2006). Mobile IPv4 uses symmetric keys and hashes by default. Since symmetric keys are hard to manage, a certificate-based key exchange was recommended, but this demands more resources. To lower the resource demand, a composite architecture was recommended (Sufatrio, 1999). The procedure uses certificates only in places where the terminal does not require processing of the public key algorithm and does not require storage of the certificate.

The result of the comparison shows that hash is by far the most efficient method in terms of key generation, but suffers from management difficulties. Lim et al. (2006) also demonstrates

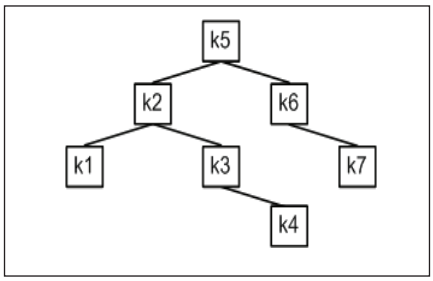
that a pure certificate-based authentication is unsuitable for mobile environments. Partial use of certificates and identity-based authentication with extensive use of hash functions can be a potential way ahead.

AUTHENTICATION OF DEVICE GROUPS

In a ubiquitous environment, moving networks appear. PANs and ad hoc connections based on various preferences emerge and fall apart. These devices communicate with each other and have usually very limited capabilities in terms of computing power and energy reserves. In order to provide secure communication between any part of the network, hierarchical key management methods emerged (Kim, Ahn, & Oh, 2006). Here a single trusted server is used to manage the group key. These entities are usually storing the keys in a binary tree, where nodes are the leaves.

Public key operations are usually required when a terminal wants to connect to a group for the first time. A group management system needs frequent key generation rounds, because it has to ensure forward and backward secrecy. Strict key management policies ensure that no new node is capable of decoding former traffic and none of the old nodes have the possibility to decrypt current traffic. To adjust resource usage to mobile environment, a management scheme which uses mainly simple operations like XOR and hash is advisable (Kim et al., 2006). As the key in the root of the binary tree is used to authenticate the whole group, keys need to be regenerated when a node leaves the network. This procedure is starting from the parent of the former node and goes up to the root. Then the management unit sends out the new keys in one message. Building a tree from keys ensures fast searches and a simple, clean structure. In addition, all keys in the internal nodes are group keys for the leaves under them. So a subset of devices can be easily addressed.

Figure 6. Keys in a binary tree



The root unit has to compute these keys in acceptable time, requiring a more complex architecture. In PANs this is usually not a problem, but when a member of a larger subnet is leaving, calculations could be more demanding. A standard group key handling method is the Tree-based Group Diffie-Hellman (TGDH), where management steps assume that all nodes have the same processing capabilities. To ensure maximal efficiency, the highest performance unit shall be the one in the root of the tree (Hong & Lopez-Benitez, 2006). When node computing capabilities are showing big differences, the overhead caused by tree transformations does not represent a drawback.

Another significant group of devices that need encryption can be found in home networks, where the focus is on management of content and personal data.

SECURE HOME NETWORK AND RIGHTS MANAGEMENT

Deployment of wired or wireless home networks happens in roughly 80% of all households with broadband access (Noll, Ribeiro, & Thorsteinsson, 2005). Network-capable multimedia devices, media players, game consoles, and digital set-top boxes are widespread and part of the digital entertainment era. Content is stored within this network, and provided through the Internet to

other users. Since the birth of peer-to-peer (P2P) networks, such technologies are in the crosshair of content providers. Recently, some software developers and a few musicians started using the torrent network for cost effective delivery of their content. A digital rights management method designed for such network is still missing.

Current right protection solutions are not compatible with each other and the user friendliness is also varying. The basic problem is, that just a very few devices are equipped with tamper resistant storage and integrated cryptographic capabilities. Beside software solutions, which are meant as weak solutions, hardware-based encryption can severely limit the lawful use of digital content. Recent lawsuits related to Sony's rootkit protection mechanism also reveals that customer rights of usage is considered to be more important than the legitimate wish of content providers to protect the content.

Trusted platform modules (TPM) are the most likely candidate for content protection in hardware-based solutions. While providing encryption capabilities, it is very likely that these components will be used to dispose the users' right to decide over the user's own resources.

The current discussions on DRM for audio content are regarded as minor when compared to high definition (HD) content protection. Even the connection to the screen has to use strong encryption, which has to exceed GSM/UMTS encryption in order to be acceptable for content providers. Enforcing a digital, end-to-end encrypted stream means that a HD-TV purchased at the end of 2006 may not work with the new encryption standards for HD. There is no current solution for computers to legally play full resolution HD. By the end of 2006 it was announced, that a workaround is arising to deal with the advanced content protection system of HD.

A more discrete, but not intrusive business model discussion for digital content management is presented in order to visualise the requirements of this market. Apple's FairPlay enables making backup copies of audio tracks, which is permitted by law in several European countries, and copy of content between the user's iPod players. This solution is considered being to open for some content providers, and the distribution is limited to a server-client infrastructure. For HD content with high bandwidth needs such a server-client infrastructure is not advisable, both from a server and network point of view. The ever growing size of P2P networks form a perfect infrastructure to deliver content with high bandwidth need practically without substantial transmission costs. P2P networks are usually run without any DRM support. An additional infrastructure supporting DRM in a P2P network used to transmit content will enable high volume distribution of digital content (Pfeifer, Savage, Brazil, & Downes, 2006). If seamless license delivery and user privacy could be guaranteed, such a network could be the foundation of a low cost content delivery scheme.

While the usage of P2P networks is an excellent idea, the recommended solution proposed by Nützel and Beyer (2006) is similar to the Sony's rootkit solution: It bypasses the user control and is thus not acceptable. While the primary goal is to secure content, the software used in such solutions acts like hidden Trojans and opens backdoors not only for the content providers, but also other hackers.

Content usage across platforms is not supported yet, as a common standard does not exist. Pfeifer et al. (2006) suggests a common management platform for DRM keys with an XML-based, standard MPEG-REL framework. Users will also produce content with digital protection, in order to ensure that personal pictures cannot be distributed electronically. Social networks and groups of interest, as well as distribution of content in PANs is a challenge for DRM development. Zou, Thukral, and Ramamurthy (2006) and Popescu, Crispo, Tanenbaum, and Kamperman (2004) propose a key delivery architecture for device groups, which could be extended by a local license manager.

The central key management unit could distribute licenses seamlessly to the device, which wants to get access, without invading user experience.

Kálmán and Noll (2006) recommend a phone-based solution. This represents a good trade-off between user experience and content protection. The phone is practically always online, most of them have Bluetooth or other short range radio transmitters, so licenses can be transmitted on demand. Since the phone has a screen and a keyboard, it is possible to request authorisation from the user before every significant message exchange, so the user can control the way licenses are distributes.

If we look aside the issues related to business aspects, computational issues still remain. Highly secure DRM entities will use asymmetric encryption and certificates. Sur and Rhee (2006) recommend a device authentication architecture, which eliminates traditional public key operations except the ones on the coordinator device. This is achieved by using hash chains including the permission, for example, a device can get keys to play a designated audio track ten times or permission to use five daily permits on demand. Such schemes allow end devices to be simpler and lower network communication overhead.

If a central device is not appreciated, a composite key management scheme may be used. The parties in the PAN will form a web of trust like in a confidentiality scheme, for example, pretty good privacy (PGP). In this web, the main key is split between nodes and cooperation is needed for significant operations. This means that if the scheme is operating on a (k, n) basis, k-1 nodes can be lost before the system needs to be generate a new key. Fu, He, and Li (2006) mention the problem of the PAN's ad hoc nature as the biggest problem. Since this scheme selects n nodes randomly, the ones that are moving between networks fast can cause instability in the system. Also, the resource need of this proposal is quite high on all nodes present.

When a scheme is enabling off-line use of license keys, attention should be given to problems arising from leaving or compromised nodes. Identity-based schemes become popular recently because of their efficiency in key distribution. The main drawback is that these proposals do not provide a solution for revocation and key renewal. Hoeper and Gong (2006) propose a solution based on a heuristic (z, m) method. The solution is similar to the threshold scheme shown before, but enables key revocation. If *z* nodes are accusing one node to be compromised, based on their own opinion, the node is forced to negotiate a new key. If a node reaches a threshold in number of regenerations in a time period, it could be locked out, since most likely an intruder is trying to get into the system or the internal security of the node is not good enough. The assumptions about the system are strongly limiting the effectiveness of the solution. The most stringent assumption is that they require to nodes to be in promiscuous mode. This can lead to serious energy problems. Another requirement is that there has to be a unit for out-of-band key distribution. This unit could be the cellular phone.

SMART CARDS AND CELLULAR OPERATORS

The use of smart cards has its roots in the basic problem of security infrastructures: even the most well designed system is vulnerable to weak passwords. A card, which represents a physical entity, can be much easier protected compared to a theoretical possession of a password. Smart cards integrate tamper resistant storage and cryptographic functions. They are usually initialised with a preshared key and creating a hash chain, where values can be used as authentication tokens.

The remote authentication server is using the same function to calculate the next member. The encryption key is the selection of a collision resis-

tant hash function. While the tokens they provide are quite secure, a problem with smart cards is that they represent a new unit that has to be present in order to enable secure communication, and user terminals must be equipped with suitable readers. The additional hardware does not only cause interoperability problems, but is usually slow, as a measurement conducted shows (Badra & Hajjeh, 2006). This becomes eminent when high traffic is associated with asymmetric encryption; sending a "hello" message with standard TLS to the smart card needed 10 seconds. In contrast, the modified TLS-KEM needed 1.5 s.

A user-friendly, seamless key delivery system can be created with the help of cellular operators and SIM cards with enhanced encryption capabilities. The SIM and USIM modules used in GSM/UMTS are quite capable smart cards. They offer protected storage with the possibility of over the air key management, good user interface, and standard architecture. Danzeisen, Braun, Rodellar, and Winiker (2006) shows the possible use of the mobile operator as trusted third party for exchanging encryption keys out of band for other networks.

Delivery of the mobile phone key to a different device can be problematic, since most devices do not have a SIM reader, or it is inconvenient to move the SIM card from the mobile phone to another device. New developments in near field communication may overcome this and enable short range secure key transfer.

BREAKING THE LAST CENTIMETRE BOUNDARY

Frequency of authentication request is a key factor in user acceptance. If a system asks permanently for new passwords or new values from the smart card hash chain, it will not be accepted by the user. On the other hand, if a device gets stolen and it asks for a password only when it is switched on, then a malicious person can impersonate the user for a long time. A potential solution is to create a wearable token with some kind of wireless transmission technology and define the device behaviour such that if the token is not accessible, it should disable itself in the very moment of notification.

Since the main challenge is not securing data transfer between the terminal and the network, but to authenticate the current user of the terminal, a personal token has to be presented. As proposed by Kálmán and Noll (2007), the mobile phone can be a perfect personal authentication token if it is extended by a wireless protocol for key distribution.

With the capabilities of user interaction, network control of the mobile phone, it can be ensured that critical operations will need user presence by requiring PINs or passwords. Possible candidates for key exchange are Bluetooth (BT), radio frequency identification (RFID), and Near Field Communications (NFC). NFC is a successor of RFID technology in very short range transmissions. BT is close to the usability limit, since its transmit range reaches several meters. But the two later ones are promising candidates. Depending on the frequency, general RFID has a range of several meters while NFC operates in the 0-10 cm range. NFC is recommended, as the range alone limits the possibilities of eavesdroppers and intruders who want to impersonate the token while it is absent. The use of repeaters in the case of NFC, a so-called wormhole attack as described by Nicholson, Corner, and Noble (2006), looks not feasible because of the tight net of repeaters required. Also, the capability of user interaction provides an additional level of security.

Mobile phones with integrated NFC functionality are already available and serve as user authentication devices. To use these devices as tokens for other terminals, they have to be placed very close to each other. This prevents accidental use in most cases. To check presence of the token, heartbeat messages might be introduced. By design, this solution is very capable of distribut-

ing preshared keys for other devices out of band. Meaning, the phone can get the keys from the cellular network from an identity provider and send it down to the appropriate device by asking the user to put the devices close to each other for a second or two.

Transmission of the key must be done only when needed, so the programmable chip on the phones has to be in a secured state by default and only activated by the user's interaction. Protection of RFID tags is shown by Rieback, Gaydadjiev, Crispo, Hofman, and Tanenbaum (2006), where a proprietary hardware solution is presented. In case of a phone-based NFC key transmission, additional active devices might be unnecessary to use, but for general privacy protection, IDs with RFID extensions must be treated with care.

Transmission of certificates would not need additional encryption over the NFC interface, while other keys may require a preshared key between the phone and the terminals, which can be done via a wired method or by the phone provider. Most providers have at least one secret key stored on phones and a public key connected to that one. Based on this, DH key exchange would be possible between terminals and the phone using the cellular network as a gateway. An NFC-enabled phone could be the central element of a home DRM service, as it is online, capable of over the air downloads, and still able to ensure user control.

ON THE DAWN ON PERSONAL CONTENT MANAGEMENT

From the viewpoint of secure data transmission and user authentication, access and distribution of digital content can be ensured. Open issues remain for moving PANs and devices with limited capability. Focus nowadays is on protecting the user's privacy. As usage of digital devices with personal information was limited, user privacy was not of primary concern for a long time. Since PANs and home networks hold a large amount of critical personal data, this has to change (Jeong, Chung, & Choo, 2006; Ren, Lou, Kim, & Deng, 2006).

In a ubiquitous environment users want to access their content wherever they are. This has to be enabled in a secure manner. With upcoming social services, also fine grained access control methods have to be deployed inside the personal infrastructure. The focus of DRM research has to shift towards the end user, who will also require the right to protect himself/herself and his/her content with the same strength as companies do.

Extending the phone's functions may be problematic because of energy consumption and limited computing power. This could be easily solved by the technology itself, since a new generation of mobile terminals is arriving every half year. The capacity and functionalities of the SIM cards will be extended, the newest 3GPP proposals are predicting high capacity and extended cryptographic possibilities.

Regarding legal aspects, extending the SIM possibilities may cause some concern, since the SIM cards are currently owned by the network operators.

CONCLUSION

Transport encryption and authentication of devices has been the subject of research for a long time and resulted in sufficient secure solutions with current technologies. The focus in recent proposals is on the limited possibilities of mobile terminals and adoption of encryption technologies for mobile and wireless links.

Distributing keys between nodes is solved, except for the first step, which usually requires out-of-band transmissions. A solution for this initial key distribution might be the mobile phone with its integrated smart card and already existing communication possibility. As phones come with NFC, they may act as contact-less cards to distribute keys between devices.

While device authentication is handled sufficiently, user identity is hard to prove. A knowledge-based password or PIN request is not a user-friendly solution. Current proposals tend to be insecure when performing the trade-off between user experience and security.

Focus on research should be paid towards personal area and home networks. These networks hold most of the user's personal private data and content, either purchased or created by the user. Currently no standard solution exists for managing content rights or for access control of own content.

KEY TERMS

Diffie-Hellman Key Exchange: Diffie-Hellman key exchange is a procedure, which allows negotiating a secure session key between parties, who do not have any former information about each other. The negotiation messages are in band, but because of the non-polynomial (NP) problem used in the procedure, adversaries are not able to compromise it.

Mutual Authentication: Mutual authentication occurs when the communicating parties can mutually check each others identity, thus reducing the possibility of a man-in-the-middle attack or other integrity attacks.

Out of Band Key Delivery: Out of band key delivery occurs when an encryption key is delivered with a mean, which is inaccessible from inside the network it will be used in. An example is to carry a key on an USB stick between parties, where the key will never be transmitted over the network.

Rootkit: Rootkit is a kind of software to hide other programs. Mainly used by Trojans, they enable hidden applications to access local resources without user knowledge.

Seamless Authentication: Seamless authentication is a method where the user is authenticated towards an entity without the burden of credential requests. For high security requirements, transparent methods are not applicable, but can provide additional security in traditional username/password or PIN-based sessions.

Session Key: Session key is a short life, randomly generated encryption key to protect one or a group of messages. The main purpose is to use expensive encryption operations only when starting a session and use a simpler to manage cipher in the later part.

Chapter 7.12
Modeling Fault Tolerant and Secure Mobile Agent Execution in Distributed Systems

INTRODUCTION

A mobile agent is a software program which migrates from a site to another site to perform tasks assigned by a user. For the mobile agent system to support agents in various application areas, the issues regarding reliable agent execution, as well as compatibility between two different agent systems or secure agent migration, have been considered. Some of the proposed schemes are either replicating the agents (Hamidi & Mohammadi, 2005) or check-pointing the agents (Park, Byun, Kim, & Yeom, 2002; Pleisch & Schiper, 2001;) For a single agent environment without considering inter-agent communication, the performance of the replication scheme and the check-pointing scheme is compared in Park et al. (2002) and Silva, Batista, and Silva (2000). In the area of mobile agents, only few works can be found relating to fault tolerance. Most of them refer to special agent systems or cover only some special aspects relating to mobile agents, such as the communication subsystem. Nevertheless, most people working with mobile agents consider fault tolerance to be an important issue (Izatt, Chan, & Brecht, 1999; Shiraishi, Enokido, & Takzawa, 2003). Mobile agents are becoming a major trend for designing distributed systems and applications in the last few years and foreseeable future. It can bring benefits such as reduced network load and overcoming of network latency (Chan, Won, & Lyu, 1993). Nevertheless, security is one of the limiting factors of the development of these systems. The main unsolved security problem lies in the possible existence of malicious hosts that can manipulate the execution and data of agents (Defago, Schiper, & Sergent, 1998). Most distributed applications we see today are deploy-

ing the *client/server paradigm*. There are certain problems with the client/server paradigm, such as the requirement of a high network bandwidth, and continuous user-computer interactivity.

In view of the deficiencies of the client/server paradigm, the *mobile code paradigm* has been developed as an alternative approach for distributed application design. In the client/server paradigm, programs cannot move across different machines and must run on the machines they reside on. The mobile code paradigm, on the other hand, allows programs to be transferred among and executed on different computers. By allowing code to move between hosts, programs can interact on the same computer instead of over the network. Therefore, communication cost can be reduced. Besides, *mobile agent* (Fischer, Lynch, & Paterson, 1983) programs can be designed to work on behalf of users autonomously. This autonomy allows users to delegate their tasks to the mobile agents, and not to stay continuously in front of the computer terminal. The promises of the mobile code paradigm bring about active research in its realization. Most researchers, however, agree that security concerns are a hurdle (Greenberg, Byington, & Harper, 1998).

In this article, we investigate these concerns. First, we review some of the foundation materials of the mobile code paradigm. We elaborate Ghezzi and Vigna's classification of mobile code paradigms (Ghezzi & Vigna, 1997), which is a collection of the *remote evaluation, code on demand,* and *mobile agent* approaches. In the next section, we address the current status of mobile code security. The following section presents the model for fault-tolerant mobile agent. In the next section, security issues of the mobile agent are discussed, and we discuss security modeling and evaluation for the mobile agent in the section after. In the following section, simulation results and influence of the size of agent are discussed. We then conclude the article.

THE MOBILE CODE PARADIGM

The mobile code paradigm is essentially a collective term, applicable wherever there is mobility of code. While different classes of code mobility have been identified, Ghezzi and Vigna proposed three of them, namely *remote evaluation, code on demand,* and *mobile agent* (1997). This classification, together with the client/server paradigm, is summarized in Table 1.

In particular, the "know-how" in Table 1 represents the code that is to be executed for the specific task. In the mobile code paradigms (*remote evaluation, code on demand*, and *mobile agent*), the *know-how* moves from one side to another side regarding where the computation takes place; while in the client/server paradigm, the *know-how* is stationary on the remote (server) side. *Resources* are the input and output for the code, whereas *processor* is the abstract machine that carries out and holds the state of the computation. The arrows represent the directions in which the specific item should move before the required task is carried out. Ghezzi and Vigna's classification is found to be comprehensive and representative of most existing mobile code paradigms (such as the rsh utility, Java applets and mobile agent systems), and we will base our discussion on this classification.

SECURITY CONCERNS OF MOBILE CODE PARADIGMS

In this section, we discuss some possible security attacks to different mobile code paradigms, and possible mechanisms against these attacks.

Security Attacks

A security attack is an action that compromises the security requirements of an application. Applications developed using different paradigms are

subject to different attacks. In the conventional client/server model, the local computer is usually assumed to be a secure premise ("*information fortress*") for code and data. This effectively limits the source of security attacks to outsiders of the local machine. Therefore, the main possible attacks are *masquerading* (pretending to be the server or the client), *eavesdropping* on the communication channel, and *forging messages* to the client or the server.

While the security fortress model is usually assumed in the client/server paradigm, it also applies to the *remote evaluation* and *code-on-demand* approaches, with the additional concern that the code receiving side must make sure the code is not harmful to run. In remote evaluation, the code receiving side is the remote side, while it is the local side in code-on-demand.

Mobile agent, on the other hand, is the most challenging area of mobile code security, due to the autonomy of agents. Mobile agent security is usually divided into two aspects: *host security* and *agent security.* Host security deals with the protection of hosts against malicious agents or other hosts, while agent security deals with the protection of agents against malicious hosts or other agents. For host security, the security fortress model can still apply. However, it hardly applies to agent security, due to the lack of trusted hardware with which to anchor security (Tschudin, 1999). There are two branches of new possible attacks to agents:

1. *Data tampering:* A host or another agent may modify the data or execution state being carried by an agent for malicious purpose.
2. *Execution tampering:* A host may change the code executed by an agent, or rearrange the code execution sequence for malicious purpose.

Security Mechanisms

Security mechanisms are mechanisms designed to prevent, detect or recover from security attacks. We see from the previous section that the main security challenges of the client/server paradigm are the mutual trust building between clients and servers, plus the protection of messages in transit. These problems can be satisfactorily solved by cryptographic techniques such as *security protocols* and *message encryption.* These mechanisms are already extensively employed in existing client/server applications. A lot of details can be found in Schneier (1996) and Stallings (1999).

As there are more possible attacks to mobile code paradigms, more mechanisms are required to secure mobile code applications. We see from a previous section that the main additional challenge to security of mobile code paradigms is the verification of the received code. One significant approach to this problem is the *sandbox model.* In the sandbox model, the code or agent received from a remote side can only access a dedicated portion of system resources. Therefore, even if the received code or agent is malicious, damage would be confined to the resources dedicated to that code or agent.

While the sandbox technique is well known and generally accepted for host security, there is yet no good mechanism for agent security. Some approaches have been proposed, and they can be classified into two categories. The first category is agent-tampering detection. These techniques aim at detecting whether an agent's execution or data have been tampered with along the journey. Some possible approaches are *range verification*, *timing information*, *addition of dummy data items and code*, and *cryptographic watermarks* (Tschudin, 1999). Another category is agent-tampering prevention. These techniques aim at preventing agent code or data being tampered with. Two representative approaches are the *execution of encrypted functions* (Sander & Tschudin, 1998) and *time-limited black-boxes* (Hohl, 1998). These approaches are enlightening in the way they open new areas in computer security. Yet they provide limited protection to agents for the time being.

Table 1. Ghezzi and Vigna's (1997) classification of mobile code paradigms

Paradigm		*Local side*	*Remote side*	*Computation takes place at*
Client/server		--	Know-how	Remote side
			Processor	
			Resources	
Mobile code Mobile code Mobile code …… …… …… …… ……	*Remote evaluation*	Know-how ----------	→	Remote side
			Processor	
			Resources	
	Code on demand	←	… Know-how	Local side
		Processor		
		Resources		
	Mobile agent	Know-how ……	→	Remote side
		Processor ----------	→	
			Resources	

Agent protection is still in its early stage, compared with the maturity of protection for hosts and client/servers, and efforts should be spent on improving the already-proposed mechanisms, or developing new protection mechanisms.

MODEL

We assume an asynchronous distributed system, that is, there are no bounds on transmission delays of messages or on relative process speeds. An example of an asynchronous system is the Internet. Processes communicate via message passing over a fully connected network.

Mobile Agent Model

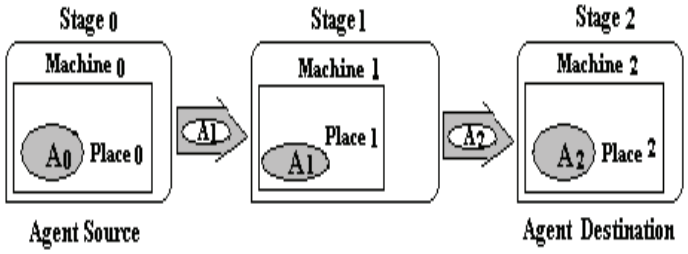
A mobile agent executes on a sequence of machines, where a place P_i ($0 \le i \le n$) provides the logical execution environment for the agent. Each place runs a set of services, which together compose the state of the place. For simplicity, we say that the agent "accesses the state of the place," although access occurs through a service running on the place. Executing the agent at a place P_i is called a stage S_i of the agent execution. We call the places where the first and last stages of an agent execute (i.e., P_i and P_n) the agent source and destination, respectively. The sequence of places between the agent source and destination (i.e., P_0, P_1, … P_n) is called the itinerary of a mobile agent. Whereas a static itinerary is entirely defined at the agent source and does not change during the agent execution, a dynamic itinerary is subject to modifications by the agent itself.

Logically, a mobile agent executes in a sequence of stage actions (Figure 1). Each stage action consists of potentially a multiple set of operations op_0, op_1,…op_n. Agent A_i ($0 \le i \le n$) at the corresponding stage S_i represents the agent that has executed the stage action on places P_j ($j < i$) and is about to execute on place P_i. The execution of A_i at place P_i results in a new internal state of the agent as well as potentially a new state of the place (if the operations of an agent have side effects, i.e., are non idempotent). We denote the resulting agent A_{i+1}. Place P_i forwards to P_{i+1} (for $i < n$).

Fault Model

Several types of faults can occur in agent environments. Here, we first describe a general fault model, and focus on those types, which are important in agent environments due to high

Figure 1. Model of mobile agent execution with three stages



occurrence probability, and those that have been addressed in related work insufficiently.

- Node failures: The complete failure of a compute node implies the failure of all agent places and agents located on it. Node failures can be temporary or permanent.
- Failures of components of the agent system: Failures of agent places, or components of agent places become faulty, for example, faulty communication units or incomplete agent directory. These faults can result in agent failures, or in reduced or wrong functionality of agents.
- Failures of mobile agents: Mobile agents can become faulty due to faulty computation, or other faults (e.g., node or network failures).
- Network failures: Failures of the entire communication network or of single links can lead to isolation of single nodes, or to network partitions.
- Falsification or loss of messages: These are usually caused by failures in the network or in the communication units of the agent systems, or the underlying operating systems. Also, faulty transmission of agents during migration belongs to this type.

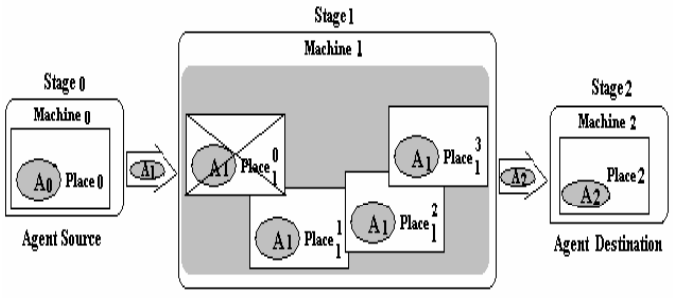
Especially in the intended scenario of parallel applications, node failures and their consequences are important. Such consequences are loss of agents, and loss of node specific resources. In general, each agent has to fulfill a specific task to contribute to the parallel application, and thus, agent failures must be treated with care. In contrast, in applications where a large number of agents are sent out to search and process information in a network, the loss of one or several mobile agents might be acceptable (Pleisch & Schiper, 2000, 2001).

Model Failures

Machines, places, or agents can fail and recover later. A component that has failed but not yet recovered is called down; otherwise, it is up. If it is eventually permanently up, it is called good (Aguilera, 2000). In this article, we focus on crash failures (i.e., processes prematurely halted). Benign and malicious failures (i.e., Byzantine failures) are not discussed. A failing place causes the failure of all agents running on it. Similarly, a failing machine causes all places and agents on this machine to fail as well. We do not consider deterministic, repetitive programming errors (i.e., programming errors that occur on all agent replicas or places) in the code or the place as relevant failures in this context. Finally a link failure causes the loss of messages or agents currently in transmission on this link and may lead to network partitioning. We assume that link failures (and network partitions) are not permanent. The failure of a component (i.e., agent, place, machine, or communication link) can lead to blocking in the mobile agent execution.

Assume, for instance that place P_1 fails while executing A_1 (Figure 2). While P_1 is down, the

Figure 2. The redundant places mask the place failure



execution of the mobile agent cannot proceed, that is, it is blocked. Blocking occurs if a single failure prevents the execution from proceeding. In contrast, an execution is non-blocking if it can proceed despite a single failure, the blocked mobile agent execution can only continue when the failed component recovers. This requires that recovery mechanism be in place, which allows the failed component to be recovered. If no recovery mechanism exists, then the agent's state and potentially its code may be lost. In the following, we assume that such a recovery mechanism exists (e.g., based on logging [Ghezzi & Vigna, 1997]). Replication prevents blocking. Instead of sending the agent to one place at the next stage, agent replicas are sent to a set of M_i places P_i^0, P_i^1,.., P_i^n (Figure 2). We denote by A_i^j the agent replica of A_i executing on place P_i^j, but will omit the superscripted index if the meaning is clear from the context. Although a place may crash (i.e., Stage 1 in Figure 2), the agent execution does not block. Indeed, P_2^1 can take over the execution of a1 and thus prevent blocking. Note that the execution at stages S_0 and S_2 is not replicated as the agent is under the control of the user. Moreover, the agent is only configured at the agent source and presents the results to the agent owner at the agent destination. Hence, replication is not needed at these stages.

Despite agent replication, network partitions can still prevent the progress of the agent. Indeed, if the network is partitioned such that all places currently executing the agent at stage S_i are in one partition and the places of stage S_{i+1} are in another partition, the agent cannot proceed with its execution. Generally (especially on the Internet), multiple routing paths are possible for a message to arrive at its destination. Therefore, a link failure may not always lead to network partitioning. In the following, we assume that a single link failure merely partitions one place from the rest of the network. Clearly, this is a simplification, but it allows us to define blocking concisely. Indeed, in the approach presented in this article, progress in the agent execution is possible in a network partition that contains a majority of places. If no such partition exists, the execution is temporally interrupted until a majority partition is established again. Moreover, catastrophic failures may still cause the loss of the entire agent. A failure of all places in M_1 (Figure 2), for instance, is such a catastrophic failure (assuming no recovery mechanism is in place). As no copy of A_1 is available any more, the agent A_1 is lost and, obviously, the agent execution can no longer proceed. In other words, replication does not solve all problems. The definition of non-blocking merely addresses single failures per stage as they cover most of the failures that occur in a realistic environment.

SECURITY ISSUES OF THE MOBILE AGENT

Any distributed system is subject to security threats, so is a mobile agent system. Issues such

as encryption, authorization, authentication, non-repudiation should be addressed in a mobile agent system. In addition, a secure mobile agent system must protect the hosts as well as the agents from being tampered with by malicious parties.

First, hosts must be protected because they continuously receive agents and execute them. They may not be sure where an agent comes from, and are at the risk of being damaged by malicious code or agents (Trojan horse attack). This problem can be effectively solved by strong authentication of the code sources, verification of code integrity, and limiting the access rights of incoming agents to local resources of hosts. This is mostly realized by the Java security model (Hohl, 1998). The main security challenge of mobile agent systems lies on the protection of agents. When an agent executes on a remote host, the host is likely to have access to all the data and code carried by the agent. If by chance a host is malicious and abuses the code or data of an agent, the privacy and secrecy of the agent and its owner would be at risk.

Seven types of attack by malicious hosts (Defago, Schiper, & Sergent, 1998) can be identified:

1. Spying out and manipulation of code;
2. Spying out and manipulation of data;
3. Spying out and manipulation of control flow;
4. Incorrect execution of code;
5. Masquerading of the host;
6. Spying out and manipulation of interaction with other agents; and
7. Returning wrong results of system calls to agents.

There are a number of solutions proposed to protect agents against malicious hosts (Chan et al., 1993), which can be divided into three streams:

- Establishing a closed network: Limiting the set of hosts among which agents travel such that agents travel only to hosts that are trusted.
- Agent tampering detection: Using specially designed state-appraisal functions to detect whether agent states have been changed maliciously during its travel.
- Agent tampering prevention: Hiding from hosts the data possessed by agents and the functions to be computed by agents, by messing up code and data of agents, or using cryptographic techniques.

None of the proposed solutions solve the problem completely. They either limit the capabilities of mobile agents, or are not restrictive enough. A better solution is being sought, and there is no general methodology suggested to protect agents. In the mean time, developers of mobile agent systems have to develop their own methodologies according to their own needs. Apart from attacks by malicious hosts, it is also possible that an agent attacks another agent. However, this problem, when compared with the problem of malicious hosts, is less important, because the actions of a (malicious) agent to another agent can be effectively monitored and controlled by the host on which the agent runs, if the host is not malicious.

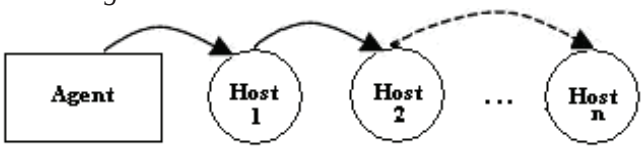
SECURITY MODELING AND EVALUATION FOR THE MOBILE AGENT

There is no well-established model for mobile agent security. One of the few attempts so far is given in Hohl (1998). Software reliability modeling is a successful attempt to give quantitative measures of software systems. In the broadest sense, security is one of the aspects of reliability. A system is likely to be more reliable if it is more secure. One of the pioneering efforts to integrate security and reliability is (Brocklehurst, Littlewood, Olovsoon, & Jonsson, 1994). In this article,

Table 2. Analogy between reliability and security

Security	Reliability
Vulnerabilities	Faults
Breach	Failure
Fail upon attack effort spent	Fail upon usage time elapsed

Figure 3. A mobile agent traveling on a network



the following similarities between security and reliability were observed.

Thus, we have *security function, effort to next breach distribution,* and *security hazard rate* similar to the *reliability function, time to next failure distribution,* and *reliability hazard rate* respectively as in reliability theory. One of the works to incorporate system security into a mathematical model is (Jonsson, 1997), which presents an experiment to model the attacker behavior. The results show that during the "standard attack phase," assuming breaches are independent and stochastically identical, the period of working time of a single attacker between successive breaches is found to be exponentially distributed.

Now, let us consider a mobile agent traveling through *n* hosts on the network, as illustrated in Figure 3. Each host, and the agent itself, is modeled as an abstract machine as in Hohl (1998). We consider only the standard attack phase described in Jonsson (1997)) by malicious hosts. On arrival at a malicious host, the mobile agent is subject to an attack effort from the host. Because the host is modeled as a machine, it is reasonable to estimate the attack effort by the number of instructions for the attack to carry out, which would be linearly increasing with time. On arrival at a non-malicious host, the effort would be constant zero. Let the agent arrive at host *i* at time T_i, for $i = 1, 2, ..., n$. Then the effort of host *i* at total time *t* would be described by the *time-to-effort function*:

$E_i(t) = k_i(t-T_i)$, where k is a constant

We may call the constant k_i the *coefficient of malice*. The larger the k_i, the more malicious host *i* is *(ki* = 0 if host *i* is non-malicious). Furthermore, let the agent stay on host *i* for an amount of time t_i, then there would be breach to the agent if and only if the following breach condition holds:

$E_i(t_i+T_i)$ > effort to next breach by host *i*

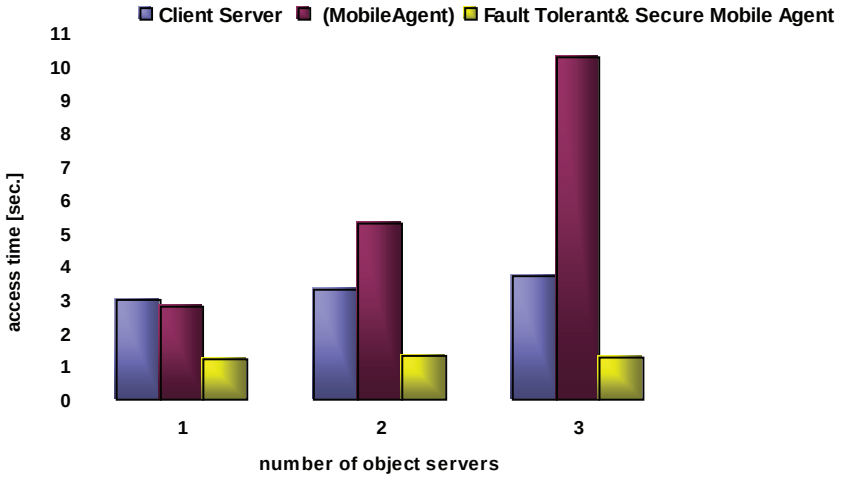
that is, $k_i t_i$ > effort to next breach by host *i*

As seen from Brocklehurst et al. (1994) and Jonsson (1997), it is reasonable to assume exponential distribution of the effort to next breach, so we have the *probability of breach at host i*,

P(breach at host *i*)
= P(breach at time $t_i + T_i$)
= P(breach at effort $k_i t_i$)
= $1 - exp(-vk_i t_i)$, *v* is a constant
= $1 - exp(-\lambda_i t_i)$, $\lambda_i = vk_i$

We may call v the *coefficient of vulnerability* of the agent. The higher the v, the higher is the

Figure 4. Access time for number of object servers



probability of breach to the agent. Therefore, the *agent security E* would be the probability of no breach at all hosts, that is,

Suppose that we can estimate the coefficients of malice k_i's for hosts based on trust records of hosts, and also estimate the coefficient of vulnerability v of the agent based on testing and experiments, then we can calculate the desired time limits T_i's to achieve a certain level of security *E*. Conversely, if users specify some task must be carried out on a particular host for a fixed period of time, we can calculate the agent security *E* for the users based on the coefficients of malice and vulnerability estimates.

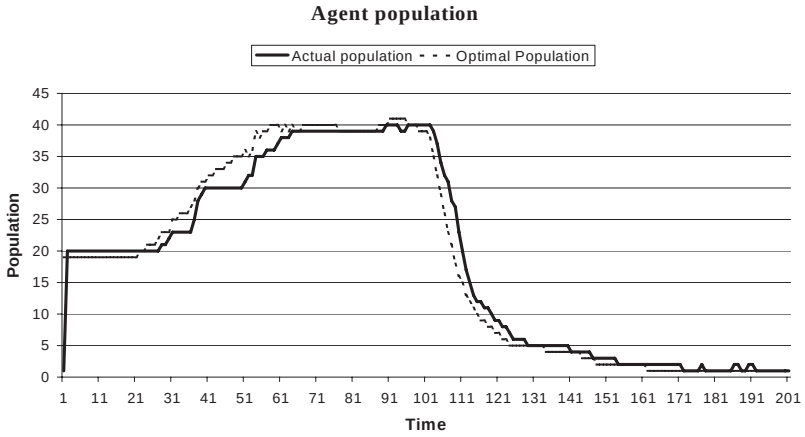
EVALUATION RESULTS AND INFLUENCE OF THE SIZE OF THE AGENT

We evaluate transactional agents in terms of access time compared with client- server model. The computation of mobile agents is composed of moving, class loading, manipulation of objects, creation of clone, and commitment steps. In the client-server model, there are computation steps of program initialization, class loading to client, manipulation of objects, and two-phase commitment.

Access time from the time when the application program starts to the time when the application program ends is measured for agents and the client-server model. Figure 4 shows the access time for a number of object servers. The non-fault tolerant and secure mobile agents show that mobile agent classes are not loaded when an agent A_i arrives at an object server. Here, the agent can be executed after Aglets classes are loaded. On the other hand, the fault tolerant and secure mobile agents mean that an agent manipulates objects in each object server where mobile agent classes are already loaded, that is, the agent comes to the object server after other agents have visited on the object server. As shown in Figure 4, the client-server model is faster than the transactional agent. However, the transactional agent is faster than the client-server model if object servers are frequently manipulated, that is, fault tolerant and secure mobile agent classes are a priori loaded.

A simulator was designed to evaluate the algorithm. The system was tested in several simulated network conditions and numerous parameters were introduced to control the behavior of the agents. We also investigated the dynamic functioning of the algorithm. Comparing to the previous case, the parameter configuration has a larger effect on the behavior of the system.

Figure 5. The size of the agent population under changing network conditions

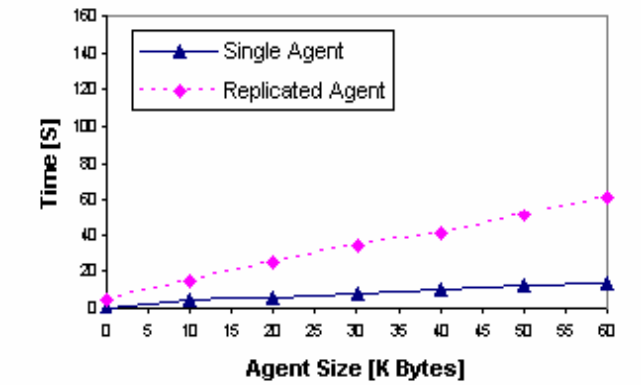


The most vital parameter was the frequency of the trading process and the pre-defined critical workload values.

Figure 5 shows the number of agents on the network in a dynamic network situation. The optimal agent population is calculated by dividing the workload on the whole network with the optimal workload of the agent. Simulation results show that by choosing the correct agent parameters the workload of agents is within ten percent of the predefined visiting frequency on a stable network. In a simulated network the population overload dynamically grows to meet the increased requirements and smoothly returns back to normal when the congestion is over.

To measure the performance of fault tolerant mobile agent system our test consists of sequentially sending a number of agents that increment the value of the counter at each stage of the execution. Each agent starts at the agent source and returns to the agent destination, which allows us to measure its round–trip time. Between two agents, the places are not restarted. Consequently, the first agent needs considerably longer for its execution, as all classes need to be loaded into the cache of the virtual machines. Consecutive agents benefit from already cached classes and thus execute much faster. We do not consider the first agent execution in our measurement results. For a fair comparison, we used the same

Figure 6. Costs of single and replicated agent execution increasing agent size



approach for the single agent case (no replication). Moreover, we assume that the Java class files are locally available in each place. Clearly, this is a simplification, as the class files do not need to be transported with the agent. Remote class loading adds additional costs because the classes have to be transported with the agent and then loaded into the virtual machine. However, once the classes are loaded into the class loader, other agents can take advantage of them and do not need to load these classes again.

The size of the agent has a considerable impact on the performance of the fault-tolerant mobile agent execution. To measure this impact, the agent carries a Byte array of variable length used to increase the size of the agent. As the results in Figure 6 show, the execution time of the agent increases linearly with increasing size of the agent. Compared to the single agent, the slope of the curve for the replicated agent is steeper.

CONCLUSION

In this article, we have presented the mobile code paradigm, which is a collection of remote evaluation, code on demand, and mobile agents, as an alternative to the conventional client/server paradigm. We examine security concerns of the mobile code paradigm, and survey existing security attacks and mechanisms to evaluate the current status of mobile code security. We conclude that the mobile code paradigm is still to be developed with respect to its security aspects and that mobile agent protection needs particular attention. To investigate the security threats to mobile agents, we implemented a simple Traveling Information Agent System, and discussed the possible attacks to the agents in this system, based on the attack model in [26].

We have identified two important properties for fault-tolerant mobile agent execution: non-blocking and exactly-once. Non-blocking ensures that the agent execution proceeds despite a single failure of either agent, place, or machine. Blocking is prevented by the use of replication. This article discussed a mobile agent model for processing transactions, which manipulate object servers. An agent first moves to an object server and then manipulates objects.

General possibilities for achieving fault tolerance in such cases were discussed and the respective advantages and disadvantages for mobile agent environments and the intended parallel and distributed application scenarios were shown. This leads to an approach based on warm standby and receiver side message logging. We have used dynamically changing agent domains to provide flexible, adaptive and robust operation. The performance measurement of Fault-Tolerant Mobile Agent System shows the overhead introduced by the replication mechanisms with respect to a non-replicated agent. Not surprisingly, it also shows that this overhead increases with the number of stages and the size of the agent.

Chapter 7.13
Security in 2.5G Mobile Systems

Christos Xenakis
University of Piraeus, Greece

ABSTRACT

The global system for mobile communications (GSM) is the most popular standard that implements second generation (2G) cellular systems. 2G systems combined with general packet radio services (GPRS) are often described as 2.5G, that is, a technology between the 2G and third generation (3G) of mobile systems. GPRS is a service that provides packet radio access for GSM users. This chapter presents the security architecture employed in 2.5G mobile systems focusing on GPRS. More specifically, the security measures applied to protect the mobile users, the radio access network, the fixed part of the network, and the related data of GPRS are presented and analyzed in detail. This analysis reveals the security weaknesses of the applied measures that may lead to the realization of security attacks by adversaries. These attacks threaten network operation and data transfer through it, compromising end users and network security. To defeat the identified risks, current research activities on the GPRS security propose a set of security improvements to the existing GPRS security architecture.

INTRODUCTION

The global system for mobile communications, (GSM) is the most popular standard that implements second generation (2G) cellular systems. 2G systems combined with general packet radio services (GPRS) (3GPP TS 03.6, 2002) are often described as 2.5G, that is, a technology between the 2G and third generation (3G) of mobile systems. GPRS is a service that provides packet radio access for GSM users. The GPRS network architecture, which constitutes a migration step toward 3G systems, consists of an overlay network onto the GSM network. In the wireless part, the GPRS technology reserves radio resources only when there is data to be sent, thus, ensuring the optimized utilization of radio resources. The fixed part of the network employs the IP technology and is connected to the public Internet. Taking advantage of these features, GPRS enables the provision of a variety of packet-oriented multimedia applications and services to mobile users, realizing the concept of the mobile Internet.

For the successful implementation of the new emerging applications and services over GPRS, security is considered as a vital factor. This is

because of the fact that wireless access is inherently less secure and the radio transmission is by nature more susceptible to eavesdropping and fraud in use than wire-line transmission. In addition, users' mobility and the universal access to the network imply higher security risks compared to those encountered in fixed networks. In order to meet security objectives, GPRS uses a specific security architecture, which aims at protecting the network against unauthorized access and the privacy of users. This architecture is mainly based on the security measures applied in GSM, since the GPRS system is built on the GSM infrastructure.

Based on the aforementioned consideration, the majority of the existing literature on security in 2.5G systems refers to GSM (Mitchell, 2001; Pagliusi, 2002). However, GPRS differs from GSM in certain operational and service points, which require a different security analysis. This is because GPRS is based on IP, which is an open and wide deployed technology that presents many vulnerable points. Similarly to IP networks, intruders to the GPRS system may attempt to breach the confidentiality, integrity, or availability, or otherwise attempt to abuse the system in order to compromise services, defraud users, or any part of it. Thus, the GPRS system is more exposed to intruders compared to GSM.

This chapter presents the security architecture employed in 2.5G mobile systems focusing on GPRS. More specifically, the security measures applied to protect the mobile users, the radio access network, the fixed part of the network, and the related data of GPRS are presented and analyzed in details. This analysis reveals the security weaknesses of the applied measures that may lead to the realization of security attacks by adversaries. These attacks threaten network operation and data transfer through it, compromising end users and network security. To defeat the identified risks, current research activities on the GPRS security propose a set of security improvements to the existing GPRS security architecture. The rest of this chapter is organized as follows. The next section describes briefly the GPRS network architecture. The third section presents the security architecture applied to GPRS and the fourth section analyzes its security weaknesses. The fifth section elaborates on the current research activities on the GPRS security and the sixth section presents the conclusions.

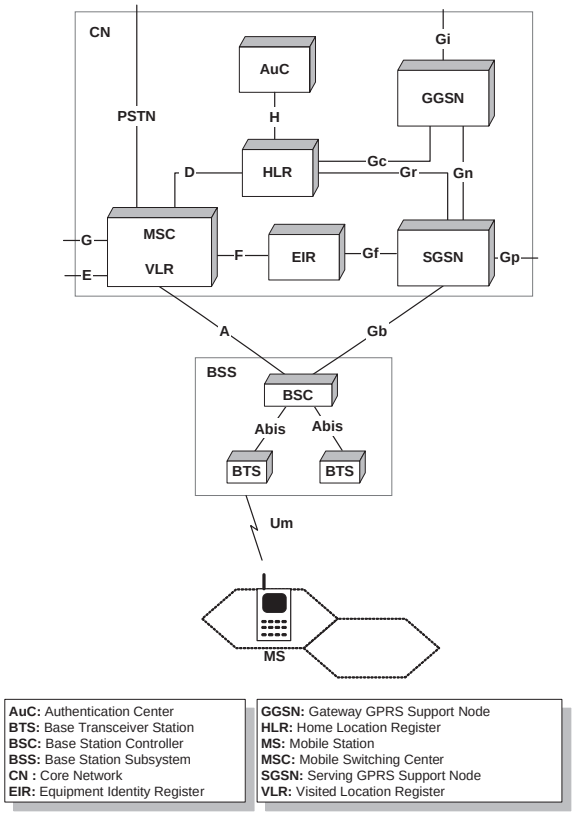
GPRS NETWORK ARCHITECTURE

The network architecture of GPRS (3GPP TS 03.6, 2002) is presented in Figure 1. A GPRS user owns a mobile station (MS) that provides access to the wireless network. From the network side, the base station subsystem (BSS) is a network part that is responsible for the control of the radio path. BSS consists of two types of nodes: the base station controller (BSC) and the base transceiver station (BTS). BTS is responsible for the radio coverage of a given geographical area, while BSC maintains radio connections towards MSs and terrestrial connections towards the fixed part of the network (core network).

The GPRS core network (CN) uses the network elements of GSM such as the home location register (HLR), the visitor location register (VLR), the authentication centre (AuC) and the equipment identity register (EIR). HLR is a database used for the management of permanent data of mobile users. VLR is a database of the service area visited by an MS and contains all the related information required for the MS service handling. AuC maintains security information related to subscribers identity, while EIR maintains information related to mobile equipments' identity. Finally, the mobile service switching centre (MSC) is a network element responsible for circuit-switched services (e.g., voice call) (3GPP TS 03.6, 2002).

As presented previously, GPRS reuses the majority of the GSM network infrastructure. However, in order to build a packet-oriented mobile network some new network elements (nodes) are

Figure 1. GPRS network architecture



required, which handle packet-based traffic. The new class of nodes, called GPRS support nodes (GSN), is responsible for the delivery and routing of data packets between an MS and an external packet data network (PDN). More specifically, a serving GSN (SGSN) is responsible for the delivery of data packets from, and to, an MS within its service area. Its tasks include packet routing and transfer, mobility management, logical link management, and authentication and charging functions. A gateway GSN (GGSN) acts as an interface between the GPRS backbone and an external PDN. It converts the GPRS packets coming from the SGSN into the appropriate packet data protocol (PDP) format (e.g., IP), and forwards them to the corresponding PDN. Similar is the functionality of GGSN in the opposite direction. The communication between GSNs (i.e., SGSN and GGSN) is based on IP tunnels through the use of the GPRS tunneling protocol (GTP) (3GPP TS 09.60, 2002).

GPRS SECURITY ARCHITECTURE

In order to meet security objectives, GPRS employs a set of security mechanisms that constitutes the GPRS security architecture. Most of these mechanisms have been originally designed for GSM, but they have been modified to adapt to the packet-oriented traffic nature and the GPRS network components. The GPRS security architecture, mainly, aims at two goals: (1) to protect the network against unauthorized access, and (2) to protect the privacy of users. It includes the following components (GSM 03.20, 1999):

- Subscriber identity module (SIM)
- Subscriber identity confidentiality
- Subscriber identity authentication
- User data and signaling confidentiality between the MS and the SGSN
- GPRS backbone security

Subscriber Identity Module (SIM)

The subscription of a mobile user to a network is personalized through the use of a smart card named SIM (ETSI TS 100 922, 1999). Each SIM card is unique and related to a user. It has a microcomputer with a processor, ROM, persistent EPROM memory, volatile RAM, and an I/O interface. Its software consists of an operating system, file system, and application programs (e.g., SIM application toolkit). The SIM card is responsible for the authentication of the user by prompting for a code (PIN), the identification of the user to a network through keys, and the protection of user data through cryptography. To achieve these functions it contains a set of security objects including:

- A (4-digit) PIN code, which is used to lock the card preventing misuse;
- A unique permanent identity of the mobile user, named international mobile subscriber identity (IMSI) (3GPP TS 03.03, 2003);
- A secret key, Ki, (128 bit) that is used for authentication; and
- An authentication algorithm (A3) and an algorithm that generates encryption keys (A8) (GSM 03.20, 1999).

Since the SIM card of a GSM/GPRS subscriber contains security critical information, it should be manufactured, provisioned, distributed, and managed in trusted environments.

Subscriber Identity Confidentiality

The subscriber identity confidentiality deals with the privacy of the IMSI and the location of a mobile user. It includes mechanisms for the protection of the permanent identity (IMSI) when it is transferred in signaling messages, as well as measures that preclude the possibility to derive it indirectly from listening to specific information, such as addresses, at the radio path.

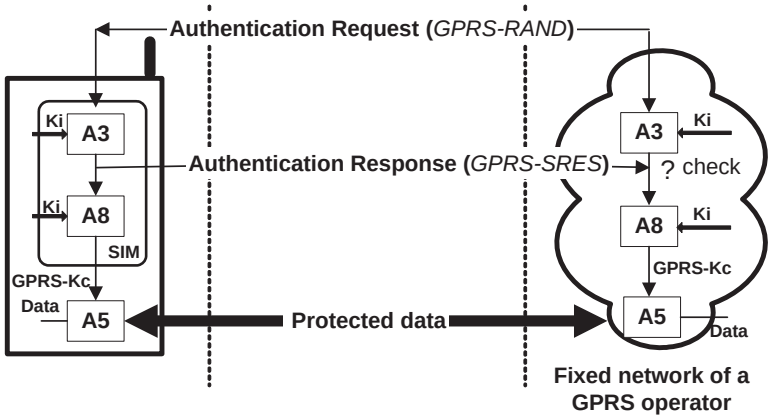
The subscriber identity confidentiality is mainly achieved by using a temporary mobile subscriber identity (TMSI) (3GPP TS 03.03, 2003; GSM 03.20, 1999), which identifies the mobile user in both the wireless and wired network segments. The TMSI has a local significance and thus it must be accompanied by the routing area identity (RAI) in order to avoid confusions. The MS and the serving VLR and SGSN only know the relation between the active TMSI and the IMSI. The allocation of a new TMSI corresponds implicitly for the MS to the de-allocation of the previous one. When a new TMSI is allocated to the MS, it is transmitted to it in a ciphered mode. The MS stores the current TMSI and the associated RAI in a non-volatile memory, so that these data are not lost when the MS is switched off.

Further to the TMSI, a temporary logical link identity (TLLI) (3GPP TS 03.03, 2003) identifies also a GPRS user on the radio interface of a routing area. Since the TLLI has a local significance, when it is exchanged between the MS and the SGSN, it should be accompanied by the RAI. The TLLI is either derived from the TMSI allocated by the SGSN or built by the MS randomly and thus, provides identity confidentiality. The relationship between the TLLI and the IMSI is only known in the MS and in the SGSN.

Subscriber Identity Authentication

A mobile user that attempts to access the network must first prove his/her identity to it. User authentication (3GPP TS 03.6, 2002) protects against

Figure 2. GPRS authentication



fraudulent use and ensures correct billing. GPRS uses the authentication procedure already defined in GSM with the same algorithms for authentication and generation of encryption key, and the same secret key, Ki, (see Figure 2). However, from the network side, the whole procedure is executed by the SGSN (instead of the BS) and employs a different random number (GPRS-RAND) and thus, it produces a different signed response (GPRS-SRES) and encryption key (GPRS-Kc) than the GSM voice counterpart.

To achieve authentication of a mobile user, the serving SGSN must possess security-related information for the specific user. This information is obtained by requesting the HLR/AuC of the home network that the mobile user is subscribed. It includes a set of authentication vectors, each of which includes a random challenge (GPRS-RAND), the related signed response (GPRS-SRES), and the encryption key (GPRS-Kc) for the specific subscriber. The authentication vectors are produced by the home HLR/AuC using the secret key Ki of the mobile subscriber.

During authentication the SGSN of the serving network sends the random challenge (GPRS-RAND) of a chosen authentication vector to the MS. The latter encrypts the GPRS-RAND by using the A3 hash algorithm, which is implemented in the SIM card, and the secret key, Ki. The first 32 bits of the A3 output are used as a signed response (GPRS-SRES) to the challenge (GPRS-RAND) and are sent back to the network. The SGSN checks if the MS has the correct key, Ki, and, then, the mobile subscriber is recognized as an authorized user. Otherwise, the serving network (SN) rejects the subscriber's access to the system. The remaining 64 bits of the A3 output together with the secret key, Ki, are used as input to the A8 algorithm that produces the GPRS encryption key (GPRS-Kc).

Data and Signalling Protection

User data and signaling protection over the GPRS radio access network is based on the GPRS ciphering algorithm (GPRS-A5) (3GPP TS 01.61, 2001), which is also referred to as GPRS encryption algorithm (GEA) and is similar to the GSM A5. Currently, there are three versions of this algorithm: GEA1, GEA2, and GEA3 (that is actually A5/3), which are not publicly known and thus, it is difficult to perform attacks on them. The MS device (not the SIM-card) performs GEA using the encryption key (GPRS-Kc), since it is a strong algorithm that requires relatively high processing capabilities. From the network side, the serving

SGSN performs the ciphering/deciphering functionality protecting signaling and user data over the Um, Abis, and Gb interfaces.

During authentication the MS indicates which version(s) of the GEA supports and the network (SGSN) decides on a mutually acceptable version that will be used. If there is not a commonly accepted algorithm, the network (SGSN) may decide to release the connection. Both the MS and the SGSN must cooperate in order to initiate the ciphering over the radio access network. More specifically, the SGSN indicates whether ciphering should be used or not (which is also a possible option) in the *Authentication Request* message, and the MS starts ciphering after sending the *Authentication Response* message (see Figure 2).

GEA is a symmetric stream cipher algorithm (see Figure 3) that uses three input parameters (GPRS-Kc, INPUT, and DIRECTION) and produces an OUTPUT string, which varies between 5 and 1,600 bytes. GPRS-Kc (64 bits) is the encryption key generated by the GPRS authentication procedure and is never transmitted over the radio interface. The input (INPUT) parameter (32 bits) is used as an additional input so that each frame is ciphered with a different output string. This parameter is calculated from the logical link control (LLC) frame number, a frame counter, and a value supplied by the SGSN called the input offset value (IOV). The IOV is set up during the negotiation of LLC and layer 3 parameters. Finally, the direction bit (DIRECTION) specifies whether the output string is used for upstream or downstream communication.

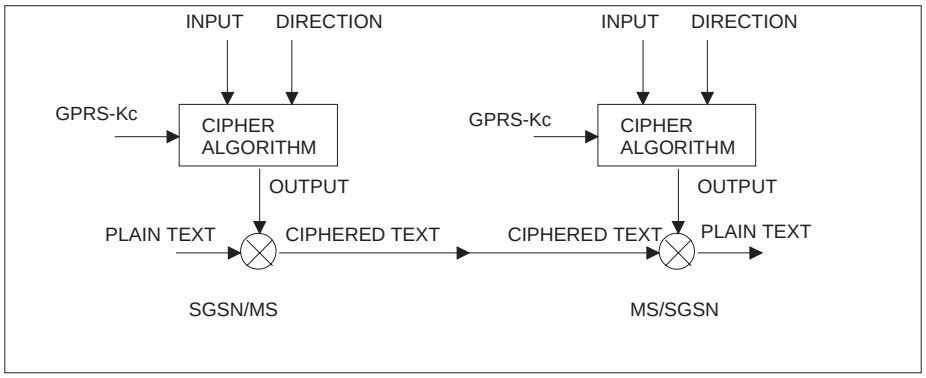
After the initiation of ciphering, the sender (MS or SGSN) processes (bit-wise XOR) the OUTPUT string with the payload (PLAIN TEXT) to produce the CIPHERED TEXT, which is sent over the radio interface. In the receiving entity (SGSN or MS), the original PLAIN TEXT is obtained by bit-wise XORed the OUTPUT string with the CIPHERED TEXT. When the MS changes SGSN, the encryption parameters (e.g., GPRS-Kc, INPUT) are transferred from the old SGSN to the new SGSN, through the (inter) routing area update procedure in order to guarantee service continuity.

GPRS Backbone Security

The GPRS backbone network includes the fixed network elements and their physical connections that convey user data and signaling information. signaling exchange in GPRS is mainly based on the signaling system 7 (SS7) technology (3GPP TS 09.02, 2004), which does not support any security measure for the GPRS deployment. Similarly, the GTP protocol that is employed for communication between GSNs does not support security. Thus, user data and signaling information in the GPRS backbone network are conveyed in cleartext exposing them to various security threats. In addition, inter-network communications (between different operators) are based on the public Internet, which enables IP spoofing to any malicious third party who gets access to it. In the sequel, the security measures applied to the GPRS backbone network are presented.

The responsibility for security protection of the GPRS backbone as well as inter-network communications belongs to mobile operators. They utilize private IP addressing and network address translation (NAT) (Srisuresh & Holdrege, 1999) to restrict unauthorized access to the GPRS backbone. They may also apply firewalls at the borders of the GPRS backbone network in order to protect it from unauthorized penetrations. Firewalls protect the network by enforcing security policies (e.g., user traffic addressed to a network element is discarded). Using security policies the GPRS operator may ensure that only traffic initiated from the MS and not from the Internet should pass through a firewall. This is done for two reasons: (1) to restrict traffic in order to protect the MS and the network elements from external attacks; and (2) to protect the MS from receiving unrequested traffic. Unrequested traffic may be

Figure 3. GPRS ciphering



unwanted for the mobile subscribers since they pay for the traffic received as well. The GPRS operator may also want to disallow some bandwidth-demanding protocols preventing a group of subscribers to consume so much bandwidth that other subscribers are noticeably affected. In addition, application-level firewalls prevent direct access through the use of proxies for services, which analyze application commands, perform authentication, and keep logs.

Since firewalls do not provide privacy and confidentiality, the virtual private network (VPN) technology (Gleeson, Lin, Heinanen, Armitage, & Malis, 2000) has to complement them to protect data in transit. A VPN is used for the authentication and the authorization of user access to corporate resources, the establishment of secure tunnels between the communicating parties, and the encapsulation and protection of the data transmitted by the network. In current GPRS implementations, pre-configured, static VPNs can be employed to protect data transfer between GPRS network elements (e.g., an SGSN and a GGSN that belong to the same backbone), between different GPRS backbone networks that belong to different mobile operators, or between a GPRS backbone and a remote corporate private network. The border gateway, which resides at the border of the GPRS backbone, is a network element that provides firewall capabilities and also maintains static, pre-configured VPNs to specific peers.

GPRS SECURITY WEAKNESSES

Although GPRS have been designed with security in mind, it presents some essential security weaknesses, which may lead to the realization of security attacks that threaten network operation and data transfer through it. In the following, the most prominent security weaknesses of the GPRS security architecture are briefly presented and analyzed.

Subscriber Identity Confidentiality

A serious weakness of the GPRS security architecture is related to the compromise of the confidentiality of subscriber identity. Specifically, whenever the serving network (VLR or SGSN) cannot associate the TMSI with the IMSI, because of TMSI corruption or database failure, the SGSN should request the MS to identify itself by means of IMSI on the radio path. Furthermore, when the user roams and the new serving network cannot contact the previous (the old serving network) or cannot retrieve the user identity, then, the new serving network should also request the MS to identify itself by means of IMSI on the radio path.

This fact may lead an active attacker to pretend to be a new serving network, to which the user has to reveal his/her permanent identity. In addition, in both cases the IMSI that represents the permanent user identity is conveyed in cleartext over the radio interface violating user identity confidentiality.

Subscriber Authentication

The authentication mechanism used in GPRS also exhibits some weak points regarding security. More specifically, the authentication procedure is one way and thus, it does not assure that a mobile user is connected to an authentic serving network. This fact enables active attacks using a false BS identity. An adversary, who has the required equipment, may masquerade as a legitimate network element mediating in the communication between the MS and the authentic BS. This is also facilitated by the absence of a data integrity mechanism on the radio access network of GPRS, which defeats certain network impersonation attacks. The results of this mediation may be the alternation or the interception of signaling information and communication data exchanged.

Another weakness of the GPRS authentication procedure is related to the implementation of the A3 and A8 algorithms, which are often realized in practise using COMP128. COMP128 is a keyed hash function, which uses two 16-byte (128 bits) inputs and produces a hash output of 12 bytes (96 bits). While the actual specification of COMP128 was never made public, the algorithm has been reverse engineered and cryptanalyzed (Barkan, Biham, & Neller, 2003). Thus, knowing the secret key, Ki, it is feasible for a third party to clone a GSM/GPRS SIM-card, since its specifications are widely available (ETSI TS 100 922, 1999).

The last weakness of the GPRS authentication procedure is related to the network ability of reusing authentication triplets. Each authentication triplet should be used only in one authentication procedure in order to avoid man-in-the-middle and replay attacks. However, this depends on the mobile network operator (home and serving) and cannot be checked by mobile users. When the VLR of a serving network has used an authentication triplet to authenticate an MS, it shall delete the triplet or mark it as used. Thus, each time that the VLR needs to use an authentication triplet, it shall use an unmarked one, in preference to a marked. If there is no unmarked triplet, then the VLR shall request fresh triplets from the home HLR. If fresh triplets cannot be obtained, because of a system failure, the VLR may reuse a marked triplet. Thus, if a single triplet is compromised, a false BS can impersonate a genuine GPRS network to the MS. Moreover, as the false BS has the encryption key, Kc, it will not be necessary for the false BS to suppress encryption on the air interface. As long as the genuine SGSN is using the compromised authentication triplet, an attacker could also impersonate the MS and obtain session calls that are paid by the legitimate subscriber.

Data and Signalling Protection

An important weakness of the GPRS security architecture is related to the fact that the encryption of signalling and user data over the highly exposed radio interface is not mandatory. Some GPRS operators, in certain countries, never switch on encryption in their networks, since the legal framework in these countries do not permit that. Hence, in these cases signaling and data traffic are conveyed in cleartext over the radio path. This situation is becoming even more risky from the fact that the involved end users (humans) are not informed whether their sessions are encrypted or not.

As encryption over the radio interface is optional, the network indicates to the MS whether and which type(s) of encryption it supports in the *authentication request* message, during the GPRS authentication procedure. If encryption is activated, the MS start ciphering after sending the

authentication response message and the SGSN starts ciphering/deciphering when it receives a valid *authentication response* message from the MS. However, since these two messages are not protected by confidentiality and integrity mechanisms (data integrity is not provided in the GPRS radio interface except for traditional non-cryptographic link layer checksums), an adversary may mediate in the exchange of authentication messages. The results of this mediation might be either the modification of the network and the MS capabilities regarding encryption, or the suppression of encryption over the radio interface.

GPRS Backbone

Based on the analysis of the GPRS security architecture (see the *GPRS security architecture* section) it can be perceived that the GPRS security does not aim at the GPRS backbone and the wireline connections, but merely at the radio access network and the wireless path. Thus, user data and signaling information conveyed over the GPRS backbone may experience security threats, which degrade the level of security supported by GPRS. In the following, the security weaknesses of the GPRS security architecture that are related to the GPRS backbone network for both signaling and data plane are presented and analyzed.

Signaling Plane

As mentioned previously, the SS7 technology used for signaling exchange in GPRS does not support security protection. Until recently, this was not perceived to be a problem since SS7 networks belonged to a small number of large institutions (telecom operator). However, the rapid deployment of mobile systems and the liberalization of the telecommunication market have dramatically increased the number of operators (for both fixed and mobile networks) that are interconnected through the SS7 technology. This fact provokes a significant threat to the GPRS network security, since it increases the probability of an adversary to get access to the network or a legitimate operator to act maliciously.

The lack of security measures in the SS7 technology used in GPRS results also in the unprotected exchange of signaling messages between a VLR and a VLR/HLR, or a VLR and other fixed network nodes. Although these messages may include critical information for the mobile subscribers and the networks operation like ciphering keys, authentication data (e.g., authentication triplets), user subscription data (e.g., IMSI), user billing data, network billing data, and so forth, they are conveyed in a cleartext within the serving network as well as between the home network and the serving network. For example, the VLR of a serving network may use the IMSI to request authentication data for a single user from its home network, and the latter forwards them to the requesting VLR without any security measure. Thus, the exchanges of signaling messages, which are based on SS7, may disclose sensitive data of mobile subscribers and networks, since they are conveyed over insecure network connections without security precautions.

Data Plane

Similarly to the signaling plane, the data plane of the GPRS backbone presents significant security weaknesses, since the introduction of IP technology in the GPRS core shifts towards open and easily accessible network architectures. In addition, the data encryption mechanism employed in GPRS does not extend far enough towards the core network, also resulting in a cleartext transmission of user data in it. Thus, a malicious user, which gains access to the network, may either obtain access to sensitive data traffic or provide unauthorized/incorrect information to mobile users and network components. As presented previously, the security protection of users' data in the fixed segment of the GPRS network mainly relies on two independent and complementary

technologies, which are not undertaken by GPRS but from the network operators. These technologies include: (1) firewalls that enforce security policies to a GPRS core network that belongs to an operator; and (2) pre-configured VPNs that protect specific network connections.

However, firewalls were originally conceived to address security issues for fixed networks and thus are not seamlessly applicable in mobile networks. They attempt to protect the cleartext transmitted data in the GPRS backbone from external attacks, but they are inadequate against attacks that originate from malicious mobile subscribers as well as from network operator personnel or any other third party that gets access to the GPRS core network. Another vital issue regarding the deployment of firewalls in GPRS has to do with the consequences of mobility. The mobility of a user may imply roaming between networks and operators, which possibly results in the changing of the user address. This fact in conjunction with the static configuration of firewalls may potentially lead to discontinuity of service connectivity for the mobile user. Moreover, in some cases the security value of firewalls is considered limited as they allow direct connection to ports without distinguishing services.

Similarly to firewalls, the VPN technology fails to provide the necessary flexibility required by typical mobile users. Currently, VPNs for GPRS subscribers are established in a static manner between the border gateway of a GPRS network and a remote security gateway of a corporate private network. This fact allows the realization of VPNs only between a security gateway of a large organization and a mobile operator, when a considerable amount of traffic requires protection. Thus, this scheme can provide VPN services neither to individual mobile users that may require on demand VPN establishment, nor to enterprise users that may roam internationally. In addition, static VPNs have to be reconfigured every time the VPN topology or VPN parameters change.

CURRENT RESEARCH ON GPRS SECURITY

The analyzed security weaknesses of the GPRS security architecture increase the risks associated with the usage of GPRS networks influencing their deployment, which realizes the mobile Internet. In order to defeat some of these risks, a set of security improvements to the existing GPRS security architecture may be incorporated. Additionally, some complementary security measures, which have been originally designed for fixed network and aim at enhancing the level of security that GPRS supports, may be applied (Xenakis, 2006). In the following, the specific security improvements and the application of the complementary security measures are briefly presented and analyzed.

SIM Card

The majority of the security weaknesses that are related to a MS and the SIM card of a mobile user have to do with the vulnerabilities of COMP128. To address these, the old version of COMP128 (currently named as COMP128-1) is replaced by two newer versions COMP128-2 and COMP128-3, which defeat the known weaknesses. There is an even newer version COMP128-4, which is based on the 3GPP algorithm MILENAGE that uses advanced encryption standard (AES). In addition, it is mentioned to the GPRS operators that the COMP128 algorithm is only an example algorithm and that every operator should use its own algorithm in order to support an acceptable level of security (Xenakis, 2006).

User Data

User data conveyed over the GPRS backbone and the public Internet most likely remain unprotected (except for the cases that the operator supports pre-established VPNs over the public Internet)

and thus are exposed to various threats. The level of protection that GPRS provides to the data exchanged can be improved by employing two security technologies: (1) the application of end-user security, and (2) the establishment of mobile IPsec-based VPN, dynamically. End-user security is applied by using application layer solutions such as the secure sockets layer (SSL) protocol (Gupta & Gupta, 2001). SSL is the default Internet security protocol that provides point-to-point security by establishing a secure channel on top of TCP. It supports server authentication using certificates, data confidentiality, and message integrity. On the other hand, IPsec protects traffic on a per connection basis and thus is independent from the applications that run above it. An IPsec-based VPN is used for the authentication and the authorization of user access to corporate resources, the establishment of secure tunnels between the communicating parties, and the encapsulation and protection of the data transmitted by the network. On-demand VPNs that are tailored to specific security needs are especially useful for GPRS users, which require any-to-any connectivity in an ad hoc fashion. Regarding the deployment of mobile VPNs over the GPRS infrastructure, three alternative security schemes have been proposed: (1) the end-to-end (Xenakis, Gazis, Merakos, 2002), (2) the network-wide (Xenakis, Merakos: IEEE Network, 2002), and (3) the border-based (Xenakis, Merakos: IEEE PIMRC, 2002). These schemes mainly differ in the position where the security functionality is placed within the GPRS network architecture (MS, SGSN, and GGSN), and whether data in transit are ever in cleartext or available to be tapped by outsiders.

Signaling Plane of the GPRS Backbone

The lack of security measures in the signaling plane of the GPRS backbone gives the opportunity to an adversary to retrieve critical information such as the permanent identities of mobile users (IMSI), temporary identities (TMSI, TLLI), location information, authentication triplets (RAND, SRES, Kc), charging and billing data, and so forth. The possession of this information enables an attacker to identify a mobile user, to track his/her location, to decipher the user data transferred over the radio interface, to over bill him/her, and so forth. To address this inability of GPRS, it has been proposed the incorporation of the network domain security (NDS) features (Xenakis, 2006; Xenakis & Merakos, 2004) into the GPRS security architecture. NDS features, which have been designed for the latter version of UMTS, ensure that signaling exchanges in the backbone network as well as in the whole wire-line network are protected. For signaling transmission in GPRS the SS7 and IP protocol architectures are employed, which incorporate the mobile application part (MAP) (3GPP TS 09.02, 2004) and the GTP protocol (3GPP TS 09.60, 2002), respectively. In NDS both architectures are designed to be protected by standard procedures based on existing cryptographic techniques. Specifically, the IP-based signaling communications will be protected at the network level by means of the well-known IPsec suite (Kent & Atkinson, 1998). On the other hand, the realization of protection for the SS7-based communications will be accomplished at the application layer by employing specific security protocols (Xenakis & Merakos, 2004). However, until now only the MAP protocol from the SS7 architecture is designed to be protected by a new security protocol named MAPsec (3GPP TS 33.200 2002).

CONCLUSION

This chapter has presented the security architecture employed in 2.5G mobile systems focusing on GPRS. This architecture comprises a set of measures that protect the mobile users, the radio access network, the fixed part of the network, and the related data of GPRS. Most of these measures

have been originally designed for GSM, but they have been modified to adapt to the packet-oriented traffic nature and the GPRS network components. The operational differences between the application of these measures in GSM and GPRS have been outlined and commented. In addition, the security measures that can be applied by GPRS operators to protect the GPRS backbone network and inter-network communications, which are based on IP, have been explored. Although GPRS has been designed with security in mind, it presents some essential security weaknesses, which may lead to the realization of security attacks that threaten network operations and data transfer through it. These weaknesses are related to: (1) the compromise of the confidentiality of subscriber's identity, since it may be conveyed unprotected over the radio interface; (2) the inability of the authentication mechanism to perform network authentication; (3) the possibility of using COMP128 algorithm (which has been cryptoanalyzed) for A3 and A8 implementations; (4) the ability of reusing authentication triplets; (5) the possibility of suppressing encryption over the radio access network or modifying encryption parameters; and (5) the lack of effective security measures that are able to protect signaling and user data transferred over the GPRS backbone network. To defeat some of these risks, a set of security improvements to the existing GPRS security architecture may be incorporated. Additionally, some complementary security measures, which have been originally designed for fixed network and aim at enhancing the level of security that GPRS supports, may be applied.

KEY TERMS

General Packet Radio Service (GPRS): GPRS is a mobile data service available to users of GSM.

Global System for Mobile Communications (GSM): GSM is the most popular standard for mobile phones in the world.

GPRS Tunneling Protocol (GTP): GTP is an IP-based protocol that carries signaling and user data with the GPRS core network.

International Mobile Subscriber Identity (IMSI): IMSI is a unique number associated with all GSM network mobile phone users.

Second Generation (2G): 2G is a short for second-generation wireless telephone technology.

Second and a Half Generation (2.5G): 2.5G is used to describe 2G systems that have implemented a packet-switched domain in addition to the circuit-switched domain.

Signaling System 7 (SS7): SS7 is a set of telephony signaling protocols which are used to set up the vast majority of the world's public switched telephone network telephone calls.

Subscriber Identity Module (SIM): SIM is a removable smart card for mobile phones that stores network specific information used to authenticate and identify subscribers on the network.

Temporary Mobile Subscriber Identity (TMSI): TMSI is a randomly allocated number that is given to the mobile the moment it is switched on and serves as a temporary identity between the mobile and the network.

ABSTRACT

During the last few years, mobile broadband access has been a popular concept in the context of fourth generation (4G) cellular systems. After the wide acceptance and deployment of the wired broadband connections, such as DSL, the research community in conjunction with the industry have tried to develop and deploy viable mobile architectures for broadband connectivity. The dominant architectures which have already been proposed are Wi-Fi, universal mobile telecommunications system (UMTS), WiMax, and flash-orthogonal frequency division modulation (OFDM). In this chapter, we analyze these protocols with respect to their security mechanisms. First, a detailed description of the authentication, confidentiality, and integrity mechanisms is provided in order to highlight the major security gaps and threats. Subsequently, each threat is evaluated based on three factors: likelihood, impact, and risk. The technologies are then compared taking their security evaluation into account. Flash-OFDM is not included in this comparison since its security specifications have not been released in public. Finally, future trends of mobile broadband ac-

cess, such as the evolution of WiMax, mobile broadband wireless access (MBWA), and 4G are discussed.

INTRODUCTION

During the last decade, wireless network technologies have greatly evolved and have been able to provide cost-efficient solutions for voice and data services. Their main advantages over wired networks are that they avoid expensive cabling infrastructure and they support user mobility and effective broadcasting. As a result, mobile wireless networks have managed to take over a large percentage of the "voice" market, since the global system for mobile communications (GSM) cellular technology has promoted the worldwide expansion of mobile telephony. Furthermore, nowadays broadband Internet has become a necessity for many home and business users. Moreover, in the context of all-IP network convergence, an increasing share of telephony subscribers is migrating towards VoIP solutions mainly due to the decreased cost compared to fixed telephony. Therefore, the main challenge is to find spectrum- and cost-efficient solutions for the provision of mobile broadband services. In this direction, a large research community of academic and industrial origin has dedicated considerable effort on designing, implementing, and deploying systems for mobile broadband access, such as Wi-Fi, universal mobile telecommunications system (UMTS), WiMax, and flash-orthogonal frequency division modulation (OFDM). According to the predictions, in the years to come, more and more of our voice samples and data packets will be carried over wireless broadband links through the Internet. Therefore it becomes imperative that these messages are secured from malicious eavesdroppers and attackers. Especially in applications such as e-banking, e-commerce, and e-government the revelation of sensitive data to unauthorized persons, unauthorized data submission, and/or the interruption of system availability can cause financial damage, user preferences' surveillance, industry espionage, and/or administrative overhead.

The purpose of this chapter is to analyze and compare the security architectures of the dominant mobile broadband technologies. More specifically, the objectives are to:

- Describe and analyze the security architectures of mobile broadband technologies.
- Identify the strong and weak points of each technology in terms of access control based on authentication, confidentiality, integrity, and physical layer resilience.
- Compare the investigated security architectures based on a risk evaluation of the identified security vulnerabilities.

MOBILE BROADBAND TECHNOLOGIES

This section discusses the mobile technologies Wi-Fi, UMTS, WiMax, and flash-OFDM. Authentication performance, confidentiality, and integrity mechanisms for each technology are analyzed.

Wi-Fi

Wi-Fi was the first widely-deployed technology for wireless computer networks. It was originally designed to provide portability support in local area networks (LANs). However, Wi-Fi has also been utilized in other scenarios, such as wireless metropolitan area networks (WMANs), since it was the first wireless technology with support for mobile communication and for a wide range of portable and mobile devices.

The Wi-Fi radio interface is based on the IEEE 802.11 standard and is available in three versions:

- **802.11a**
  - **Frequency:** 5.5 GHz,
  - **Modulation:** OFDM
  - **Bandwidth:** 54 Mbps
- **802.11b**
  - **Frequency:** 2.4 GHz
  - **Modulation:** Direct sequence spread spectrum (DSSS)
  - **Bandwidth:** 11 Mbps
- **802.11g**
  - **Frequency:** 2.4 GHz
  - **Modulation:** OFDM
  - **Bandwidth:** 54 Mbps

In this context, Wi-Fi alliance is an organization testing products in order to evaluate that they correctly implement the set of standards defined in the IEEE 802.11 specification. After the products have successfully passed these tests, they are allowed to use the Wi-Fi logo.

Security Architecture

Wi-Fi security standards include wired equivalent privacy (WEP), Wi-Fi protected access (WPA), and WPA2. WEP was the first introduced security standard. WPA was designed to be a security protocol that corrects the security deficiencies of WEP and to be backward compatible with existing hardware. The last development in Wi-Fi security is the WPA2 standard which was published in June 2004 by the IEEE 802.11i group. WPA2 was designed to offer a further improved security scheme (Edney & Arbaugh, 2003). The aforementioned security specifications are analyzed and compared in the following paragraphs.

Authentication

Authentication services are utilized to allow a client to communicate with the serving access point. After successful authentication, a session is initiated and it can be terminated by either the client or the access point. Wi-Fi provides the following link-layer authentication schemes:

- Closed system authentication
- Media access control (MAC) filtering
- WEP suthentication—Shared RC4 key
- WPA and WPA2 authentication—802.1X/extensible authentication protocol (EAP)

Closed system authentication, MAC filtering, and WEP authentication are not recommended due to their well-known serious security flaws (Borisov, Goldberg, & Wagner, 2001; Lynn & Baird, 2002; Welch & Lathrop, 2003).

WPA and WPA2 security schemes have some major design differences from WEP, since the authentication and the confidentiality processes operate totally independently from each other (Baek, Smith, & Kotz, 2004). The authentication process of WPA and WPA2 adopts the three-entity model of IEEE 802.1x which was originally designed for the point-to-point protocol (IEEE, 2001). The three entities involved in this protocol are the client, the access point (AP), and the authentication server (AS). First, the client request to obtain access to the network. The AP acts as a network guard, allowing access only to the clients that the AS has authenticated. Finally, the AS is responsible for deciding whether the client is allowed to access the network. These three entities utilize EAP to exchange communication messages in order to coordinate the authentication process (Stanley, Walker, & Aboba, 2005).

In addition, there is a lighter version of WPA, called WPA-preshared key (WPA-PSK). This version is based on a shared secret key or passphrase in order to authenticate the wireless clients. As a result, an attacker can use a wireless sniffer to capture the 4-way WPA handshake, log the packets, and then try a brute force attack using a dictionary file (Van de Wiele, 2005). Thus, if WPA-PSK is deployed, the robustness of the

network security totally depends on the length and the complexity of the secret key.

Encryption

Encryption services are utilized to provide confidentiality over wireless communication links. In Wi-Fi networks the following encryption schemes are available:

- WEP based on the RC4 (Ron's Code 4) stream cipher
- WPA encryption based on the temporal key integrity protocol (TKIP)
- WPA2 encryption based on the advanced encryption standard (AES)

WEP is a weak implementation of the RC4 stream cipher and WEP encryption is thus not recommended (Borisov et al., 2001; Stubblefield, Ioannidis, & Rubin, 2002; Welch & Lathrop, 2003).

WPA encryption is based on TKIP. It incorporates the basic functionalities of WEP, but improvements have been made to address the security flaws. The length of the initialization vector (IV) has been increased from 24 bits to 48 bits and therefore the possibility of reused keys has been significantly decreased. Furthermore, WPA does not directly utilize the master keys. Instead it constructs a hierarchy of derived keys to be utilized in the encryption process. Finally, WPA dynamically cycles keys while transferring data. Since keys are regularly changed, a malicious user has a very short time window to attempt an attack.

WPA2 was designed from scratch taking the vulnerabilities of the previous security architectures into account. WPA2 allows various network implementations, but the default configuration utilizes the advanced encryption standard (AES) and the counter mode CBC MAC protocol (CCMP). AES is a block cipher, operating on blocks of 128 bit data, and is a replacement of the RC4 algorithm used by WPA. AES is much more robust since it has already been tested in various security architectures without revealing serious vulnerabilities. CCMP comprises of two main parts. The first is the counter mode (CM) which is responsible for the privacy of the data in combination with AES. The second is the cipher block chaining message authentication code (CBC-MAC) providing data integrity checking and authentication.

Integrity

Integrity services are responsible for making sure that transmitted information is not replayed or modified during transmission. The following techniques are applicable in Wi-Fi networks:

- WEP cyclic redundancy heck 4 (CRC-32) Checksum
- WPA Integrity
- WPA2 Integrity

WEP checksum is a noncryptographic linear function of the plaintext. This means that multiple messages may correspond to a single 32-bit number. Hence, an experienced intruder could modify the plaintext in such a way that the checksum remains unchanged. Furthermore, due to the linearity of both the RC4 stream cipher and the CRC-32 checksum, the attacker is able to change the message even when he does not know the plaintext (Welch & Lathrop, 2003).

WPA has incorporated mechanisms for the prevention of replay attacks. More specifically, the TKIP sequence counter (TSC) based on the IVs is utilized, so that the receiver can identify and reject "replayed" messages. Furthermore, WPA uses an improved integrity mechanism in order to generate the message integrity check (MIC). This mechanism, called Michael, is able to detect possible attacks and deploy countermeasures to prevent new attacks.

WPA2 utilizes CCMP for providing integrity services. CCMP generates a MIC using the CBC-

MAC method. In this method, even the slightest change in the plaintext will produce a totally different checksum.

Security Vulnerabilities

Although the Wi-Fi security architecture has been greatly improved since WEP, there are still vulnerabilities which cannot be addressed by WPA2. These vulnerabilities can lead to a number of link layer denial-of-service (DoS) attacks (Van de Wiele, 2005). All the DoS techniques described here are fairly easy to use with freely available tools found on the Internet. In most of the cases, the attacker will use different forged MAC addresses to mount DoS attacks. These attacks can be detected by specialized hardware (e.g., air monitor, security aware access point) which can detect the misuse of the infrastructure. Furthermore, this specialized hardware can notify the people responsible for the follow-up of a DoS incident and give an estimate on where the attacker is located by considering the signal and noise levels.

Disassociation Storm

Before any wireless communication can occur, a client has to send an association frame to the access point asking to join the network. Similarly, after the end of the wireless session, the access point or client has to send a disassociation frame to terminate the connection. The frames of these messages are broadcasted and can be sniffed by an attacker. The attacker can then flood the network with spoofed disassociation frames every time the client tries to join the network, thus disrupting the association process and the network access.

Authenticated / Deauthenticated Storm

The aforementioned principle can be exploited in order to disconnect a client and try to keep the client disconnected. This technique starts by sending a spoofed deauthentication frame followed by a disassociation frame in order to make sure that the client has disconnected from the legitimate access point. In a more advanced version of this attack, a fake probe request and some beacon frames are transmitted in order to force the client to connect to a rogue access point which ignores or monitors the client's traffic.

UMTS

Universal mobile telecommunications system (UMTS) is one of the third generation (3G) wireless cellular technologies for mobile communication. Mobile devices like smartphones, laptops, and handheld computers can be used. UMTS is standardized by the 3G partnership project (3GPP) and it is mainly deployed in Europe and Japan. Theoretically UMTS supports up to 1920 Kbps data transfer rates, but currently the real world performance can reach 384 Kbps. It uses the W-code division multiple access (CDMA) technology over two 5 MHz channels, one for uplink and one for downlink. The specific frequency bands originally defined by the UMTS standard are 1885-2025 MHz for uplink and 2110-2200 MHz for downlink.

In UMTS network topology, a mobile station is connected to a visited network by means of a radio link to a particular base station (Node B). Multiple base stations of the network are connected to a radio network controller (RNC) and multiple RNCs are controlled by a general packet radio service (GPRS) support node (GSN) in the packet-switched case. The visitor location register (VLR) and the serving GSN keep track of all mobile stations that are currently connected to the network. Every subscriber can be identified by its international mobile subscriber identity (IMSI). In order to protect against profiling attacks, this permanent identifier is sent over the air interface as infrequently as possible. What is more, locally valid temporary mobile subscriber identities (TMSI) are used to identify subscrib-

ers whenever possible. Every UMTS subscriber has a dedicated home network with which the subscriber shares a long term secret key Ki. The home location register (HLR) keeps track of the current location of all subscribers of the home network. Mutual authentication between a mobile station and a visited network is carried out with the support of the current serving GSN (SGSN) or the mobile switching center (MSC)/VLR respectively.

The new series of 3.5G mobile telephony technologies, known as high speed packet access (HSPA), will provide more bandwidth to the end-user, improved network capacity to the operator, and enhanced interactivity for data applications. HSPA refers to the improvements made in the UMTS downlink, known as high speed downlink packet access (HSDPA), and the UMTS uplink, usually referred to as high speed uplink packet access (HSUPA) but also referred to as enhanced dedicated channel (E-DCH).

HSDPA provides a bandwidth of 14.4 Mbps/user. For multiple-input-multiple-output (MIMO) systems up to 20 Mbps can be achieved. Both HSDPA and HSUPA can be implemented in the standard 5 MHz carrier of UMTS networks and can coexist with original UMTS networks. As HSPA specifications refer only to the access network, there is no change required in the core network (CN) except from the high data-rate links required to handle the increase in clients' traffic generated by HSPA.

Security Architecture

The 3G security architecture is based on GSM, but certain improvements are added in order to correct the described security vulnerabilities.

Authentication

Authentication and key agreement (AKA) is the main security protocol of UMTS in the 3GPP specification. According to AKA, a mobile device and a base station have to authenticate each other. Figure 1 provides an overview of the AKA process. The authentication vector includes the following components:

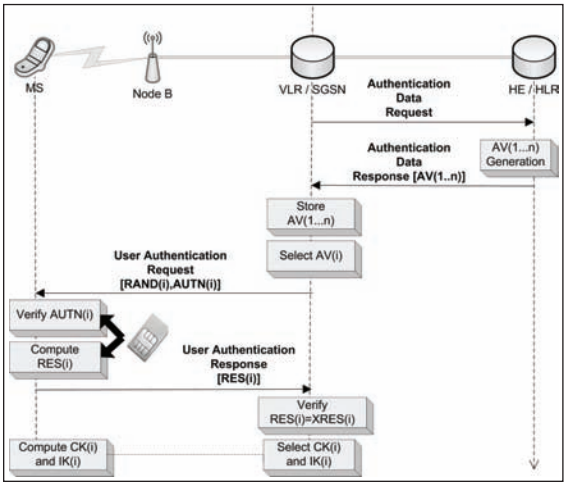
a. A random number (RAND)
b. An expected response (XRES)
c. A cipher key (CK)
d. An integrity key (IK)
e. An authentication token (AUTN)

RAND and XRES are utilized by the network to authenticate the mobile station (MS), whereas AUTN is utilized by the MS to authenticate the network. After the mutual authentication, the two communicating parties can agree on the CK and the IK which will be used throughout the rest of the session.

Confidentiality and Integrity

UMTS employs the UMTS encryption algorithm (UEA) in order to provide information confidentiality. The encryption process of UEA is based on the f8 algorithm. One of the main improvements

Figure 1. 3GPP authentication and key agreement (AKA)



of UMTS is that the link layer encrypted channel is established between the MS and the GSN instead of the BS, as in GSM. Furthermore, UEA is utilized to protect not only the data channels but also certain signalling channels.

For user confidentiality UMTS utilizes the same mechanism as GSM. Instead of the IMSI, a temporary identity (TMSI) assigned by VLR is used to identify the subscriber in the communication messages exchanged with the BS. However, the IMSI is still transmitted in clear-text over the air while establishing the TMSI. This has been proved to be a starting point for security attacks against UMTS.

Data integrity in 3GPP is assured explicitly through the UMTS integrity algorithm (UIA). The UIA operation is based on the f9 algorithm. UIA is utilized to protect both communication and signalling. UEA and UIA are presented in Figure 2.

GSM Compatibility

UMTS has been designed to be backwards compatible with GSM. It includes standardized security features in order to ensure world-wide interoperability and roaming. More specifically, GSM user parameters are derived from UMTS parameters using a set of predefined conversion functions. However, GSM subscribers roaming in 3GPP networks are supported by the GSM security context, which is vulnerable to the aforementioned GSM vulnerabilities.

Security Vulnerabilities

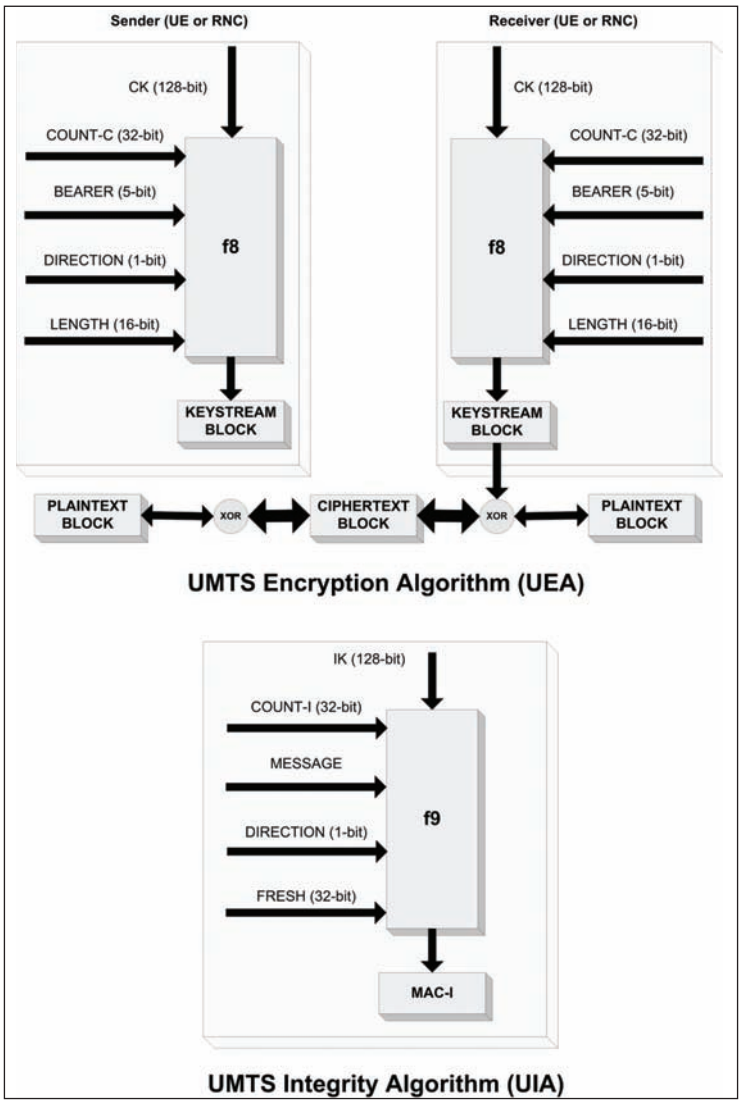
3G security has been significantly improved compared to GSM. However, there are still vulnerabilities related to the backwards compatibility with GSM. Meyer and Wetzel (2004a, 2004b) present a man-in-the-middle attack which can be mounted even if the subscriber utilizes a 3G enabled device within a 3G base station coverage. The described attack goes far beyond the anticipations of the 3GPP group. UMTS subscribers are vulnerable to what 3GPP calls a "false base station attack" even if subscribers are roaming in a pure UMTS network and even though UMTS authentication is applied.

This attack can be categorized as a "roll-back attack." This category of attacks exploits weaknesses of old versions of algorithms and protocols by means of the mechanisms defined to ensure backward compatibility of newer and stronger versions. According to this technique, the attacker acts on behalf of the victim's mobile station in order to obtain a valid authentication token AUTN from any real network. It is assumed that the attacker has already retrieved the IMSI of the targeted subscriber, since the latter is sent in clear-text when establishing a TMSI. The attacker can capture the AUTN by initiating the AKA procedure with any legitimate network. The next step is to impersonate a valid GSM base station to the victim mobile station. The mobile station connects and verifies the rogue BS, since it possesses a valid AUTN. Subsequently, the rogue BS is configured by the attacker to utilize "no encryption" or weak encryption. Finally, the attacker can send to the mobile station the GSM cipher mode command including the chosen encryption algorithm. The man-in-the-middle attack is mounted and the attacker can use passive or active eavesdropping without being detected.

WIMAX

The IEEE 802.16 or broadband wireless access (BWA) Working Group was established in 1999 to prepare specifications for broadband wireless metropolitan area networks. The first 802.16 standard was approved in December 2001 and was followed by three amendments: 802.16a, 802.16b and 802.16c. In 2004 the 802.16-2004 standard (IEEE-SA, 2006) was released and the earlier 802.16 documents including the a/b/c amendments were withdrawn. An amendment

Figure 2. UMTS encryption and integrity algorithm



to the standard 802.16e (IEEE-SA, 2006) addressing mobility was introduced in 2005. The main additions of the 802.16e were low density parity check (LDPC) codes at the physical layer, enhanced MIMO setup functions, new states for MS operation, parameter-defined power saving classes of mobiles, and enhanced FFT sizes for scalable OFDMA.

WiMax aims at providing high data rate triple-play wireless services to fixed users, to nomadic users, and to users of mobile devices. It is based on a low latency quality of service (QoS) architecture in order to provide real-time multimedia services. It operates on the 2-6 GHz (IEEE802.16e) and 10-66 GHz (IEEE802.16-2004) frequency bands and it uses the OFDMA technology for modulation and medium access.

Security Architecture

WiMax has been designed with security in mind, especially after the serious vulnerabilities dis-

covered in the original Wi-Fi security protocol. The IEEE 802.16 specifications include a security sublayer within the MAC layer. The IEEE 802.16 security architecture is based on the following issues:

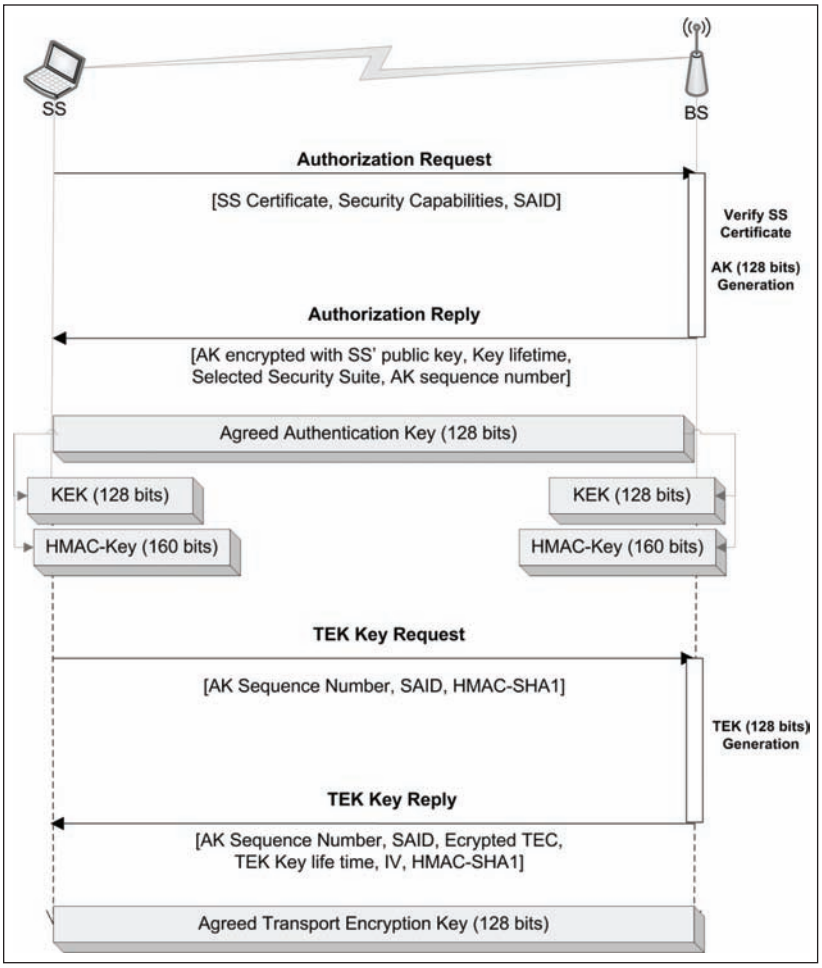
- **Authentication:** The baseline authentication architecture, by default, employs a public key infrastructure (PKI) based on X.509 certificates. The base station (BS) validates the client's certificate before permitting access to the physical layer (see Figure 3). First, the subscriber station (SS) sends to the BS an authorization request containing the certificate, the available security capabilities, and the security association identifier (SAID). The BS verifies the certificate and generates a 128 bit authentication key (AK). Then, the BS sends to the SS an authorization reply, which contains the AK encrypted with SS's public key, the AK's lifetime, the selected security suite, and an AK sequence number. The SS uses its private key to recover the AK, which can now be utilized as an authentication token in further communication.
- **Key exchange:** The SS and the BS can agree on a transport encryption key (TEK), which will be utilized for data encryption (see Figure 3).
  TEK is randomly generated by the BS. The AK established during authentication is used to derive two additional keys:
  - Message authentication key (HMAC key), which is utilized to provide message integrity and AK confirmation during the key exchange process.
  - Key encryption key (KEK), which is utilized for encrypting the TEK before sending it back to the SS. The modes for encrypting TEK are:
    a. 3DES with a 112 bit KEK
    b. AES with a 128 bit KEK
    c. RSA using SS's public key
- **Data encryption and integrity:** The modes for implementing data privacy are:
  - Data encryption standard (DES) with a 56 bit key and cipher block chaining (CBC), which utilizes the Initialization Vectors obtained during Key Exchange,
  - AES with a 128 bit key and counter mode with cipher block chaining message authentication code protocol, which provides message integrity and replay protection.

Security Vulnerabilities

WiMax supports unilateral device level authentication (Barbeau, 2005), which can be implemented in a similar way as Wi-Fi MAC filtering based on the hardware device address. Therefore, address sniffing and spoofing make a MS masquerade attack possible. In addition, the lack of mutual authentication makes a man-in-the-middle attack from a rogue BS possible. However, a successful man-in-the-middle attack is difficult because of the time division multiple access (TDMA) model in WiMax. The attacker must transmit at the same time as the legitimate BS using a much higher power level in order to "hide" the legitimate signal. Furthermore, WiMax supports mutual authentication at user network level based on the generic extensible authentication protocol (EAP) (Aboba, Blunk, Vollbrecht, Carlson, & Levkowetz, 2004). EAP variants, EAP- transport layer security (TLS) (X.509 certificate based) (Aboba & Simon, 1999) and EAP-subscriber identity module (SIM) (Haverinen & Salowey, 2004), are supported.

In the data privacy domain, the main security threat is the transmission of unencrypted management messages over the wireless link. Eavesdropping of management messages is a critical threat for users and a major threat to a system. For example, an attacker could use this vulnerability to verify the presence of a victim at its location before perpetrating a crime. Addi-

Figure 3. WiMax authentication and key exchange process



tionally, it might be used by a competitor to map the network. Another major vulnerability is the encryption mode based on DES. The 56 bit DES key is easily broken by brute force with modern computers. Furthermore, the DES encryption mode includes no message integrity or replay protection functionality and is thus vulnerable to active or replay attacks. The secure AES encryption mode should be preferred over DES.

Finally, there is a potential for DoS attacks because authentication operations trigger the execution of long procedures. For example, a DoS attack could flood a MS with a high number of messages to authenticate. Due to low computational resources, the MS will not be able to handle a large amount of invalid messages, rendering the DoS attack successful.

FLASH-OFDM

Fast low-latency access with seamless handoff orthogonal frequency division multiplexing (flash-OFDM) is an OFDM-based proprietary system which specifies the physical layer, as well as higher protocol stack layers. It is an all IP technology and it aims to compete with GSM/3G networks. Already implemented flash-OFDM technology

operating in the 450 MHz frequency band can offer a maximum download speed of 5.3 Mbps and an upload speed of 1.8 Mbps.

Design objectives have included design of a high capacity physical layer, a packet-switched air interface, a contention-free and QoS-aware MAC layer, and efficient operations using existing Internet protocols. The air interface is designed and optimized across all protocol stack layers. Fast hopping across all tones in a pseudorandom predetermined pattern is employed. Channel coding and modulation are carried out on a per-segment basis and can be individually optimized for each channel. The ability to send segments of arbitrary size enables the MAC layer to perform efficient packet switching over the air interface. Given segments can be dedicated for use with predefined functionality. Thus there is no need to send overheads, such as message headers. Therefore, network layer traffic experiences small delays and no significant delay jitter.

Security Architecture

The security relies on "defence in depth," that is, virtual private network (VPN) tunnelling and end-to-end encryption are used. Security specifications for flash-OFDM have not been presented in public (Lehtonen, Ahonen, Savola, Uusitalo, Karjalainen, Kuusela et al., 2006).

Security Analysis

A security analysis of the mobile broadband technologies Wi-Fi, UMTS, and WiMax is presented. Inclusion of flash-OFDM in this comparison is not possible because of the unavailability of public security specifications. Threats are analyzed with respect to the likelihood of occurrence, the impact on the network operation, and the global risk they represent. In the following paragraphs, we first describe in detail the evaluation and comparison methodology, and then a group of tables is presented in which the security threats of the investigated technologies are evaluated. Security threats are classified based on four main axes: authentication, confidentiality, integrity, and physical layer resilience. Finally, the security evaluations of the studied technologies are compared and presented in a concise overview table.

Methodology

The evaluation and comparison methodology was based on the method described by Barbeau, (2005) and ETSI (2003). More specifically, three main criteria are considered: likelihood, impact, and risk. "Likelihood" refers to the probability that an attack associated with a specific threat is successfully launched. In this context, two variables are considered:

a. The technical difficulties of mounting the attack in terms of the required software, hardware, and estimated time duration.
b. The attacker's motivation in terms of the level of network access or the severity of the system malfunction that the attack achieves.

Three levels of likelihood are available as described in Table 1. "Impact" refers to the consequences of an attack in terms of user and network security. The two variables of impact are:

a. User impact in terms of the severity of network access degradation.
b. System impact in terms of the severity of network degradation or outage.

Three levels of impact are available as described in Table 1. According to the level of likelihood and impact, numerical values from a predefined range are assigned to each criterion (see Table 1). For a specific threat, the "risk" refers to an overall threat level which is determined by the product of the likelihood value and impact value.

Table 1. Evaluation and comparison methodology

		Variables		
Criteria	**Cases**	**Difficulty**	**Motivation**	**Rank**
Likelihood	**Unlikely**	Strong	Low	**1**
	Possible	Solvable	Reasonable	**2**
	Likely	None	High	**3**
		User	**System**	
Impact	**Low**	Annoyance	Very limited outages	**1**
	Medium	Loss of service	Limited outages	**2**
	High	Long time loss of service	Long time outages	**3**

Risk = Likelihood x Impact			
Risk	**Minor**	No need for countermeasures	**1-3**
	Major	Threat need to be handled	**3-6**
	Critical	High priority	**6-9**

Security threats which result in a high evaluated risk value are critical and additional measures should be taken to protect the network perimeter, whereas threats which have a low risk can be tolerated without employing countermeasures.

In this point, it is worth noting that this quantitative ranking is subjective. However, this is a useful evaluation and comparison methodology which can stimulate a structured discussion based on the evaluation criteria, that is, likelihood, impact, and risk. The comparison axes are authentication, confidentiality, integrity, and physical layer resilience.

Objective-Based Comparison

This section applies the aforementioned methodology on four main objectives of wireless security architectures: authentication, confidentiality, integrity, and physical layer resilience. For each objective, a thorough discussion describes the rationale behind the ranking of the security threats.

Authentication Evaluation

Wi-Fi includes four security threats which are all ranked to have a high impact on the system, since the attacker can exploit them to override the authentication checks or launch a combination of attacks which will grant him full network access. However, the likelihood ranking greatly varies. Closed system authentication and MAC filtering are very likely to be attacked by sniffing software which is readily available on the Internet. WEP attacks are more complicated, because a combination of software is required to induce and capture network traffic and then exploit the weak IVs in order to crack the key. WPA-PSK is even more difficult to break since it requires a brute force attack. The resilience of WPA-PSK is greatly dependent on the length and the complexity of the preshared key.

UMTS is far more resilient to authentication attacks, since most of the security gaps have been identified during the deployment of GSM and tackled in the specification design of UMTS. However, UMTS includes two main authentication vulnerabilities which can be exploited to launch a man-in-the-middle attack (high impact). The IMSI hijack threat refers to the deployment of a rogue BS in order to initiate an authentication procedure and steal the IMSI of a mobile user. The motivation for this attack is high, but the equipment is expensive and complicated to configure. AUTN capture is the second step of the attack and it refers to capturing an authentication token by masquerading a MS. It assumes that the IMSI Hijack attack has been already successfully launched. However, this attack does not require the deployment of a rogue BS and therefore it is more possible to happen.

In the WiMax architecture, the main security threat is the device-level authentication mode. When this mode is utilized without certificate support, it is as vulnerable as MAC filtering and it can be exploited to launch MS or BS masquerading attacks. A less critical vulnerability is the DoS attack which can be launched by flooding authentication requests. This attack mostly affects the MS due to its limited processing resources, but it is not a major threat since it has a medium

impact and a low motivation.

Confidentiality Evaluation

Wi-Fi includes some major vulnerabilities. It supports a null mode encryption which is configured as default in the majority of the commercial access points. WEP encryption can provide an elementary level of protection, but it is still too weak to keep the intruders out. WPA-PSK offers a satisfactory level of confidentiality, if long and complex keys are utilized. The ranking of the Wi-Fi confidentiality vulnerabilities is similar to authentication ranking, since both objectives are based on the same mechanisms.

UMTS incorporates strong encryption algorithms which have eliminated the deficiencies of its predecessor GSM. Nevertheless, the backwards compatibility with GSM can be exploited to compromise dual-band mobile devices by launching a man-in-the-middle attack. In this attack, the rogue BS can mandate the MS to use null mode encryption or one of the GSM encryption modes which can be easily broken (Biham & Dunkelman, 2000; Biryukov, Shamir, & Wagner, 2000). However, this is an unlikely attack since it requires the deployment of a BS and a prior successful launch of the IMSI hijack and AUTN capture attacks.

WiMax security architecture includes two main shortcomings. First of all, the DES encryption mode provides an inadequate level of confidentiality, since it can be easily broken. In addition, the eavesdropping of unencrypted management frames can be easily established, but it cannot greatly affect the system if robust authentication and integrity mechanisms have been deployed.

Integrity Evaluation

Wi-Fi supports null mode which leaves the messages totally unprotected against modification and replay attacks. WEP CRC-32 integrity mechanism provides a moderate level of protection, but there is no replay protection and the integrity protection can be overridden by an experienced attacker.

The UMTS architecture includes a major shortcoming, namely the inadequate replay protection of authentication tokens. This vulnerability can have a high impact since it allows the reuse of the token retrieved by an AUTH capture attack and the completion of the UMTS man-in-the-middle attack. However, it requires a prior successful launch of IMSI hijack and AUTN capture. Therefore it results in a high technical difficulty.

WiMax supports two modes that can greatly compromise information integrity. The first is the DES mode which does not support integrity and replay protection of data frames. The second is the null MAC mode for management frames, which can allow the intruder to inject modified management frames and affect the network operation.

Physical Layer Resilience Evaluation

The resilience of the physical layer of each technology is evaluated with respect to jamming and scrambling. Jamming is achieved by introducing a source of noise strong enough to significantly reduce the capacity of the channel. Scrambling is similar to jamming, but it takes place for short intervals of time and it is targeted to specific frames or parts of frames.

Wi-Fi comprises of the three different specifications IEEE 802.11a/b/g which all utilize random medium access techniques but operate on different physical channels. IEEE 802.11a/g operate on a 5 MHz OFDM channel, whereas IEEE 802.11b operates on a 5 MHz DSSS channel. The DSSS is more resilient to narrowband jamming than OFDM and therefore jamming has a higher impact on IEEE802.11a/g. However, if the attacker wants to jam all the channels, the attacker has to jam a bandwidth of 40 MHz, which is quite difficult. Scrambling is easier to launch because of the random medium access layer.

UMTS operates on two 5 MHz DSSS chan-

nels, one for the uplink and one for the downlink. It is resilient to narrowband jamming because of the DSSS modulation, but it is still vulnerable to scrambling because of the random access.

WiMax operates on a 1.25-20 MHz OFDM channel and it employs TDMA techniques. Thus, it can be vulnerable to jamming especially if it operates on a narrow channel, but it is resilient to scrambling due to the TDMA.

OVERALL COMPARISON

The results from authentication, confidentiality, integrity, and physical layer resilience evaluation are presented in Table 2.

As follows, the overall comparison results:

- **Wi-Fi:**
  - **Authentication:** 6.75
  - **Confidentiality:** 6
  - **Integrity:** 6
  - **PHY Resilience:** 5
  - **AVERAGE RISK:** 5.94
- **UMTS**
  - **Authentication:** 4.5
  - **Confidentiality:** 3
  - **Integrity:** 3
  - **PHY Resilience:** 3.5
  - **AVERAGE RISK:** 5.94
- **WiMax**
  - **Authentication:** 6.5
  - **Confidentiality:** 6
  - **Integrity:** 7.5
  - **PHY Resilience:** 3
  - **AVERAGE RISK:** 5.75

Wi-Fi has the highest average risk, which is quite reasonable because of the initial lack of security mechanisms in the Wi-Fi specification and the subsequent failure of WEP. WPA and WPA2 modes are much more secure, but the poor usability and the limited security awareness have constrained their wide deployment. UMTS proved to be quite robust by eliminating the security inefficiencies of its predecessor GSM. However, an attacker can still exploit some backward-compatibility issues to launch a man-in-the-middle attack. WiMax's performance was not satisfactory enough mainly due to the provision of weak security modes. Nevertheless, the practical performance is greatly dependent on the actual security decisions of the network operators. These decisions vary according to the provided service requirements.

Table 2. Security evaluation

AUTHENTICATION EVALUATION				
Technology	**Threat**	**Likelihood**	**Impact**	**Risk**
Wi-Fi	Closed System	3	3	9
	MAC Filtering	3	3	9
	WEP	2	3	6
	WPA-PSK	1	3	3
Average Risk				**6,75**
UMTS	IMSI Hijack	2	3	6
	AUTN Capture	1	3	3
Average Risk				**4,5**
WiMAX	Device-level Authentication	3	3	9
	DoS on MS	2	2	4
Average Risk				**6,5**
CONFIDENTIALITY EVALUATION				
Technology	**Threat**	**Likelihood**	**Impact**	**Risk**
Wi-Fi	Null	3	3	9
	WEP	2	3	6
	WPA-PSK	1	3	3
Average Risk				**6**
UMTS	Rogue BS – Null / Weak	1	3	3
Average Risk				**3**
WiMAX	DES mode	3	3	9
	Management Frames	3	1	3

	Scrambling	2	2	4
Average Risk				**2,5**
WiMAX	Jamming	1	3	3
	Scrambling	1	3	3
Average Risk				**3**

FUTURE TRENDS

Broadband wireless access networking is presently a rapidly evolving ICT area. Three important development trends can be identified:

- WiMax evolution for long range broadband wireless access.
- Development of a broadband wireless access technology supporting high speed mobility.
- Emerging 4G wireless cellular technology.

WiMax Evolution

The WiMax standard was finalized in June 2004. WiMax has the potential to change telecommunications as it is known today. "It eradicates the resource scarcity that has sustained incumbent service providers for the last century. As this technology enables a lower barrier to entry, it will allow true market-based competition in major telecommunications services like voice, video and data" (Ohrtman, 2005).

WiMax can offer a point-to-point range of 50 km with a throughput of 72 Mbps. The WiMax technology will make personal broadband services profitable to service providers and will be available to business and consumer subscribers at affordable prices. The first mobile WiMax products are expected to be introduced into the market in the first quarter of 2007. New technologies such as MIMO and beam forming for higher throughput and capacity will be introduced in 2007 (WiMax Forum, 2006).

Mobile Broadband Wireless Access (MBWA)

The IEEE 802.20 (or MBWA) Working Group was established in December 11, 2002, with the aim to develop a specification for an efficient packet-based air interface that is optimized for the transport of IP based services. The goal is to enable worldwide deployment of affordable, always-on, and interoperable BWA networks. The group will specify the lower layers of the air interface, operating in licensed bands below 3.5 GHz and enabling peak user data rates exceeding 1 Mbps at speeds of up to 250 km/h. A draft version of the specification was approved in January 18, 2006.

4G – Future Wireless Cellular Technology

Frameworks for future 4G networks, which seamlessly integrate heterogeneous mobile technologies in order to provide enhanced service integration, QoS, flexibility, scalability, mobility, and security, are currently being developed. However, these frameworks raise security vulnerabilities. An international consortium presents requirements and recommendations for the evolving 4G mobile networking technology (Akhavan, Vivek Badrinath, & Geitner, 2006). The 4G technology, which is at its infancy, is supposed to allow data transfer up to 100 Mbps outdoor and 1 Gbps indoor. The International Telecommunications Union (ITU) defines 4G as downlink throughput of 100 Mbps or more, and corresponding uplink speeds of at least 50 Mbps.

The 4G technology will support roaming for interactive services such as video conferencing. The cost of the data transfer will be comparatively low and global mobility will be possible. The networks will be all IPv6 networks. WLAN, 2.5G, 3G, and other networks such as SATCOM, WiMAX, and Bluetooth will be integrated in 4G networks. The antennas will be much smarter and improved access technologies like OFDM and MC-CDMA will be used. More efficient algorithms at the physical layer will reduce the inter-channel interference and cochannel interference.

Security Issues

Seamless convergence of heterogeneous wireless networks provides new security challenges for the research community. Global authentication architectures are needed which can operate independently of the wireless physical protocol. In addition, specifications are needed for maintaining the confidentiality and the integrity of the communication data while the user terminal is in a hand-off state. In this direction, a forum of mobile operators called fixed mobile convergence alliance (FMCA) is working on defining specifications for the convergence of heterogeneous networks in the context of all IP 4G wireless systems.

Security policy issues are:

- The use of lightweight and flexible authentication, authorization, account, and audit (AAAA) schemes,
- The use of Trusted Computing (Reid, Nieto, & Dawson, 2003), and
- Different security polices for different services are recommended for 4G systems (Zheng, He, Xu, & Tang, 2005a).

Several security architecture proposals for 4G wireless systems have been made:

- Zheng, He, Yu, and Tang (2005b) propose a security architecture with:
  - Network access security features.
  - Network area security features for secure data exchange between network nodes.
  - User area security features for secure access to ME/USIM.
  - Application security for secure end-to-end data exchange.
- Integration of the SSL security protocol and a public key infrastructure is outlined and evaluated by Kambourakis, Rouskas, and Gritzalis (2004).
- A hierarchical trust model for 4G wireless networks is proposed by Zheng et al. (2005a).

CONCLUSION

In this chapter, the dominant mobile broadband technologies have been evaluated and compared based on their security performance. Three technologies were taken into consideration: Wi-Fi, UTMS, and WiMax. Their security architectures have been presented and analyzed in order to highlight the main security deficiencies. The evaluation and comparison methodology was based on assigning qualitative rankings to security threats with respect to the following criteria: likelihood, impact, and risk. The methodology was applied on four evaluation axes: authentication, confidentiality, integrity, and physical layer resilience. According to the comparison results, Wi-Fi is more liable to security attacks, followed by WiMax and UMTS. However, WiMax has not been widely tested under real-world systems due to its recent release. More security vulnerabilities may therefore be discovered in the future. Finally, the security architecture of UMTS is quite robust because of the lessons learned from GSM, but it is still not invincible against an experienced attacker with the right equipment.

KEY TERMS

Authentication: Verification of the identity of a user or network node who claims to be legitimate.

Broadband: A network connection with a bandwidth of about 2 Mbps or higher.

Confidentiality: A cryptographic security service which allows only authorized users or network nodes to access information content.

EAP: Extensible authentication protocol (EAP) is an authentication protocol used with 802.1X to pass authentication information messages between a suppliant and an authentication server.

Integrity: A security service which verifies that stored or transferred information has remained unchanged.

UMTS: Universal mobile telecommunication system (UMTS) is a global third generation wireless cellular network for mobile telephony and data communication with a bandwidth up to 2 Mbps which can be upgraded up to 20 Mbps with high speed packet access (HSPA).

Wi-Fi: Wireless local area networking based on IEEE 802.11 standards.

WiMax: Wireless metropolitan area networking based on IEEE 802.16 standards.

WPA, WPA2: Wi-Fi protected access (WPA) is a protocol to secure wireless networks created to patch the previous security protocol WEP. WPA implements part of and WPA2 implements the entire IEEE 802.11i standard. In addition to authentication and encryption, WPA also provides improved payload integrity.

This work was previously published in Handbook of Research on Wireless Security, edited by Y. Zhang, J. Zheng, and M. Ma, pp. 759-775, copyright 2008 by Information Science Reference, formerly known as Idea Group Reference (an imprint of IGI Global).

Chapter 7.15
Developing a Theory of Portable Public Key Infrastructure (PORTABLEPKI) for Mobile Business Security

Sashi Nand
Rushmore University, Grand Cayman, BWI

INTRODUCTION

This chapter looks at how a public key infrastructure (PKI) can increase the wireless network's security by requiring certificate-based authentication for access. It also develops a theory of PORTABLEPKI. Finally, a framework for testing PORTABLEPKI and future research opportunities are discussed.

MOBILE BUSINESS

Mobile Business (m-business) can simplistically be understood as follows:

M-Business = Internet + E-Business + Wireless

M-business is the application infrastructure required to maintain business relationships by means of mobile devices. M-business is also the logical extension of electronic business (e-business) to address new customer channels and integration challenges. There is an interconnection of business processes within an organization and between external parties. For the notion of "business without boundaries" to prevail, back-end applications and data must be re-engineered to take complete advantage of the features offered by m-business (Kalakota & Robinson, 2002).

The most challenging and complex aspects of the m-business revolution are the design implementation, security, and integrity of mobile-enhanced business processes because they transcend traditional and regulatory boundaries (Stanley, 2004).

WIRELESS NETWORK

Wireless technologies are based on communication without land-based physical connections. For example, traditional telephone handsets use continuous cabling for connectivity, hence it is wired. Wireless telephony, on the other hand, uses radio waves rather than cables to broadcast network traffic and data transmission.

The two primary areas of wireless technology are mobile phones and mobile computers. Mobile implies portability—a device such as a mobile phone, PalmPilot, or laptop that travels with the user and can be used either off-line or online:

- *Mobile and off-line* means that the device can be used to run self-contained applications while not connected to the Internet or other telephony devices.
- *Mobile and online* is commonly called wireless. This means that the experience is based on a live connection supplied via satellite, cellular, or radio transmission. An online device will always be 'on' in the presence of any wireless network—seamlessly connecting to the Internet or some other system (Kalakota & Robinson, 2002).

What is a Wireless Network?

In a wireless network, radio waves carry the signal at least part of the way. The greater the proportion of the wireless to wired, the more wireless we consider the network. Three basic wireless networking technologies include:

- **Wireless Private Area Networks (WPANs):** Refer to confined short-range networks, for example computers connected while traveling such as mobile phones, laptops, and personal digital assistants (PDAs).
- **Wireless Local Area Networks (WLANs):** Refer to same local-range networks, for example computers connected within the same area such as an office building or home.
- **Wireless Wide Area Networks (WWANs):** Refer to long-range networks, for example computers connected over long distances such as a university campus, city, or town (Shaw, 2003).

SECURITY

With any new technology—especially wireless networking—concerns and questions arise about security of data transmission (Shaw, 2003). Security is a process of minimizing risk, threat, or the likelihood of harm (Pipkin, 2000).

Wireless communications are inherently more open to attack than wired data transfer because the physical layer is the uncontained cyber-space (Campbell, Calvert, & Boswell, 2003).

An insecure wireless connection exposes users to intrusion, which can lead to a loss of protection for confidential information, interception of messages, or abused connections. Some examples are:

- E-mail can be intercepted, read, or changed.
- A hacker who hijacks a session can replace a user's credentials with false information gaining access to the system.
- An unauthorized person can log on to a wireless network that is not secure and use the resources, or obtain financial gain through deception including free connectivity to the Internet (Chan, 2004).

Security dominates discussions about wireless communication. The reason is simple: removing the wires simultaneously removes the access restrictions. In fact, many wireless networks begin life completely unsecured because vendors design wireless access points (WAPs) and WLAN cards with ease of installation and usage in mind. Configuration of security settings does not equate

with ease of use. For this reason, a secure network needs to be set up intentionally and consciously (Randall & Sosinsky, 2005).

Even the most technically efficient and well-managed wireless network will be of little use if the network is not secured (Shaw, 2003). When implementing a wireless network, a plan must be developed for securing the network to reduce the likelihood of risks and threats.

METHODS OF SECURING WIRELESS NETWORKS

Security of wireless networks is specifically covered by the Institute of Electrical and Electronic Engineers (IEEE) 802.11i security specification. Some of the common methods of protecting a wireless network are as follows.

Media Access Control (MAC) Filtering

One of the most basic ways of protecting a wireless network is to implement MAC filtering. At the WAP, configure those MAC addresses (the low-level firmware address of a wireless card) that are allowed to connect to the WAP. Although this sounds like an ideal and easy way to secure a wireless network, consider the following weaknesses:

- It is easy to spoof an approved MAC address.
- MAC filtering is hard to manage.
- MAC filtering authenticates only the computer, not the user.
- The size of the approved MAC list is limited.

Wired Equivalent Privacy (WEP)

WEP provides encryption services to wireless networking. When a wireless connection enables WEP, the wireless network interface card (NIC) encrypts each data packet transmitted on the network using the Rivest Cipher version 4 (RC4) stream cipher algorithm. The WEP then decrypts the data packets on receipt. The weakness in WEP's implementation is two-fold:

- The symmetric encryption key is rarely changed.
- The initialization vector (IV) is only 24 bits and is re-used over time, thereby giving rise to a pattern of usage which can be easily identified and exploited (Komar & Microsoft PKI Team, 2004).

Wi-Fi Protected Access (WPA)

This is an encryption standard produced by the Wireless Fidelity (Wi-Fi) Alliance to address the security issues found in WEP. The following enhancements are included in WPA:

- **Increased Data Encryption:** WPA implements Temporal Key Integrity Protocol (TKIP), which uses a per-packet key mixing function, a message integrity check (MIC) known as *Michael*, and an extended IV with rules on sequencing. In addition, WPA implements a re-keying mechanism so that the same key is not used for long periods of time.
- **Dependency on 802.1x Authentication:** The use of 802.1x authentication is optional for WEP encryption only. WPA requires 802.1x authentication to ensure that only authorized users or computers are allowed to connect to the wireless network. 802.1x authentication also ensures mutual authentication so that a wireless client does not connect to a rogue network, rather than an authorized network.

Weaknesses in the current WEP algorithm implemented in current WLANs have been ex-

posed. The new security supplement to the 802.11 MAC standard is 802.11i, which will address security holes in the 802.11a, b, and g protocols, and improve encryption, key management, distribution, and user authentication. This standard is worth remembering, because these improvements to security may be available as firmware and later hardware upgrades for existing Wi-Fi networks (McCullough, 2004).

The current WPA definition includes forward compatibility with the new 802.11i security specification. 802.11i adds secure fast handoffs, secure de-authentication, and secure disassociation with WAPs. 802.11i also implements strong forms of authentication from the Advanced Encryption Standard (AES) (Komar & Microsoft PKI Team, 2004).

Public Key Infrastructure

PKI significantly increases the security of wireless networks because it requires encryption as well as a certificate-based authentication for access. PKI uses pairs of cryptographic keys (public key and private key) provided by a trusted third party, known as a certification authority (CA), which is verified by a registration authority (RA). Central to the workings of PKI, a CA issues a digital certificate, which positively identifies a holder of keys. The CA maintains accessible directories of valid certificates and also a list of certificates it has revoked.

PKI brings to the electronic world the security and confidentiality normally provided by physical documents such as handwritten signatures, sealed envelopes, and established trust relationships that are part of traditional paper-based transactions. These security and confidentiality features are as follows:

- **Confidentiality:** Ensures that only intended recipients can read files, or changes can only be implemented with a valid key.
- **Data Integrity:** Ensures files cannot be changed.
- **Authentication:** Ensures that participants in an electronic transaction are who they claim to be.
- **Non-Repudiation:** Prevents participants from denying involvement in an electronic transaction (Austin, 2001).

Vendors can provide security solutions that install digital certificates on the end devices itself, optimizing the PKI implementation especially for the wireless environment. For example, Microsoft Windows Server 2003 PKI provides the necessary certificates for 802.x authentication for wireless as well as wired networks. When a user or computer performs 802.1x authentication for wireless or wired network, the following two authentication types are available:

- **Extensible Authentication Protocol with Transport Layer Security (EAP/TLS):** A certificate-based authentication method that provides mutual authentication between the user or computer and the Remote Authentication Dial-In User Service (RADIUS) server when implemented for a wireless networking solution.
- **Protected Extensible Authentication Protocol (PEAP):** Allows the transmission of other EAP types within a TLS secure channel (Komar & Microsoft PKI Team, 2004).

Thus, in an open, untrusted, and insecure wireless network environment, cryptography provides the security and PKI provides the trust to enhance m-business (Deloitte & Touche Research Team, 2001).

The lack of security in mobile business is the fundamental problem. In order to better understand and examine ways in which this problem may be solved, a research theory that addresses

this critical issue of security using PKI is developed in the following section.

DEVELOPING A THEORY OF PORTABLE PKI (PORTABLEPKI)

There can be situations where it is absolutely critical to use PKI, but it comes at a cost. Nevertheless, despite its costs and complexity, laying down a sound theoretical foundation, combined with best business practices and robust technological infrastructure, will enhance the usage of PKI and the security of mobile business. Hence Portable Theory of PKI (PORTABLEPKI) has been developed.

There is no definite meaning given to the term "theory," and there are many views on what constitutes a theory. The standard or the orthodox view has been used to construct PORTABLEPKI theory. According to this view there exists a phenomena in the real world (P-Field). Observation of phenomena leads to abstractions by an individual's reason (C-Field) (Staunton, 1976). A theory begins in the 'unreal' world of abstraction, that is, in the human mind (C-Field). In order for it to be useful, theory must eventually relate to the 'real' world, the world of experience (P-Field). Three types of relationships in the theoretical structure are:

1. **Syntactics:** Rules of language. If expressed in English, then the relationship refers to the rules of grammar. If the theory is mathematical, then the relationship refers to the rules of mathematics.
2. **Semantics:** Rules of correspondence or operational definitions which link the concepts to objects in the real world. Semantics concern the relationship of a word, sign, or symbol to a real-world object or event. It is the semantic relationship that makes a theory realistic and meaningful.
3. **Pragmatics:** The effect of words or symbols on people. We are interested in how concepts and their measured correlations in the real world affect people's behavior (Nand & Unhelkar, 2003).

The first step of PORTABLEPKI theory is to identify the research problem in the P-Field by observing the use of PKI in the real world of mobile business. The next step is to develop the conceptual and theoretical structure, including the causal links and chains, and state the hypothesis (H). Then the hypothesis can be written in simple English stating the relationship of each clause whether they are directly or indirectly related. The real-world effect on stakeholders also has to be shown. The overall theory of PORTABLEPKI can be viewed as a set of principles for the purpose of enhancing growth and acceptance of PKI, as well as to enhance the security of m-business. A framework for testing this theory is provided in the next section.

A FRAMEWORK FOR TESTING PORTABLEPKI

An empirical research program based on the inductive-deductive approach developed by Abdel-Khalik and Ajinkya can be modified to test this theory of PORTABLEPKI (Godfrey, Hodgson, & Holmes, 1997). This involves the following eight stages:

Stage 1: Identify a Research Problem by Observation

PKI is one of the remedies to m-business security problems. An examination can be made of the following six factors influencing use of PKI technology in m-business in Australia (Nand & Unhelkar, 2003):

- **Environment:** Includes security, globalization, market competition, regulating

forces, telecommunications, and political influence.

- **Organization:** Includes corporate governance, management, organizational structure, and resources.
- **Business Strategy:** Includes strategic planning, business process re-engineering, total cost of ownership, and return on investment.
- **IT Strategy:** Includes strategic planning, system development, system maintenance, technological risk (including wireless), and complexity of PKI.
- **PKI Technology:** Includes necessity of trust, PKI initiatives, PKI availability, and PKI success stories.
- **People:** Includes PKI skills, PKI training and dissemination of information, and employee culture.

Stage 2: Develop the Conceptual and Theoretical Structure, Including Causal Links and Chains

To develop a rationale as to why firms do or do not use PKI, the study would test the effect of some selected independent variables for the use of PKI. Two independent variables which influence use of PKI are industry type (service or non-service) and the number of years of IT experience. The dependent variable is the level of usage of PKI.

Stage 3: Operationalize the Theoretical Constructs and Relationships, and State the Specific Hypothesis to be Tested

Two hypotheses that have been developed to test this theory are:

- **Hypothesis 1:** Higher usage of PKI technology is expected in the service industry compared with the non-service industry.
- **Hypothesis 2:** Greater usage of PKI technology is expected in organizations that have a greater number of years of IT experience.

Stage 4: Construct the Research Design

The survey research method can be adopted to obtain data from organizations Australia-wide.

Stage 5: Implement this Design by Sampling and Gathering Data

A sample of Australian companies from at least one service industry and one non-service industry can be selected and company details recorded using a database.

Stage 6: Analyze Observations in Order to Test Each Hypothesis

Descriptive statistics and Chi-Square Test can be used to process and analyze the collected data using Microsoft Excel together with PHStat, Prentice-Hall's statistical add-in for Excel. With descriptive statistics frequency, distributions of all responses to the national survey can be recorded using simple tabulations and cross-tabulations on the Microsoft Excel spreadsheet. By using Chi-Square Test, hypotheses 1 and 2 can be tested together with PHStat. This test involves comparison of actual frequency with expected frequency.

Stage 7: Evaluate the Results

Determine whether or not the results support the theory of PORTABLEPKI.

Stage 8: Consider the Specific Limitations and Constraints

Refer to the procedures undertaken in Stages 1-7, and ask: Are there any limitations to the

way the theory was developed or tested? Do any refinements to the theory appear warranted? If the answer is 'yes' to either question, then return to the appropriate stage and attempt to remedy the limitation.

CONCLUSION AND FUTURE DIRECTIONS

Theories play an important role in understanding and changing the world. This chapter has developed a theory of PORTABLEPKI, which breaks new ground. The next step is to test the hypotheses stated in this chapter using the framework provided here and to validate the reality of PKI usages. This will lead to the refinement of PORTABLEPKI theory. People dealing with information security systems have to be ever vigilant because security is an unending mission. While creativity and innovation are what drives new technology, it also gives rise to its associated security problems. Hence the implementation of PORTABLEPKI theory will lead to increased usage of PKI which consequently will enhance the security of both wired and wireless networks and mobile businesses.

This is an initial step for the development of the theory of PORTABLEPKI for the purpose of increasing the security of m-business. The future direction is for the PORTABLEPKI theory to be tested by selecting one specific service industry (e.g., automobile telematics (wireless telemetry) industry) and one non-service industry (e.g., mining oil and gas). This testing will either confirm or negate the PORTABLEPKI theory. Further work could then be undertaken to refine this theory for other stages of development in m-business.

Chapter 7.16
Authentication, Authorisation, and Access Control in Mobile Systems

Josef Noll
University Graduate Center – UniK, Norway

György Kálmán
University Graduate Center – UniK, Norway

ABSTRACT

Converging networks and mobility raise new challenges towards the existing authentication, authorisation, and accounting (AAA) systems. Focus of the research is towards integrated solutions for seamless service access of mobile users. Interworking issues between mobile and wireless networks are the basis for detailed research on handover delay, multi-device roaming, mobile networks, security, ease-of-use, and anonymity of the user. This chapter provides an overview over the state of the art in authentication for mobile systems and suggests extending AAA mechanisms to home and community networks, taking into account security and privacy of the users.

INTRODUCTION

Today's pervasive computing environments raise new challenges against mobile services. In future visions, a converged user access network is projected. This means, that one network will be used to deliver different services, for example, broadcast TV, telephony, and Internet. Composed from mobile (e.g., Universal Mobile Telecommunications System [UMTS]), wireless (IEEE 802.11, IEEE 802.16, IEEE 802.20), and wired (cable, Asymmetric Digital Subscriber Line [ADSL]), these networks hide the border between the telecom, broadcast, and computer networks. The common service enables roaming terminals, which can access services independently of the currently used networking technology. Market players in both areas transform into wireless service providers across access networks. Telecom provide packet

switched data and mobile services over the fixed network, while Internet service providers run voice over IP (VoIP) and video on demand (VoD) over mobile networks.

The changing environment also changes the management plane of the underlying networks. Providers on converged networks have to change their accounting and billing methods and need to redefine their business models. While commercial players demonstrate early examples, research in the AAA area focuses on providing a backplane for the upcoming ubiquitous services run over converged networks.

BACKGROUND

The AAA methods employed in current networks were developed for a single type of network, resulting in two different systems, one for telecommunication services and one for computer networks. This chapter addresses AAA in global system for mobil communications (GSM) and UMTS and computer network solutions based on Internet Engineering Task Force (IETF) standards.

The computer networks provide a unified AAA access, and research focuses on extending the existing methods to be suitable for telecommunication services. Extensions for Remote Authentication Dial In User Service (RADIUS) and Diameter are proposed. RADIUS is the current de facto standard for remote user authentication. It uses Universal Datagram Protocol (UDP) as transport. Authentication requests are protected by a shared secret between the server and the client, and the client uses hash values calculated from this secret. The requests are sent in plaintext except for the user password attribute. The Diameter protocol provides an upgrade possibility as compared to RADIUS. While enhancing the security through supervised packet transmission using the transmission control protocol (TCP) and transport layer encryption for reducing man-in-the-middle attacks, it lacks backward compatibility.

Both methods have a different background. The computer networks targeted the person using a computer in a fixed network environment, while mobile systems addressed a personal device in a mobile network. Thus a challenge for telcos is to enhance seamless network authentication towards user authentication for service access. Most companies are also Internet service providers (ISPs), this would be a natural unification of their AAA systems.

A generic approach is taken by extension of the Extensible Authentication Protocol (EAP) family. Development efforts of the Internet and telecommunication world were united on EAP. This protocol family has the potential for becoming the future common platform for user authentication over converged networks. EAP is a universal authentication framework standardised by IETF, which includes the authentication and key agreement (AKA) and Subscriber Identity Module (SIM) methods. EAP-AKA is the standard authentication method of UMTS networks.

Beside the fundamental differences of communication and computer networks, mobility is the key issue for both. Network services should not only be accessible from mobile terminals, but they should be adapted to the quality of service (QoS) requirements of a mobile/wireless link. Improvements of AAA methods are of fundamental importance for mobility, providing fast handover, reliable and secure communications on a user-friendly and privacy protecting basis.

Subscriber Authentication in Current Networks

In GSM networks, the integrated AAA is used for any type of user traffic. The authentication is just one way the user has to authenticate himself/herself towards the network.

To be more precise, the user is authenticated with a PIN code towards the SIM in the mobile phone, then the device authenticates itself towards the network. Device authentication instead of user

authentication can hinder the upcoming personalised services because it is hiding the user behind the device. In UMTS, the authentication of the device is two-way. A device can also check the authenticity of the network with the help of keys stored on the SIM.

Integration of the mobile authentication with different external services is not widespread. The telecom providers have some internal services, which can authenticate the subscriber based on the data coming from the network. Credentials could be basically the CallerID, the Temporary International Mobile Subscriber Identity (TIMSI) or other data transformed with a hash function. Access control and authorisation is more an internal network task. Without considerable extension, the current mobile networks are more islands than connecting networks in the area of AAA. Equipment manufacturers are now recommending various IP multimedia subsystem (IMS) solutions for mobile providers in order to enable integrated and third party service convergence and to enable multimedia content over today's networks.

AAA protocols employed in computer networks are meant to provide services for authenticated users. Current single sign-on (SSO) protocols, like RADIUS, Diameter, or Kerberos provide the identity of the user to third parties. SSOs can use digital certificates, public key infrastructure (PKI) and other strong encryption methods. But, none of them is able to provide such a complete solution like the integrated AAA of the mobile network. Computer network protocols lack the support for fast mobility of moving clients and optimise resource usage for low bandwidth connections.

With incorporating seamless authentication used in network internal services in telecom world and SSO solutions provided by various protocols from computer networks, a unified AAA system will achieve a enhanced user acceptance and service security. In such a system, secure key storage and tamper resistant handling is crucial. Smart cards for key storage and generation will fulfil the security requirements, but usage and distribution of the smart cards is cumbersome. As most users have a mobile phone, the SIM card is a candidate to be a primary smart card used for AAA in a ubiquitous environment (Kálmán & Noll, 2006).

AAA IN CONVERGED NETWORKS

A converged network carries several types of traffic and enables seamless information exchange between different terminals, regardless of transport medium. To enable converged AAA, research work is going on in different areas: enabling wireless LAN (WLAN)-mobile network interworking, enhancing network mobility in wireless computer networks, and reducing resource requirements in cryptography.

Interworking Between Mobile and Wireless Networks

Network convergence is most significant in the wireless environment, having to face varying QoS measures on the radio interface, for example, propagation delay, variation of delay, bit error rate, error free seconds, distortion, signal to noise ratio, duration of interruption, interruption probability, time between interruption, bit rate, and throughput. These parameters will depend on the user and terminal environment and underline that an optimum access will have to use all available wireless and mobile connections. Leu, Lai, Lin, and Shih (2006) have provided the fundamental differences of these networks, summarised in Table 1.

Increased demand for security has improved the security on wireless links, resulting in Wi-Fi protected access (WPA) and WPA2 as draft implementations of the IEEE 802.11i standard. This standard aims at incorporating protocols of the EAP family, especially transport layer security (TLS) and SIM.

Table 1. Comparison of cellular and WLAN networks

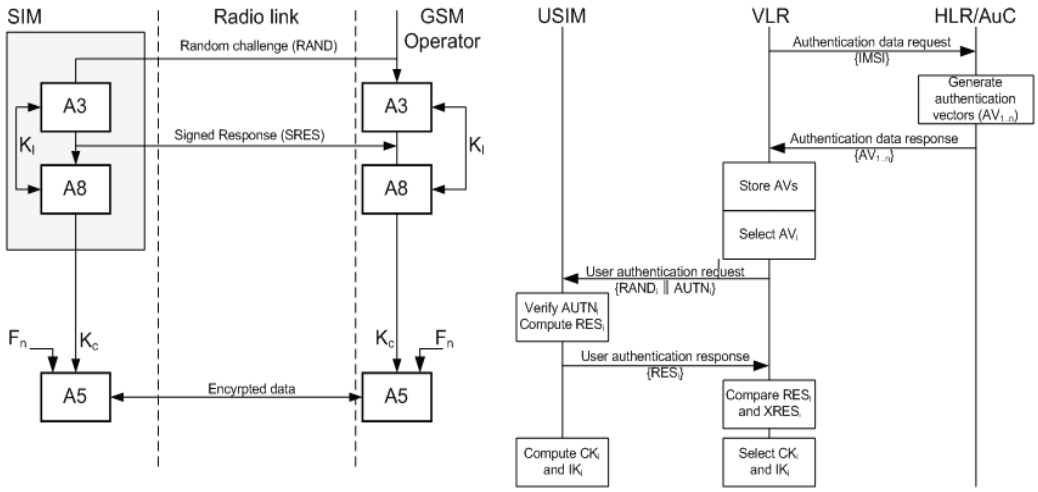
	Cellular	**WLAN**
Coverage	Country-wide	Local
Security	Strong	Depends on setup
Transmission rate	Low	High
Deployment cost	High	Low
License fee	Very high	No need
Construction	Difficult	Easy
Mobility support	High	Poor

Most cellular operators are now providing WLAN services using the Universal Access Method (UAM) for authentication. UAM uses a layer 3 authentication method, typically a Web browser to identify the client for access to the WLAN. This raises the problem of mutual authentication, which has been a problem also in GSM networks. By extending to EAP-SIM it would be possible to enable SIM-based authentication in these environments for SIM-enabled devices.

Roaming between access providers is a second issue. Since data between access points are carried over an IP backbone, it is natural to use a network-based protocol such as Radius, suggested by Leu et al. (2006). Transport encryption inside the backbone is indifferent from normal wired practice, hence out of scope for this chapter. In a converged network, where users can switch between mobile networks and WLAN services, a common AAA system has to be operational to ensure correct operation. A unified billing scheme is proposed by Janevski et al. (2006), suggesting to use 802.1x on the WLAN side as shown on Figure 2. The mobile networks WLAN connection is suggested through the RADIUS server used also for access control in 802.1x.

The use of the IEEE 802.1x standard allows seamless authentication, since preshared certificates and key negotiation are provided to the cellular network, where the user is already

Figure 1. Authentication in GSM and UMTS

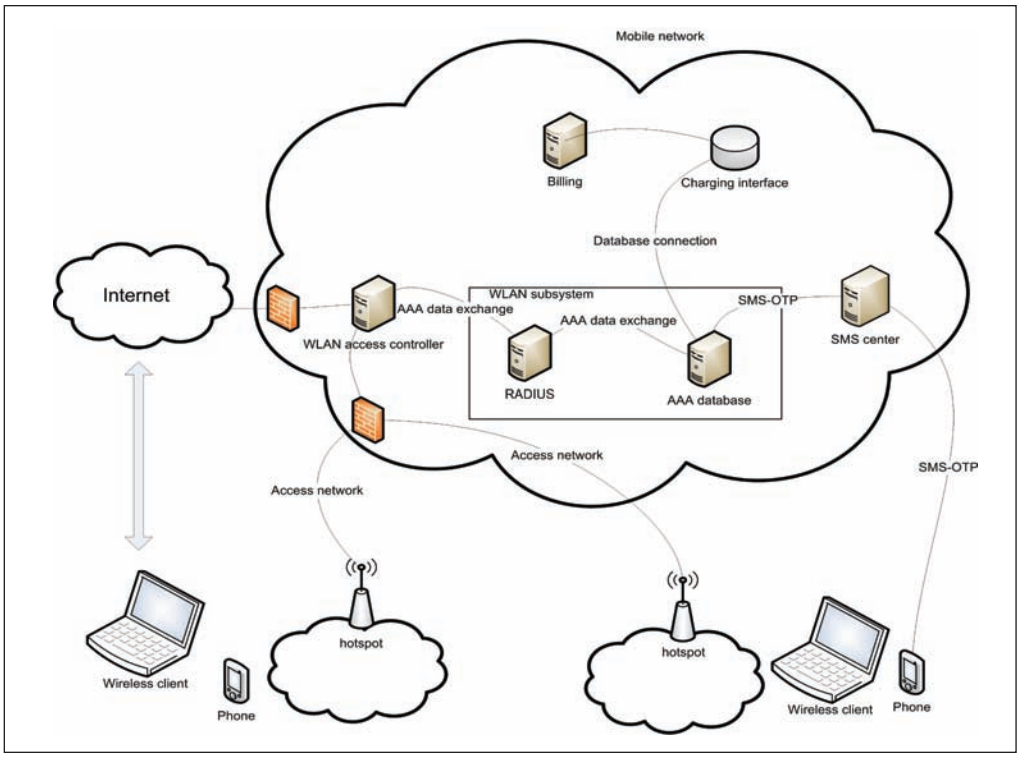


authenticated. With the use of digital certificates, the system is getting closer to the preferred view of pervasive systems, where the user and the service providers are mutually identified. Since these systems authenticate the user towards several services, privacy is a primary concern. A possible solution, recommended by Ren, Lou, Kim, and Deng (2006) has a secure authentication scheme while preserving user privacy.

In pervasive environments a user connected will experience seamless authentication to all services when connected through a SSO service. Malicious tracking of his/her behaviour or eavesdropping of authentication messages can compromise the user credentials. The SSO service has to be extremely prudent when sending user-related information. Keeping a reasonable level of privacy, the system should deal with questions in location privacy, connection anonymity, and confidentiality (Ren et al., 2006). The recommendations are based on blind signatures and hash chains. Using hash is highly recommended, since a good hash function can provide good foundation for anonymous access and its resource needs are not too high for the current mobile devices, as sometimes blind signatures based on Rivest-Shamir-Adleman (RSA) scheme may be. In certain environments, the GSM integrated functions may also be used.

The user retains full control over authentication credentials when composing and generating authentication tokens like the identities suggested by Chowdhury and Noll (2007). Initial service access can be achieved showing one of these tokens after mutual identification between the service and the user. Based on these tokens, no user data can be retrieved nor traced back. If all of the initial identification steps succeed, the exchange of the required credentials can proceed using a freshly negotiated session key.

Figure 2. Integration of radius and mobile network authentication



The base of most authentication techniques is a preshared key, delivered to the user device out-of-band. Authentication can be done for example in mobile phones by inserting a master private key on the SIM at the activation of the card (Kálmán & Noll, 2006).

A different approach is to extend the current mobile network with additional elements to enable network integrated AAA also in an Internet environment. Khara, Mistra, and Saha (2006) suggest including a new node, called Serving GPRS Access Router. This entity acts as a gateway for the WLAN traffic to enter the general packet radio services (GPRS) backbone and enable GPRS signalling to control WLAN. The new protocol set eliminates the need of Signalling System 7 (SS7) in addition to the IP backbone. Khara et al. claim that this solution is superior in terms of speed and overhead compared to the RADIUS-based methods suggested previously. The main drawback is the need of special dual mode devices with a split IP layer, a solution which might not be practical having in mind the basis of 2.5 billion mobile phones available in the market.

For mobile devices limited computational resources and battery power require an effective AAA mechanism. Extension of the GPRS/UMTS network could be potentially more expensive than deploying RADIUS authentication. Handover delay caused by terminal mobility is an issue which might favour GPRS/UMTS protocols.

Authentication in Converged Networks

From the data traffic's point of view, the speed of the network's internal routines does not play a primary role, in VoIP and other sensitive services, QoS is a key parameter. Delay reduction is currently the topic having intensive focus. Interconnecting mobile and IP networks for data traffic is not a challenge, since GPRS has an IP backbone, and UMTS is practically an IP network. Most of the problems begin when the network has to provide a certain QoS in order to support service with time-critical transmission, that is, voice or video calls. Delay in the wired network can be reduced by additional bandwidth to reduce collisions, alternate routing paths, or other methods. But in wireless environments, where terminals move around and connect to different networks, which may be "far" away in terms of network topology, switching the data transfer path is a challenging task.

In the IP world, Mobile IPv6 (MIPv6) was introduced to deal with mobility problems. This protocol works flawlessly for clients that are changing networks with quite low frequency and are connected to a wired network, where additional signalling and other overheads are not causing bandwidth problems. The convergence time of the routing in MIPv6 is quite slow. In a wireless environment every additional message exchange or signalling overhead has a direct influence on usability. When the terminal is moving fast between these distant networks, it may reach a speed, where the routing of MIPv6 can not keep the connection in a correct state. This means that while data traffic could be able to transmit with low average speed, QoS cannot be kept on an adequate level to support VoIP or VoD services, for example. To fight this problem, several micro-mobility (local area) protocols were developed to support fast moving nodes. Different approaches are used, for example in hierarchical MIPv6 with fast handover adds a *local home agent* into the network. Seamless handoff for MIPv6 tries to lower the handover time with instructing the nodes to change networks based on precalculated patterns.

Handoff between neighbouring IP networks could be done in reasonable time if they are cooperating, but with introducing converged network access, it is likely that the terminal moves between WLAN and UMTS networks and back in less than a minute. Session mobility, for example a VoIP call without interruption, cannot be achieved using current protocols. The key is to reduce

the handoff delay in interworking networks. To reduce delay inside the UMTS network, Zhang and Fujise (2006) show a possible improvement for the integrated authentication protocol. One cause of the long delay is getting an authentication vector (AV) if the Serving GPRS Support Node (SGSN) and Home Location Register (HLR) are far away. While roaming, the AV consumption is higher, if the terminal is moving frequently or it is producing significant traffic. The specifications allow a high blocking ratio of 20% for the UTMS network in case of requesting new AVs. The proposal claims to lower this rate to 2%. For each authentication instance, the SGSN consumes one AV from a first in first out (FIFO) storage.

A fundamental question is to allow the size of the AV vector to be customised based on the terminal's behaviour. In the default way, the SGSN executes a distribution of authentication vector (DAV) procedure if all AVs are consumed. Communication between the terminal and the SGSN cannot proceed until the reply is received from the HLR, inserting a potentially high delay into the system. This can lead to call failure, errors in location update, or unacceptable delays in services running on GPRS. The proposed protocol from Zhang and Fujise (2006) implies no change in case of the first authentication to the SGSN, but keeps track of the number of available AVs and sends out a new request when hitting a predefined level. This level can be customised for a network, to reduce or even remove the possible delay of waiting for an AV. The proposal also changes the basic behaviour, asking for new AVs when they are consumed. The original 3rd Generation Partnership Project (3GPP) system asks for them when a new event comes in and no AVs are available.

While reducing delay inside the GPRS network can reduce block probability in reaching network services, also handover functions in IP have to be revised in order to achieve reasonably fast mobility support. The basic challenge is that currently AAA and MIPv6 are operated independently. This means that the terminal has to negotiate with two different entities in order to get access to the new network.

In MobileIPv6, the terminal is allowed to keep connections to a home agent (HA) and a correspondent node (CN), even when the terminal changes point of attachment to that network. The terminal has two addresses, the home address (HoA) and the care-of address (CoA). The HoA is fixed, but the CoA is generated by the visited network. The mobile IP protocol binds these two addresses together. To ensure an optimal routing in the network, the terminals switch to *route optimalisation* mode after joining a new network. Then it executes a *return routability* procedure and a *binding update* (BU) to communicate to the correspondent node directly. The return routability procedure consists of several messages, which together induce a long delay.

The handover between networks implies even more steps and consumes more time: movement detection, address configuration, home BU, return routability procedure, and a BU to the correspondent node. The terminal cannot communicate with the CN before the end of the procedure.

Fast handover capability is a major research item in IETF for MIPv6, including the standards FMIPv6 and HMIPv6. In addition to these schemes, Ryu and Mun (2006) introduce an optimisation in order to lower the amount of signalling required and thus lower the handover delay between domains. In an IPv6 system, the IP mobility and AAA are handled by different entities. This architecture implies unnecessary delays. Several solutions are proposed to enable the mobile terminal to build a security association between the mobile node and the HA. This enables home BU during the AAA procedure. Route optimisation is a key topic in efficient mobility service provision. MIPv6 optimises the route with the use of the return routability procedure. In wireless environments, the generated signalling messages represent a considerable part of the whole overhead. Moving route optimisation into the AAA procedure can reduce the delay

by nearly 50% (Ryu & Mun, 2006). This was enabled by embedding the BU message into the AAA request message and so optimising the route while authenticating. This solution can solve MIPv6's basic problem of supporting different administrative domains and enable scalable large scale deployment.

Lee, Huh, Kim, and Lee (2006) define a novel communication approach to enable communication between the visited AAA servers for a faster and more efficient authentication mechanism. If a terminal visits a remote network, the AAA must be done by the remote system. IETF recommends integrating Diameter-based authentication into the MIPv6 system. But, when the user is using services on the remote network, the remote AAA has to keep a connection with the home AAA. The proposed new approach of Lee, Huh, et al. suggests enabling faster authentication when the terminal moves between subnets inside a domain by exchanging authentication data between visited AAA servers without the need of renegotiation with the HA. Connection to the HA is needed only after the authentication when the terminal executes a BU.

One other aspect is shown by Li, Ye, and Tian (2006) suggesting a topology-aware AAA overlay network. This additional network could help MIPv6 to make more effective decisions and to prepare for handovers and other changes in network configuration. Based on the AAA servers and connections between, a logical AAA backbone can be created, which can serve as administration backbone for the whole network. Signals delivered over this network are topologically aware, so the optimal route can easily be selected and signalling messages can be transmitted over the best route. In exchange to the build cost of this backbone network and some additional bandwidth consumed, MIPv6's security and performance can be enhanced.

As the route of the service access is secured, optimised and delay reduced, one basic problem still remains: how to ensure that the user is the one, the network thinks he/she is. Lee, Park, and Jun (2006) suggest using smart cards to support interdomain roaming. The use of the SIM might be preferable because of its widespread use and cryptographic capabilities (Kálmán & Noll, 2006). The problem of having multiple devices is also raised here, since a system based on the SIM as smart card will require SIM readers in every device—if a secure key exchange method between the devices is not in place.

Lee, Park, et al. (2006) suggest an entity called *roaming coordinator* ensuring seamless roaming services in the converged network. This additional node provides context management services and enables seamless movement between the third generation (3G) network and WLAN to enforce security in converged networks. In order to provide good user experience in a pervasive environment, additional intelligence needs to be added to the traditional AAA systems to ensure that the terminal selects the most appropriate connection method. This method has to be based on the context and has to be supported in all networks. A smart-card-based secure roaming management framework enables the transfer of the terminals context without renegotiating the whole security protocol set. When the terminal moves into a new network, the roaming coordinator, AAA servers, and proxies take charge of the authentication process. The coordinator, having received a roaming request, evaluates the available networks and chooses the best available one, and then triggers the context transfer between the corresponding AAA servers. When transferring whole user contexts, the system has to consider privacy requirements of the user's identity and his/her profile.

Anonymity and Identity

In pervasive environments, privacy is of key importance. With computers all around, gathering information about traffic, movements, service access, or physical environment, customer privacy

must be protected. Køien (in press) suggests a protocol, which is able to provide better protection for the user's privacy than the normal 3G network. Changes in the EAP-AKA protocol are suggested to use only random generated user authentication values. He defines three user contexts implying different key management and authentication schemes, like existing keys for short-term and fresh keys for medium-term access. Identity-based encryption is recommended to enable a flexible binding of the security context to protect the permanent subscriber identity and location data, which will only be discoverable by the home register. The main drawback of the suggested protocol is its higher computing requirements as compared to EAP-AKA, potentially limiting the applicability.

Security and Computing Power

A security protocol in a wireless environment should be fast and secure, and it has to be effective in terms of computing power and low data transfer need. In low power environments an authentication scheme with high security and low computing power is advised. One solution is based on hash functions and smart cards, allowing minimised network traffic and short message rounds used for authentication. Anonymity can be ensured through one-time passwords. While accepting the advantages of a system with smart cards, the use of extra hardware like a card reader is not advisable, due to compatibility issues and power requirements.

Software-based solutions have an advantage, as they only require computing power. Showing the importance of power consumption, a comparison of cryptographic protocols is presented by Lee, Hwang, and Liao (2006) and Potlapally, Ravi, Raghunathan, and Jha (2006) showing, that twice of the transmit energy of one bit is needed to run asymmetric encryption on that piece of information. Symmetric encryption needs, in contrast, around one half of the transmit energy. Most overhead is generated by session initialisation, meaning longer sessions induce lower overhead. There is a trade-off between security and session length. While negotiation overhead is getting lower with long sessions, security risks are getting higher.

This overhead can be lowered by special hardware or software solutions. Hardware needs some power and bigger silicon, while software requires a faster CPU. Hash functions have an energy requirement of around half a percent compared to PKI in generating session keys (Potlapally et al., 2006). Key exchange protocols using elliptic curve Diffie-Hellman (DH) come out much more energy efficient as compared to the same traditional strength DH. The DH calculations demonstrate the trade-off between power consumption and security. In order to have an efficient operation, the security protocol needs to have the possibility to adapt encryption to the needs of the current application. Authentication token generation can be problematic for devices with limited computing capabilities. Personal area networks (PAN) with multiple devices raise this problem by their very nature.

Security in Personal Area and Home Networks

Efficient authentication and certificate management ensures better usability of PAN devices. By using efficient security protocols, content-adaptive encryption, efficient key and certificate management, considerably longer battery operation is achievable. To enable key management in a PAN a personal certificate authority (CA) entity is suggested (Sur & Rhee, 2006; Sur, Yang, and Rhee, 2006), which will be responsible for generating certificates for all mobile devices within the PAN or home device domain (Popescu, Crispo, Tanenbaum, & Kamperman, 2004). Because of the context of use, the authentication protocol is focused on efficiency by reducing computational overheads for generating and verifying

signatures.

Main focus is on reducing PKI operations, which have been proven to be energy consuming. Instead, it proposes to use hash chains to lower communication and computational costs for checking certificates. Former research suggested hash trees in order to authenticate a large number of one-time signatures. By extending these with fractal-based traversal, it has been proven that these trees provide fast signature times with low signature sizes and storage requirements. The personal CA has to be a unique trusted third party in the PAN. It needs to have a screen, a simple input device, and has to always be available for the members of the network. A cell phone with the SIM is a perfect candidate to be a personal CA (Kálmán & Noll, 2006).

In home environments, basically two types of authentication are distinguished: (1) user authentication, and (2) device authentication (Jeong, 2006). Mutual authentication has to be used in order to prevent impersonation attacks (*identity theft).* This requires an SSO infrastructure, which can be for example Kerberos or RADIUS. A special aspect of resource access over the home LAN is that specific privileges are given to selected programs. The AAA server maintains an access control list to ensure correct privilege distribution.

To build the initial trust relationships some kind of user interaction is needed. The key should initially be distributed out-of-band, for example on an USB stick, or by using short range wireless technology, Near Field Communication (NFC), for example (Noll, Lopez Calvet, & Myksvoll, 2006). On home networks, where power consumption is not a problem, PKI may be used for negotiating session keys between devices, since key management in a PKI is simpler than in symmetric encryption and the delay caused by checking certificates and so forth will not be noticeable in this environment. Users authenticated towards the AAA infrastructure can access the resources seamlessly. Initial authentication is done with PKI. In case of mobile devices, also the home AAA can use previously calculated hash values in chain to lower computational cost. These AAA infrastructures can be connected to a providers AAA, for example to use in digital rights management (DRM) or home service access from a remote network (Popescu et al., 2004).

A user moving with his/her devices to the home raises another AAA challenge, the mobile nodes.

Mobile Nodes (Network Mobility)

Movement of whole networks like PANs or networks deployed on a vehicle, introduce a new level of AAA issues. In a conventional network a standard mobility support does not describe route optimisation. Several procedures are suggested to provide this functionality for mobile nodes, like Recursive Binding Update Plus (RBU+), where route optimisation is operated by MIPv6 instead of the network mobility (NEMO) architecture. This means, that every node has to execute its own BU with the corresponding HAs. To solve problems with pinball routing, it uses the binding cache in the CN. When a new BU message arrives, the RBU+ has to execute a recursive search, which leads to serious delays with a growing cache size. One potential route optimisation is presented by Jeong (2006).

A designated member of the network, called a mobile router is elected to deal with mobility tasks to reduce network overhead. The AAA protocol for this environment defines a handover scheme and tree-based accounting to enable efficient optimisation. They recommend using dual BU (DBU) procedure instead of the existing procedures like RBU+ as a solution for the reverse routing problem raised by mobility. DBU operates with additional information placed into the messages sent in a BU process. This is the CoA of the top level mobile router (TLMR). By monitoring the

messages, the CNs in the subnet can keep optimal route towards the TLMR.

Moving subnets are the subject of eavesdropping and possible leakage of the stored secrets. A secure AAA is proposed for network mobility over wireless links, which deals with these problems (Fathi et al., 2006). Secret leakage can be caused by malicious eavesdroppers, viruses, or Trojans. A possibility is to store the keys in tamper resistant modules, like smart cards, the SIM, or trusted hardware modules. Deploying additional modules can be problematic and expensive. Fathi et al. propose a protocol based on a short secret, which can be remembered by humans and used in a secure protocol called Leakage-resilient authenticated key exchange protocol (LR-AKE). This protocol is used for AAA to reduce NEMO latency under 300 ms in order to provide session continuity, for example in VoIP applications, which is important in keeping a good user experience. However, short passwords as proposed with LR-AKE are not advisable. If complex, they will be noted down by the user, and if weak, they are easy to guess.

As network mobility has considerable security issues, it may be not the way to go. Functionality of a mobile network might be achieved by using a dedicated device as a gateway of the PAN. Only this device will show up in the wireless network, and all traffic originating and arriving to the PAN will go through this device and its HA.

After these technical issues of authentication the next chapter will deal with authentication from the user viewpoint.

Customer Ergonomics

There is always a trade-off between user security and ease of use. If the system is prompting for a password for every transaction, it can assume with quite high probability, that the access is enabled just for the correct user. But, that is unacceptable for most of the users in private environments, where convenience is more valued than security. In corporate networks, policies are just enforced and users have to accept it. It would however be problematic if the credentials were only asked once at start-up or connecting to the network, since mobile devices are threatened by theft, loss, and other dangers by their nature of use.

Smart cards could be a solution to have a good trade-off between the usability and security. Since the user will have a token, which he/she has to care of, and exchange keys generated by it, at least it could be secured that the user who is accessing a specified service holds the authentication token. The mobile phone with the integrated smart card, the SIM, is a potential tool for this purpose. As indicated by Leu et al. (2006) the requirement of carrying a SIM reader or equipping all the equipment with SIM cards is neither convenient nor cost effective. The possibility of secure key exchange between user equipment shall be provided.

The cell phone can act as a key negotiator, with its tamper resistant cryptographic functions integrated into the SIM and then exchange the session keys with other terminals with the use of a short range wireless solution. Currently, most of the security problems, besides the user behaviour, are coming from security holes in the software. Having the capability to download new software over the air to the phone ensures the use of recent updates and eliminates this type of security threat (Kálmán & Noll, 2006). Compared to a security token, it may be better to use the phone, since the SIM card can be locked by the provider, so if the device gets lost, the authentication credentials can be withdrawn within short time.

OUTLOOK

Current research is focused on merging basic network functions to enable pervasive computing and network access. The result of these efforts is a converged infrastructure, which is able to handle

most of user needs in high quality. The problem of QoS control in wireless systems remains an open one, but experiences of VoIP and VoD services in wireless networks show the adaptability of the user to the current environment.

Mobility of packet data is still to be enhanced, with the challenge of reducing the handover delay. Remote access to home content is just beginning to be spread between early adopters. MIPv6 will address most of the issues sometime in the future, and with the promising extensions, the protocol will be able to handle sessions together with the AAA infrastructure without service interruption. Mobile networks will use WLAN as a high capacity data service, although upcoming solutions and MIPv6 extensions may be able to threaten their use inside dense populated areas, assuming global Wi-Fi roaming mechanisms are in place.

Efforts are being made towards an easy deployable home AAA infrastructure, which can later bear the tasks associated with inner (user management, remote access, user content DRM, purchased media DRM) and outer (authentication towards corporate, provider- or public-based AAA) authentication and access control.

Educating the user might be the biggest challenge, as mobile phone users represent the whole population, and not just the *educated* computer community. The enforcement of the use of smart cards is advisable, where the possible use of the mobile phone shall be investigated.

Now, we can experience the dawn of new social and community services over the Internet. This raises the problem of privacy protection as never before. AAA services must take care of user credentials, and even must ensure that data collected from different AAA providers cannot be merged. So, research in the area of one-way functions, blind signatures, and different PKI methods is recommended.

Finally, current market players also have to change their business plans. Research in the economical area has to point out new objectives to ensure a good working, open, and secure AAA infrastructure which can be used by every service provider while keeping information exchange on the required minimal level.

CONCLUSION

The biggest effort in AAA systems is on extending the capabilities of the existing solutions in telecommunication and in computer networks to an integrated network approach enabling seamless service access of mobile users.

While telecom solutions are usually more secure, user privacy is not a primary concern here. In computer networks AAA solutions are more open and flexible, while the widespread model of "web of trust" methods is not acceptable for commercial service exchange. Ongoing research indicates the potential for a common mobile/Internet authentication suite, potentially based on the EAP.

Interworking issues between mobile and wireless networks are the basis for detailed research on handover delay, multi-device roaming, mobile networks, security, ease-of-use, and anonymity of the user. This chapter provided an overview of the state of the art in authentication for mobile systems.

Extended AAA mechanisms are suggested for home and community networks, taking into account security and privacy of the users. These networks will keep a high amount of personal data, and thus need stronger privacy protection mechanisms. By using link layer encryption, smart cards, and secure key transfer methods the security and privacy protection can be greatly enhanced.

KEY TERMS

Authentication, Authorisation, and Accounting (AAA): AAA is a system that handles all users of the system to ensure appropriate right management and billing.

Converged Network: Converged network is a network carrying various types of traffic. Such a network is providing services to different terminals, which can access and exchange content regardless of the current networking technology they are using.

Diameter: Diameter is a proposed successor of RADIUS. It uses TCP as a transport method and provides the possibility to secure transmissions with TLS. It is not backward compatible with RADIUS.

Digital Rights Management (DRM): DRM is a software solution that gives the power for the content creator to keep control over use and redistribution of the material. Used mostly in connection with digital media provider companies, but in pervasive environments, users may also require a way to have a fine-grained security infrastructure in order to control access to own content.

Extensible Authentication Protocol (EAP): EAP, a flexible protocol family, which includes TLS, IKE protocols, and also the default authentication method of UMTS, EAP-AKA.

International Mobile Subscriber Identity (IMSI), Temporary-IMSI (TMSI): IMSI and TIMSI is the unique identity number used in UMTS to indentify a subscriber. The temporary one is renewed from time to time, and that is the only one that is used over the air interface.

Public Key Infrastructure (PKI): PKI is a service that acts as a trusted third party, manages public keys, and binds users to a public key.

Remote Authentication Dial in User Service (RADIUS): RADIUS is the de facto remote authentication standard over the Internet. It uses UDP as a transport method and is supported by software and hardware manufacturers. Privacy problems may arise when used on wireless links, since only the user password is protected by an MD5 hash.

Rivest-Shamir-Adleman (RSA): RSA is the de facto standard of public key encryption.

Smart Card: Smart card is a tamper resistant pocket sized card, which contains tamper resistant non-volatile storage and security logic.

Subscriber Identity Module (SIM): SIM is the smart card used in GSM and UMTS (as USIM) networks to identify the subscribers. It has integrated secure storage and cryptographic functions.

Chapter 7.17
Antecedents of Consumer Trust in B2C Electronic Commerce and Mobile Commerce

Dan J. Kim
University of Houston Clear Lake, USA

ABSTRACT

Despite the importance of trust in electronic commerce including mobile commerce, there is insufficient theory and model concerning the determinants of consumer trust in business-to-consumer electronic commerce. Thus, the purpose of this chapter is to (1) identify the major antecedents of a consumer's trust in electronic commerce and mobile commerce contexts through a large-scale literature review, (2) develop an integrative trust antecedent reference model summarizing the antecedents of consumer trust, and (3) discuss six categories of mobile applications as future trends of technologies and key issues related to consumer trust area in electronic commerce. In addition, to provide the validity of the proposed reference model, this chapter also proposes a research model derived from the reference model and discusses the constructs of the proposed model in detail. The chapter concludes that building trust is not simply an issue related to consumer-technology-buyer, but it is a complex issue that involves the interactions of key elements (buyer, seller, third-party, technology, and market environment) at least.

INTRODUCTION

Trust is important in exchange relations because it is a key element of social capital (Mayer, Davis, & Schoorman, 1995), and is related to firm performance, satisfaction, competitive advantage, and other favorable economic outcomes. Trust is identified as an important factor in several literatures, including marketing, behavioral science, and electronic commerce (Beatty, Mayer, Coleman, Reynolds, & Lee, 1996; Czepiel, 1990; Dirks & Ferrin, 2001, 2002; Hoffman, Novak, & Peralta, 1999; Jarvenpaa, Knoll, & Leidner, 1998; Kramer, 1999). According to the study conducted by Urban, Sultan, and Qualls (2000), consumers make electronic commerce (e-commerce) transac-

tion decisions based on trust. Therefore, lack of trust is one of the most frequently cited reasons for online consumers not engaging in exchange relationships with Internet vendors in e-commerce (Lee & Turban, 2001).

Mobile commerce (m-commerce) extends current e-commerce channels into more convenient "anytime, anyplace, and personalized" environment. As an emerging subset of e-commerce, m-commerce faces the same problems troubling e-commerce plus a few of its own due to the limitations of mobile technology (Siau & Shen, 2003). The limitations include restricted computation powers, memory, small screens, low-resolution displays, tiny multifunction keypads, battery life, unfriendly user interface for mobile devices, low bandwidth, unstable network connection, relatively high usage cost, and vulnerability of wireless data transmission. Therefore, building consumer trust in m-commerce is a particularly intimidating task due to the unique limitations of mobile technology.

Since consumer trust plays an essential role in online transactions, it is important to identify antecedents that affect a consumer's trust in e-commerce and m-commerce areas. Several researchers and professionals (Ba, Whinston, & Zhang, 1999; Beatty et al., 1996; Brynjolfsson & Smith, 2000; Czepiel, 1990; Hoffman et al., 1999; Jarvenpaa et al., 1998; Ratnasingham, 1998; Urban et al., 2000) have focused on various issues of trust in e-commerce. Even so, some scholars (Ratnasingham, 1998) have argued that the study of trust has been problematic for several reasons. These include problems with the definition of trust, confusion between trust and its antecedents, difficulties of observing and measuring trust, the tendency of particular disciplines to provide only partial descriptions of trust antecedents, and a lack of specificity about who the parties are (e.g., trustor and trustee) in research contexts in which trust is relevant (Mayer et al., 1995).

This chapter attempts to consider some of the above issues. First, we identify the major antecedents of a consumer's trust in electronic commerce and mobile commerce contexts through a large-scale literature review, second, develop an integrative trust antecedent reference model summarizing the antecedents of consumer trust, and finally discuss six categories of mobile applications as future trends of technologies and key issues related to consumer trust area in electronic commerce. In addition, this study also proposes a theoretical research model derived from the integrative trust antecedent reference model and discusses the constructs of the proposed model in detail to provide the validity of the reference model.

BACKGROUND: ANTECEDENTS OF TRUST

Trust Antecedents in E-Commerce Studies

Several researchers have tried to categorize antecedents or factors of a consumer trust (Barney & Hansen, 1994; Doney & Cannon, 1997; McKnight, Choudhury, & Kacmar, 2002b; Walczuch, Seelen, & Lundgren, 2001; Zucker, 1986). Zucker (1986) proposed three major ways to build trust: (1) process-based (e.g., reputation, experience), (2) characteristic-based (e.g., disposition), and (3) institutional-based (e.g., third-party certification). Mayer et al. (1995) defined trust as a behavioral intention based upon the expectations of another person. Based on this definition, they proposed a model of dyadic trust in organizational relationships that includes the characteristics of both the trustor and trustee that influence the formation of trust. The three characteristics included in the model, representing the perceived trustworthiness of the trustee, are benevolence, integrity, and ability. Doney and Cannon (1997) developed five distinct trust building processes in business relationships: (1) calculative process (trustor calculates the costs and/or rewards of

a target acting), (2) prediction process (trustor develops confidence that target's behavior can be predicted), (3) capability process (trustor assesses the target's ability to fulfill its promises), (4) intentionality process (trustor evaluates the target's motivations), and (5) transference process (trustor draws on proof sources from which trust is transferred to the target). They also categorized characteristics of supplier firm, salesperson, and the relationship into four types. Barney and Hansen (1994) and Lewis and Weigett (1985) defined the three levels of customer trust: (1) strong trust, (2) semistrong trust, (3) weak trust. Bhattacherjee (2002) proposed three key dimensions of trust: (1) trustee's ability, (2) benevolence, and (3) integrity, based on cross-disciplinary literature review on dimensions of trust. Recently, Kim, et al. (2005) identified four different entities of e-commerce market structure: consumer, seller, third party, and technology. Based on the four entities, they investigated the determinants of online trust and divide the determinants into six dimensions: consumer-behavioral, institutional, information content, product, transaction, and technology dimension.

Trust and National Culture

National culture also influences individual and organizational trust development processes (Doney, Cannon, & Mullen, 1998). Hofstede (1991, 1994) revealed the five cultural dimensions: individualism/collectivism, uncertainty avoidance, power distance, masculinity/femininity, and long/short term orientation on life. *Individualism* refers to the degree the society reinforces individual or collective achievement and interpersonal relationships; *uncertainty avoidance* refers to the degree of tolerance for uncertainty and ambiguity within the society—that is, unstructured situations; *power distance* refers to the degree of equality, or inequality, between people in the country's society; *masculinity* refers to the degree the society reinforces, or does not reinforce, the traditional masculine work role model of male achievement, control, and power; and *long/short term orientation of life* refers to the degree the society embraces, or does not embrace, long-term devotion to traditional, and forward thinking values (Hofstede, 1980, 1991, 1994).

Based on Hofetede's framework and using individualism/collectivism and power distance as independent variables, Strong and Weber (1998) examined the theory that trust is culturally determined in organization's contexts. They concluded that differences in trust exist globally between cultures. Griffith, Hu, and Ryans (2000) designated the United States and Canada as *Type I culture* with an "individualistic-small power distance-weak uncertainty avoidance" type of culture to contrast with *Type II culture* countries (Chile and Mexico) with "collectivistic-large power distance-strong uncertainty avoidance" characteristics. Although no significant difference in the strength of the trust-commitment relationship was found between Type I and Type II cultures, the study discovered that Type I cultures have a higher possibility of forming a trusting relationship with other Type I cultures, rather than with Type II cultures.

Several cultural studies (Mayer & Tan, 2002; Park & Jun, 2003; Png, Tan, & Wee, 2001; Soh, Kien, & Tay-Yap, 2000; Tan, Wei, Watson, Clapper, & McLean, 1998; Tan, Wei, Watson, & Walczuch, 1998) have shown that the dimensions of national culture affect the development, adoption, and impact of information communication technology (ICT) infrastructure and its applications in the field of information systems. However, only a handful of studies (Gefen & Heart, 2006; Jarvenpaa, Tractinsky, Saarinen, & Vitale, 1999; Lim, Leung, Sia, & Lee, 2004; Pavlou & Chai, 2002) to date have aimed at the effect of national culture on trust in computer-mediated electronic commerce transactions.

Jarvenpaa et al. (1999) used Hofstede's dimensions to compare Internet trust in individualistic and collectivistic cultures to conduct a study on a

cross-cultural validation of an Internet consumer trust model. They found that consumers in different cultures may have differing expectations of what makes a Web merchant trustworthy. Although no strong cultural effects were found regarding the antecedents of trust, their study ignited examinations of cultural differences in the antecedents of trust and the levels of trust in the context of e-commerce. Incorporating Hofstede's three cultural dimensions (i.e., individualism/collectivism, power distance, and long-term orientation) along with the theory of planned behavior, Pavlou and Chai (2002) conducted an empirical study to explain e-commerce adoption across cultures using data from consumers in the United States and China. The results of the study support the theory that cultural differences play a significant role in consumers' e-commerce adoption. Lim et al. (2004) identified two national culture dimensions (i.e., individualism-collectivism and uncertainty avoidance) and their interaction that influences Internet shopping rates across countries. They also found that trust mediates the relationship between cultural differences and Internet shopping adoption decisions. Cross-validating the scale of trust and its antecedents in both the U.S. and Israel, a cross cultural study by Gefen and Heart (2006) found that trust beliefs may be a relatively unvarying aspect of e-commerce but the effects of predictability and familiarity on trust beliefs may differ across national cultures.

Trust Antecedent in M-Commerce Studies

Mobile commerce is defined as business activities and processes related to an e-commerce transaction conducted through wireless communications networks that interface with mobile devices (Tarasewich, Nickerson, & Warkentin, 2002). Several studies (Anckar & D'Incau, 2002; Booz, 2000; Kannan, Chang, & Whinston, 2001; Malhotra & Segars, 2005; Siau, Lim, & Shen, 2001) identified the following distinctive mobile capabilities or values which drive one of the most promising innovative application services in near future: ubiquity, time-criticality, spontaneity/immediacy, constancy, convenience, personalization, location discovery, and so forth.

Ubiquity is the ability to allow mobile users to obtain information and conduct mobile transactions any place through Internet-enabled mobile devices. *Time-criticality* refers to the ability to access time-sensitive information immediately (Malhotra & Segars, 2005; Sadeh, 2002). A similar value to time-criticality, *spontaneity/immediacy* refers to the mobile capability for mobile users to get information and complete transactions in real-time. *Constancy* refers to the accessibility to network applications anytime and anywhere (Baldi & Thaung, 2002; Clarke, 2001; Malhotra & Segars, 2005). The constancy feature of mobile service provides the mobile value related to *convenience*. Since mobile devices are personal devices, they contain individual information as well as personal preferences. Thus, *personalization* refers to the ability to customize content and uses of mobile devices (Sadeh, 2002). Another mobile value is *location discovery* which allows mobile service providers to do location-based marketing and to deliver promotional offerings based on a user's current geographic position (Clarke, 2001). Since mobile devices are always on and carry user identity, the location of the mobile user can be tracked (Baldi & Thaung, 2002; Kannan et al., 2001; Malhotra & Segars, 2005).

Studies on trust in m-commerce are scarce due to the novelty of mobile commerce area. Siau and Shen (2003) developed a framework for building customer trust in mobile commerce. They identified two components of customer trust in mobile commerce: (1) mobile technology and (2) mobile vendor. Another study of trust in m-commerce conducted by Siau, Sheng, and Nah (2003) proposed a framework for trust in mobile commerce which outlines the variables influencing trust

Table 1. Selected studies of antecedents/processes of trust in e-commerce and m-commerce

Study topic and author(s)	Category of Antecedents	Sub categories or Set of Antecedents
Three levels of customer trust (Barney & Hansen, 1994; Lewis & Weigert, 1985)	Strong trust	Interactions, cognitive trust (e.g. the similarity), emotional trust
	Semi-strong trust	Rational-calculation-based trust (e.g. a company's reputation, the threat of punishment)
	Weak trust	Transferred trust (e.g. a well developed market, or word-of-mouth)
Three central modes of trust production (Zucker, 1986)	Process-based	Reputation, brands, gift-giving
	Characteristic-based	Family background, ethnicity, sex
	Institutional-based	Professional, firm associations, bureaucracy, banks, regulation
Three dimensional generic typology of trust (Mayer et al., 1995)	Ability	Competency, experience, institutional endorsements, knowledgeability
	Integrity	Fairness, fulfillment, loyalty, honestly, dependability, reliability,
	Benevolence	Concern, empathy, faith, receptivity
Five distinct trust building processes (Doney & Cannon, 1997)	Calculative process	Firm's reputation, size, willingness to customize, confidential information sharing, length of relationship with firm, length of relationship with salesperson
	Prediction process	Length of relationship with firm, salesperson likeability, salesperson similarity, frequent social contact with salesperson, frequent business contact with salesperson, length of relationship with salesperson
	Capability	Salesperson expertise, salesperson power
	Intentionality	Firm's willingness to customize, firm's confidential information sharing, salesperson likeability, salesperson similarity, frequent social contact with salesperson
	Transference	Firm's reputation, supplier firm size, trust of supplier firm, trust of salesperson
Trust of a supplier firm and salesperson (Doney & Cannon, 1997)	Characteristics of the supplier firm and firm relationship	Reputation, size, willingness to customize, confidential information sharing, length of relationship
	Characteristics of the salesperson and salesperson relationship	Expertise, power, likeability, similarity, frequent business contact, frequent social contact, length of relationship
A trust model for consumer internet shopping (Lee & Turban, 2001)	Trustworthiness of Internet merchant	Ability, integrity, benevolence
	Trustworthiness of Internet shopping medium	Technical competence, reliability, medium understanding
	Context factors	Effectiveness of third party certification, effectiveness of security infrastructure
	Other factors	Individual trust propensity, etc

Table 1. continued

Study topic and author(s)	Category of Antecedents	Sub categories or Set of Antecedents
An integrative typology of trust (McKnight, Choudhury, & Kacmar, 2002a)	Disposition to trust	Faith in humanity, trusting stance
	Institution-based trust	Situational normality, general competence, integrity, benevolence, structural assurance
	Trusting beliefs	Competence beliefs, benevolence beliefs, and integrity beliefs
	Trusting intentions	Willingness to depend, subjective probability of depending
Online trust: a stakeholder perspective (Shankar, Urban, & Sultan, 2002)	Website characteristics	Navigation, user friendliness, advice, error free
	User characteristics	Internet savvy, past Internet shopping behavior, feeling or control
	Other characteristics	Online medium, trustworthiness of firm, perceived size of firm
Psychological antecedents of consumer trust (Walczuch & Lundgren, 2004)	Personality-based	Extraversion, neuroticism, agreeableness, conscientiousness, openness to experience, propensity to trust
	Perception-based factors	Perceived reputation (e.g., word-of-mouth), perceived investment, perceived similarity, perceived normality, perceived control, perceived familiarity
	Experience-based	Experience over time, satisfaction, communication
	Knowledge-based factors	Information practices, security technology
	Attitude	Computers & the internet, Shopping
Process-oriented Multi-dimensional Trust Formation (Kim et al., 2005)	Consumer-Behavioral Dimension	Demographic factors, experience, familiarity, individual culture, traditions, privacy, etc.
	Institutional Dimension	Reputation, accreditation, authentication, approvals (e.g., advisors and guarantors), customer communities (e.g. eBay's feedback forum), legal requirements and authorities, etc.
	Information Content Dimension	Accuracy, currency, completeness, non-bias, credibility, website brand royalty, entertainment, usefulness, etc.
	Product Dimension	Durability, reliability, brand equity, quality, variety, customization, competitiveness and availability, etc.
	Transaction Dimension	Transparency, pricing and payment options, financial planning (complexity), sales-related service (refund policy, after-sales, etc.), promotions, delivery fulfillment, etc.
	Technology Dimension	Quality of media transmission, interface design and contents, security, reversibility, digital certificate, public-key cryptography (infrastructure), authenticity, integrity, confidentiality, non-repudiation, attributes of the system (benevolence, competency, predictability), etc.

Table 1. continued

Study topic and author(s)	Category of Antecedents	Sub categories or Set of Antecedents
A Trust-based Consumer Decision Making (Kim, Ferrin, & Rao, (Forthcomming))	Cognition (observation)-based	Privacy protection, security protection, system reliability, information quality, etc.
	Affect-based	Reputation, presence of third-party seals, referral, recommendation, buyers' feedback, word-of-mouth, etc.
	Experience-based	Familiarity, Internet experience, e-commerce experience, etc.
	Personality-oriented:	Disposition to trust, shopping style, etc.
Framework of trust-inducing features (Wang & Emurian, 2005)	Graphic design	Use of three-dimensional, dynamic, and half-screen size clipart, symmetric use of moderate pastel color of low brightness and cool tone, use of well-chosen, good-shot photographs
	Structure design	Easy-to-use navigation, accessible information, navigation reinforcement, application of page design techniques
	Content design	Brand-promoting information, disclosure of all aspects of the customer relationship, seals of approval or third-party certificate, use of comprehensive, correct, and current product information, use of a relevant domain name
	Social-cue design	Inclusion of representative photograph or video clip, use of synchronous communication media
Customer Trust in Mobile Commerce (Siau & Shen, 2003)	Mobile Technology	Initiate trust formation (feasibility) Continuous trust development (reliability, consistency)
	Mobile Vendor	Initiate trust formation (familiarity, reputation, information quality, third-party recognition, attractive reward, Continuous trust development (site quality, competence, integrity, privacy policy, security controls, open communication, community building, external auditing)
Trust in mobile commerce (Siau et al., 2003)	Vendor Characteristics	Reputation, brand reputation, availability, privacy policy
	Website Characteristics	Website design, ease of input and navigation, readability, accuracy, richness
	Technology of wireless services	Connection speed, coverage area, transaction data, authentication
	Technology of mobile services	User interface, ease of input and navigation, readability
	Other factors	Third-party regulation, word-of-mouth

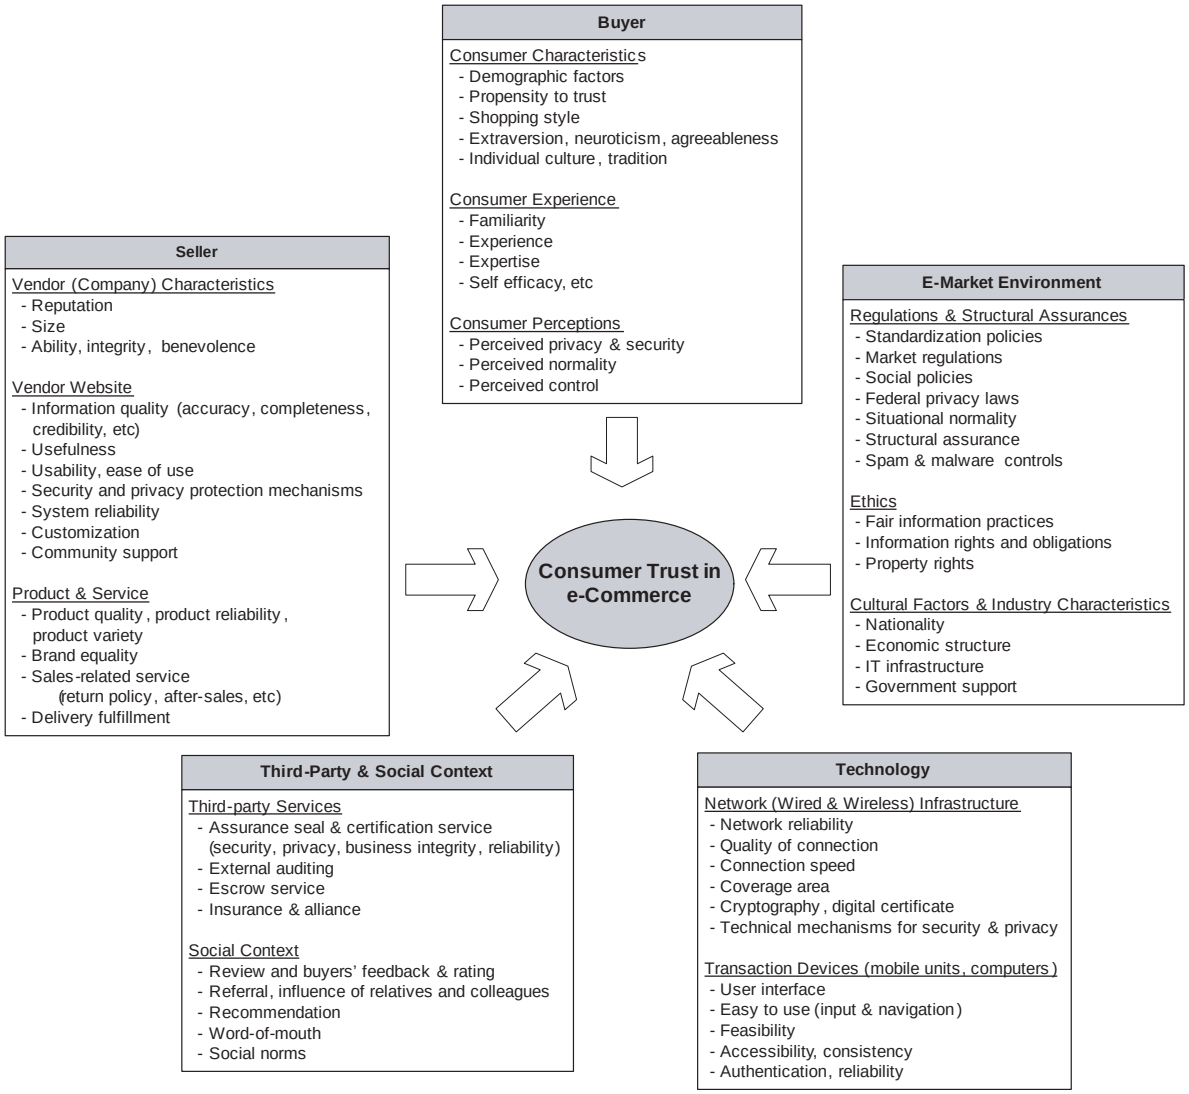
building in mobile commerce. Table 1 provides a summary of selected studies of antecedents/processes of trust in e-commerce.

AN INTEGRATIVE TRUST ANTECEDENT REFERENCE MODEL

The literature review depicts that various factors and entities influence the complex process

of engendering customer trust in e-commerce. A process- oriented, multi-dimensional trust formation model recently proposed by Kim et al. (2005) is well reflected in the actual online exchange process. The model consists of six dimensions of trust formation process and four different entities representing three ingredients of e-commerce transactions: trustor (buyer), trustee (seller), and environment (third party and technology). Although the model describes a holistic, multi-dimensional trust formation processes in a succinct manner the phenomena of trust formation in e-commerce transaction, it does not capture some environmental factors which influence trust

Figure 1. An integrative trust antecedent reference model



formation process such as cultural factors, national industry characteristics, market regulations, ethics, social context, and so forth. Therefore, along with the four entities of e-commerce markets suggested by Kim et al. (2005), I suggest five entities of e-commerce markets, to include buyer, seller, third-party and social context, technology, and market environment factors. Finally, after reclassifying and reorganizing determinants of trust in e-commerce and m-commerce areas, an integrative trust antecedent reference model (see Figure 1) is proposed in an effort to synthesize existing literature on enhancing consumer trust in e-commerce and m-commerce.

The integrative trust antecedent reference model shows that cultivating consumer trust involves the interactions of five entities at least. A *buyer* (i.e., trustor) has several subdimensional factors influencing his or her trust belief such as personal characteristics (e.g., propensity to trust, individual culture, demographic elements, and so on), individual experiences (e.g., familiarity, Web experience, self-efficacy, and so on), and individual perceptions (e.g., perceived privacy, perceived security, perceived normality, and so on). As a trustee, a seller also possesses several sub-dimensional factors.

Plank, Reid, and Pullins (1999) suggested a definition of trust toward multiple objects: salesperson, product, and company. According to their definition of trust, trust is a global belief on the part of the buyer that the salesperson, product, and company will fulfill their obligations as understood by the buyer. In e-commerce context, a seller could be multiple objects: Web site, product, and company. Thus, three subdimensional factors of an e-commerce *seller* (i.e., trustee) are vendor (company) characteristics (e.g., size, reputation, ability, integrity, and benevolence), Web site elements (e.g., information quality, usefulness, usability, system reliability, and so on), and product service factors (e.g., product quality, product reliability, product variety, after-sales service, delivery fulfillment, and so on). *Third-party and social context* are important entities in e-commerce transactions. Third parties are impartial organizations which include individual mechanisms delivering business confidence through an electronic transaction (Kim et al., 2005). Social contexts are about how the trustee is viewed by the people around. Third-party services include assurance seals and business certification services, escrow service, and so on. Examples of social context are buyers' reviews and feedbacks, referral, word-of-mouth, and so forth.

Technology is the major entity which makes a difference between e-commerce and traditional brick-and-mortar transactions because all e-commerce transactions take place primarily through wired and/or wireless network infrastructure. Network infrastructure and end-unit devices for electronic transactions are identified as subdimensional factors. Network reliability, connection quality, speed, and coverage area for wireless networks and user interface, easy to use, and reliability for mobile units are specifically important. Although Web site characteristics could be classified as technology subdimensions, they are arranged as a seller side component because a Web site is a seller's storefront. Finally, electronic market (e-market) environmental factors are another important entities influencing consumer trust in e-commerce. *E-market environment* has several subdimensional factors that include regulations and structural assurances (e.g., standardization policies, market regulations, structural assurances, and so forth), ethics (e.g., fair information practices, information and property rights, and so forth), and national culture and industry characteristics (e.g., nationality, economical structure, government support, and so forth).

FUTURE TRENDS AND KEY ISSUES RELATED TO CONSUMER TRUST

The exponential growth of wired broadband and wireless mobile networks will be expected

to drive the future development of e-commerce and provide new opportunities in m-commerce beyond e-commerce (Maamar, 2003). Enhancing the current e-commerce applications and business models in the market, there are six categories of mobile applications which utilizing the major unique features of mobile technology (i.e., anytime, anywhere, and personalized service).

The six categories of mobile applications are: (1) commerce transaction applications (e.g., mobile-shopping, micro-payments, bill payment, mobile banking, mobile trading, hotel reservation, and so forth), (2) communication applications (e.g., e-mail, char/SMS, multi-media SMS, mobile conferencing, broadcast, news flash, and so forth), (3) content delivery applications (e.g., information browsing, and directory service, interactive online gaming, music/video/game downloading, off-line games, flight schedules, weather information, and so forth),(4) community applications (finding buddies, mobile blog, dating, mobile community for referral and recommendation, and so forth), (5) customization (e.g., scheduling, location based services, personal dieting, information filtering, and so forth), (6) connection (e.g., mobile tracking, mobile inventory management, geographic positioning systems, and so forth).

While there are many potential advantages of the new "niche" technology, there are many problems and issues as well. Using the five entities of the integrative trust antecedent reference model, some key challenges are identified in e-commerce and m-commerce areas (Cavoukian & Gurski, 2002; Maamar, 2003; Yeo & Huang, 2003).

1. Issues related to trustors (buyers)

- User comfort level of e-commerce transaction
- Privacy and security issues because of tracking and location based service
- Restricted data collection and control of personal information
- Individual culture
- Experiences
- Self-efficacy
- Different perceptions

2. Issues related to trustees (sellers)

- Pricing issue
- Marketing issue
- Consumer retention issue
- Fulfillment issue
- Customization and advertising issues
- Web interface development issue for mobile devices
- Information quality
- Application development issue

3. Issues related to third-party and social context

- Effectiveness of third-party assurance services
- Fair feedback and rating systems
- Open community in e-commerce and m-commerce areas
- Social influence

4. Issues related to technology

- Wired and wireless technology infrastructure
  - Global standardizations of new technologies
  - The lack of network security
  - Slow bandwidth and efficient use of limited bandwidth
  - Strong encryption technology
  - Open source technology
  - Mobile payment issues
  - Virus and malware (spyware, adware, phishing, and hacking) control issues
- Transaction device technology
  - Small display screen

- Comfortable user interface
- Open platform for wireless devices
- Computational power—hardware and software

5. Issues related e-market environment

- Cultural issues
- Market regulations and social polices
- International and inter-states taxation
- Information and property rights
- Digital dividend
- Government regulation and support issues

Supplemental Study

In order to provide the validity of the proposed integrative trust antecedent reference model, a research model titled "Antecedents of Consumer Trust in B2C E-Commerce" is developed. The research constructs of the model are discussed in detail below.

A RESEARCH MODEL: ANTECEDENTS OF CONSUMER TRUST IN B2C E-COMMERCE

In traditional commerce, trust is affected by the characteristics of customers and the selling party (salespersons and company) and interactions between the two parties involved (Burt & Knez, 1996; Doney & Cannon, 1997; Shapiro, Sheppard, & Cheraskin, 1992; Swan, Bowers, & Richardson, 1999). It is also true in electronic commerce. Therefore, drawing from a part of the integrative trust antecedent model, three categories of antecedents influencing a consumer's trust toward an electronic commerce vendor are selected. The three categories and some trust antecedents from previous studies are summarized as follow:

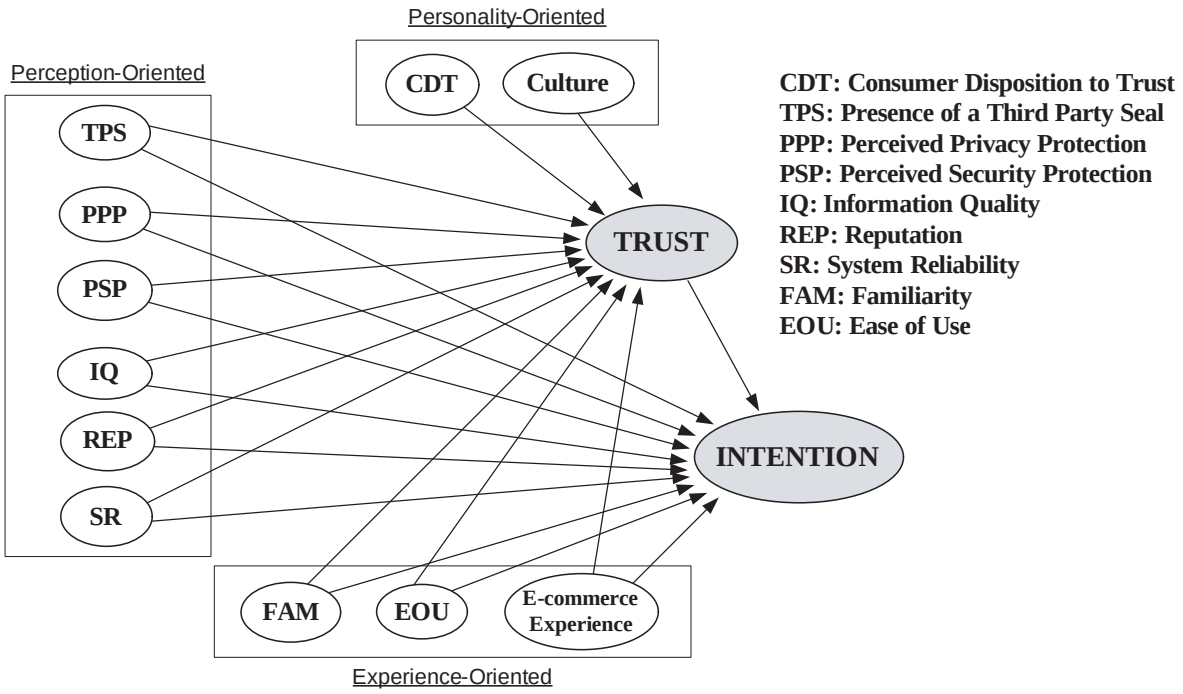
Consumer Side Antecedents

1. **Consumer personality-oriented:** Disposition to trust, shopping style, culture, and so forth
2. **Consumer experience-oriented:** Familiarity, ease of use, Internet experience, e-commerce experience, satisfaction, and so forth
3. **Consumer perception (observation) toward e-commerce vendor Web site:** Presence of third party assurance services, privacy protection, security protection, information quality, system reliability, and so forth.

The personality-oriented and experience-oriented antecedents are related to the characteristics of consumers, which are not easy to improve and manage by selling party perspectives. The perception-oriented antecedents are associated with salespersons (Web sites), company (brand image), and interactions (interface) between the two parties. In light of the difficulty of controlling all antecedents at the same time, this study proposes a research model mainly focusing on the perception-oriented antecedents with some personality and experience-oriented antecedents. Consumer disposition to trust, culture, familiarity with a selling party, ease-of-use, and Internet experience are included in the research model because some studies have shown evidence that they are strong antecedents of consumer trust (Gefen, 2000; Luhmann, 1979; Mayer et al., 1995; Rotter, 1971).

Even though we are interested in the antecedents of trust, there is concern that some antecedents of trust may have a direct effect on purchase intention (McKnight & Chervany, 2002; McKnight, Cummings, & Chervany, 1998). Therefore it is necessary at least to propose the direct effects from antecedents to a consumer's

Figure 2. Research model: Antecedents of consumer trust in B2C e-commerce



purchase intention. Figure 2 shows the research model including direct paths from antecedents to trust and intention, and the description of each construct and their relationships with trust are following.

An online *consumer trust (TRUST)* is defined as a consumer's subjective belief that the selling party or entity will fulfill its transactional obligations as the consumer understands them and as such transactions are enabled by electronic processes. Trust plays a vital role in almost any commerce involving monetary transactions (Gefen, 2002; Jarvenpaa et al., 1999; Urban et al., 2000). Internet business is much more based on the consumer's trust in the processes, in contrast to that of traditional business involving brick and mortar stores, where trust is based on face-to-face personal relationships. Peter Grabosky, in *The Nature of Trust Online*, supports the idea that the key to success in Internet business is the establishment of trusted processes (Grabosky, 2001). This fact mandates that Internet sellers create an environment in which a prospective consumer can be relaxed and confident about any prospective transactions. Thus we propose that a consumer trust positively influences a consumer's purchase intention of electronic transaction.

Intention to purchase (INTENTION) refers to the degree to which a consumer intends to purchase from a certain vendor through the Web. The theory of reasoned action (TRA) presumes that volitional behavior is determined by inten-

tions to act. Ajzen and Fishbein (1980) point out that behavior intention (intention to purchase, in this study) is a predictor of actual behavior (purchase), and there is a strong correlation between behavioral intentions and actual behavior (Sheppard, Hartwick, & Warshaw, 1988; Venkatesh & Davis, 2000). Consumer's purchase intention is one of the interesting variables for most e-shopping vendors.

Consumer disposition to trust (CDT) refers to a customer's personality traits that lead to generalized expectations about trustworthiness, which is a consumer-specific antecedent of trust. Since consumers have different developmental experiences, personality types, and cultural backgrounds, they differ in their inherent propensity to trust (Gefen, 2000). This tendency is not based upon experience with or knowledge of a specific trusted party, but it is the result of ongoing lifelong experience and socialization (Kahneman, 2003; McKnight et al., 1998; Rotter, 1971). If a consumer has a high tendency to trust others in general, this disposition is especially influential when customers have not had an extensive personal interaction with the selling parties (McKnight et al., 1998; Rotter, 1971). Consumer disposition to trust is an antecedent of trust, but it is not directly related to a consumer behavior intention.

Culture is defined by Hofstede (1994) as "the collective programming of mind which distinguishes one national group or category of people from another" (p. 5). Several studies (Mayer & Tan, 2002; Png et al., 2001; Soh et al., 2000; Tan, Wei, Watson, Clapper, et al., 1998; Tan, Wei, Watson, & Walczuch, 1998) have shown that the dimensions of national culture affect development, adoption, and impact of information communication technology (ICT) infrastructure and its applications in the field of information systems. Even though culture is a crucial aspect of trust, it has been overlooked by previous e-commerce studies. Only a handful of studies (Gefen & Heart, 2006; Jarvenpaa et al., 1999; Lim et al., 2004; Pavlou & Chai, 2002) to date have aimed at the effect of culture on trust in computer-mediated electronic commerce transactions. Since e-commerce transactions are sometimes required international interactions, understanding the cross-national aspects (i.e., culture) of trust building is essential (Gefen & Heart, 2006).

Familiarity with the online selling party (FAM) is a consumer experience-oriented antecedent of trust, which refers to the degree of consumer's acquaintance with the selling party. Familiarity would include enough knowledge to search for products and information and to order through the Web site's purchasing interface. Familiarity is a "precondition or prerequisite of trust" (Luhmann, 1979), which is an antecedent of trust because familiarity leads to an understanding of the current actions while trust deals with beliefs about the future actions of other entities (Gefen, 2000). For example, a consumer's familiarity based on previous good experience with salesperson (i.e., Web site), their services (i.e., searching products and information, and so forth) let the consumer create concrete ideas of what to expect for the future. As in electronic commerce in general, the more customers are familiar with such a selling party, the more their favorable expectations (trust) are likely to have been confirmed. It is thus hypothesized that more familiarity with a selling party should affect customer's trust on the selling entity.

Ease of use (EOU) of a Web site primarily deals with ease of navigation, ease of searching for products and information, and ease of understanding content. These trappings, along with the user's movement throughout the site, are as integral to the overall user experience as the transaction the user wants to execute. Like the importance of user interface design for software development, the Internet Web site interface design has received enormous research attention, since poorly designed sites have an adverse influence on consumer's shopping behavior (Lohse & Spiller, 1998). We posit that ease of use increases a consumer's trust toward the selling party.

The relationship between *e-commerce experience* and trust is found to be strongly associated (Gefen, 2000). In the traditional "brick-and-mortar" business environment, trust is mainly build through repeated successful transaction experiences (Lunn & Suman, 2002). It could be true at the "brick-and-click" or "pure-click" business environments. Thus, a positive e-commerce transaction experience is an antecedent of consumer trust, which is also directly related to a consumer purchase intention.

The presence of a third party seal (TPS) refers to the assurance of Internet vendors by third party certifying bodies (e.g. banks, accountants, consumer unions, and computer companies). Recently, a wide variety of third party seals were introduced to help create trust in electronic commerce. The purpose of seals is to provide assurance to consumers that a Web site discloses and follows its operating practices, that it handles payments in a secure and reliable way, that it has certain return policies, or that it complies with a privacy policy that says what it can and cannot do with the collected personal data (Castelfranchi & Tan, 2001; Koreto, 1997; Shapiro, 1987). An example of the third party involved in the trust of online transactions is TRUSTe, a non-profit, privacy seal program. The TRUSTe trust mark on Web sites informs buyers that the owners have openly agreed to disclose their information gathering and dissemination practices, and that their disclosure is backed by credible third-party assurance (Benassi, 1999). The basic argument of the presence of a seal and consumer trust is that the seals on a vendor's site issued from certificate authorities may assure consumers that the site is a reliable and credible place to do business. Therefore, when Internet customers see the seal on a given site, it creates extra trust in that selling site.

Perceived privacy protection (PPP) refers to a consumer's perception of the likelihood or intention of Internet vendors to protect consumers' personal information, which is collected during electronic transactions, from unauthorized use or the disclosure of confidential information. At the time of a transaction, the online seller collects the names, e-mail addresses, phone numbers, and home addresses of buyers. Some sellers pass the information on to telemarketers. For many online consumers, loss of privacy is a main concern. In a recent survey, 92% of survey respondents indicated that they do not have confidence that companies will keep their information private, even when the companies promise to do so (Light, 2001). These increasing consumer concerns are forcing sellers to take privacy protection measures to increase their trustworthiness and thereby to encourage online transactions. Consumers often perceive that one of the obligations of a seller is that the seller should not share or distribute the buyer's private information. Since this is a perceived obligation of the seller under the contract, buyers will be more likely to trust a seller who they believe will protect personal privacy.

Perceived security protection (PSP) refers to a consumer's perception that the Internet vendor will fulfill security requirements, such as authentication, integrity, encryption, and nonrepudiation. How a consumer perceives security protection when making online transactions depends on how clearly she or he understands the level of security measures implemented by the seller (Friedman, 2000). When an ordinary consumer finds security features (e.g., a security policy, a security disclaim, encryption, a safe shopping guarantee, SSL technology, and so forth) in the seller's Web site, he or she can recognize the seller's intention to fulfill the security requirements during the online transactions. This positively affects the trustworthiness of the seller as far as security is concerned, and, thus the consumer feels comfortable completing the transaction.

Even the definition of information is a complex concept and quality of information may be interpreted in multiple ways (e.g., accuracy, relevance, timelines, reliability, sufficiency, and so forth), *information quality (IQ)* refers to a consumer's general perception of the accuracy and

completeness of Web site information as it relates to products and transactions. It is well recognized that information on the Internet varies a great deal in quality, ranging from highly accurate and reliable, to inaccurate and unreliable, to intentionally misleading. As well, it is often very difficult to tell how frequently the information in Web sites is updated and whether the facts have been checked or not (Pack, 1999). Thus, potential purchasers on the Internet are likely to be particularly attentive to the quality of information on a Web site because the quality of information should help them make good purchasing decisions. To the extent that consumers perceive that a Web site presents quality information, they are more likely to have confidence that the vendor is reliable, and therefore will perceive the vendor as trustworthy. As buyers perceive that the Web site presents quality information, they will perceive that the seller is interested in maintaining the accuracy and currency of information, and, therefore, will be more inclined to fulfill its obligations and be in a better position to fulfill its obligations.

Reputation of selling party (REP) refers to the degree of esteem in which public consumers hold a selling party. Positive reputation has been considered a key factor for creating trust in organizations by marketing (Doney & Cannon, 1997; Ganesan, 1994) and electronic commerce (Jarvenpaa et al., 1999). Reputation building is a social process dependent on the past interactions (e.g., whether that business partner was honest before) between consumers and selling party (Zacharia & Maes, 2000).

A positive reputation provides information that the selling party has honored or met its obligations toward consumers in the past, or, in the case of a negative reputation, that it has failed to honor or meet its obligations. Based on this reputation information, a consumer may infer that the selling party is likely to continue in its behavior. In the case of a positive reputation, one is likely to infer that the company will honor its specific obligations to oneself, and therefore conclude that the selling party is trustworthy. By the same reasoning, an individual may conclude that the selling party will not honor its specific obligations, and hence conclude that it is untrustworthy. A positive reputation generates a feeling of trust and willingness to engage in the transaction.

System reliability (SR) refers to the consumer's perception that a Web vendor system is always available and fast and makes few errors at all levels, that the transaction record is correct, and that services will not fail during a transaction. As a technical dimension to support electronic commerce, system reliability considers key factors such as the following: access is always fast and available, very few errors are allowed at all levels, the transaction record is correct and remains correct, and services do not fail during a transaction. For example, a site may not totally fail but site access may become so slow that sales may be lost. This is not a hard failure, but may be classified as a soft failure. Even under soft failure, consumer's trust regarding that site may be negatively affected.

CONCLUSION

Wired and wireless technologies bring together a broad range of evolution or revolution influencing today's business life. Many studies have indicated that trust is critical for the growth and success of e-commerce. Since we already have observed the negative consequences of a lack of confidence and trust on the growth of e-commerce, trust issues including security and privacy concerns must be addressed in the early stage of mobile commerce development. In the electronic business world, building trust is not simply an issue related to consumer-technology-buyer, but it is a complex issue that involves the key interactions of five elements (i.e., buyer, seller, third-party, technology, and market environment) at least.

Chapter 7.18
Trust Models for Ubiquitous Mobile Systems

Mike Burmester
Florida State University, USA

ABSTRACT

This chapter introduces the notion of trust as a means to establish security in ubiquitous mobile network systems. It argues that trust is an essential requirement to enable security in any open network environments, and in particular, in wireless ad hoc environments where there is no network topology. In such environments, communication can only be achieved via routes that have to be trusted. In general it may be hard, or even impossible, to establish, recall, and maintain trust relationships. It is therefore important to understand the limitations of such environments and to find mechanisms that may support trust either explicitly or implicitly. We consider several models that can be used to enable trust in such environments, based on economic, insurance, information flow, and evolutionary paradigms.

INTRODUCTION

Wireless mobile networks are a paradigm for mobile communication in which wireless nodes do not rely on any underlying static network infrastructure for services such as packet routing, name resolution, node authentication, or distribution of computational resources. The communication medium is broadcast. Nodes in range communicate in a direct peer-to-peer manner, while nodes out of range establish routing paths dynamically through other nodes where possible. The recent rise in popularity of mobile wireless devices and technological developments have made possible the deployment of wireless mobile networks for several applications. Examples include emergency deployments, disaster recovery, search-and-rescue missions, sensor networks, military (battlefield) operations, and more recently e-commerce. Since the network nodes are mobile, the network topology frequently changes: Communication links are

established or broken as nodes move in and out of range, and the network may get partitioned with the connectivity restricted to the partitions. As a result it may be much harder (or even impossible) to establish trust associations.

The trend in trust management is to view trust implicitly through delegation of privilege via certificates. Certificates can be chain-linked (linking à priori trust relationships) and used to propagate and distribute trust over insecure media, without the danger of being manipulated.

In this chapter, we give an overview of several models that can be used to support trust in mobile networks, based on economic, insurance, information flow, and evolutionary paradigms.

TRUST IN WIRELESS MOBILE NETWORKS

We consider environments in which there may be no fixed underlying network infrastructure, such as static base stations, for services such as packet routing, name resolution, node authentication, or the distribution of computational resources. In such environments, recalling and maintaining trust relationships is particularly challenging. Mobile systems share many of the complexities of fixed infrastructure systems. For example, nodes may have (Burmester & Yasinsac, 2004):

1. No prior relationship or common peers
2. No shared proprietary software
3. Different transmission, memory and processing capabilities
4. Different mobility characteristics
5. Different lifetime properties

Defining Trust

Trust is a highly abstract concept and it is unlikely that any simple definition can comprehensively capture all the subtleties of its essence. Informally we may define trust as a behavioral expectation of one party toward another. There are two perspectives in this definition, one in which a party *awards* trust to another (Alice trusts that Bob's public key is PK(Bob)), the other in which a party *gains* trust from another (Alice has convinced Bob that her public key is PK(Alice)).

Representing Trust: Certificates vs. Tokens

In any stateful trust model, trust must be represented by some type of persistent structure. Certificates are the de facto standard for representing trust relationships that are protected by cryptography. Certificates are portable and bind a cryptographic key (a digital string) to an entity, thus guaranteeing the authenticity of actions performed by that entity. Trust tokens are another structure that can be used to represent trust in a more direct way, analogous to the relation between checks and cash. Checks guarantee payment by tying the purchaser to some identifying information (like a certificate), while the value of cash is self-contained.

Trusted Third Parties

A trusted third party (TTP) can facilitate significantly the establishment of trust in mobile environments. For example, if two parties *A* and *B* who do not know each other have a trust relationship with a third party *T*, then *T* can be an effective intermediary for transactions between *A* and *B*. However in general, wireless mobile networks may not have any infrastructure components that are typically used as TTPs. In such cases, TTPs have to be elected or assigned by using an appropriate election or assignment protocol.

MODELS FOR TRUST IN WIRELESS MOBILE ENVIRONMENTS

Trust is *context* driven (e.g., A may trust *B* for event *x*, but not for event *y*). Trust may also be qualitative rather than Boolean (e.g., A may trust *B* more than *C*). Finally, trust relationships may be fixed or dynamic. Dynamic trust relationships are most appropriate for the requirements of mobile environments.

Models for dynamic trust must support establishing, changing, and permanently revoking trust between parties, and must also consider network environment issues. In the following sections we shall consider several models that can be used to support trust in wireless mobile networks (Burmester & Yasinsac, 2004).

A Mathematical Model for Trust: The Trust Graph

We may represent the trust in a network by a directed graph, the *trust graph*, whose links (A, B) correspond to the explicit trust that node *A* has in node *B*. Such links are indicated by $A \Rightarrow B$. The implicit trust that a node *X* has in another node *Y* is then represented by a trust path from *X* to *Y* :

$$X = X_0 \Rightarrow X_1 \Rightarrow X_2 \ldots \Rightarrow X_{n-1} \Rightarrow X_n = Y,$$

in which node *X* awards trust to node *Y* via a chain of intermediary nodes X_i, where X_i awards trust explicitly to the next node X_{i+1} in the chain. Such trust may be supported by certificates. For example, node X_i may certify (digitally sign) that key $PK(X_{i+1})$ is the public key of node X_{i+1}. A chain of certificates can then be used for implicit certification. This is essentially the trust model for the X509 PKI authentication infrastructure (ISO/IEC 9594-8, 1995). This particular trust infrastructure is hierarchical, with trust centrally managed (by a Root Certifying Authority, which is also a single-point-of-failure). PGP (Zimmermann, 1995) uses a web of trust in which trust is distributed "horizontally." See Burmester and Desmedt (2004) for a discussion on security issues of hierarchical vs. horizontal infrastructures.

In the basic trust graph model, trust is transitive but not necessarily reflexive. That is, even though *A* may award trust to *B*, *B* may not award trust to *A*. However, trust is binary: $A \Rightarrow B$ is either true or false. Therefore, there is a natural trust metric which is one unit for explicit trust. This is also the trust of a trust path that links A to *B*. In this model the trust that *A* awards to *B* is represented by the trust flow of *A*, *B*, which is also the connectivity of *A*, *B*. This model is appropriate for Byzantine faults environments in which the adversary can corrupt a bounded number of nodes, and trust has to be based on à priori beliefs, and not statistical profiles.

A Model Based on a Weighted Trust Graph

There are several other ways to define trust. For a stochastic model based on statistical profiling, we can define the explicit trust that *A* awards to (or has in) *B* as the probability with which *A* trusts *B*, based on, say, a history of good behavior by *B*. See the next section for a discussion on trust based on observed behavior. In this model we have a weighted trust graph in which each link $A \Rightarrow B$ is assigned a weight $t \in [0,1]$, which corresponds to the (explicit) trust that *A* has in *B*. If $\pi 1, \pi 2, \ldots, \pi n$ are (all) the trust paths that link *X* to *Y*, then the implicit trust that *X* has in *Y* can be computed as follows (Burmester, Douligeris, & Kotzanikolaou, 2006):

$$\Sigma_{\pi_i} \prod_{t \in \pi_i} t \; - \; \Sigma_{\pi_i \neq \pi_j} \prod_{t \in \pi_i \cup \pi_j} t + \ldots + (-1)^{n+1} \prod_{t \in \pi_1 \cup \ldots \cup \pi_n} t$$

For example, if there are three disjoint paths from *X* to *Y* with trust weights (t_1,t_2), (t_3,t_4), (t_5,t_6)

respectively, then the implicit trust that *X* has in *Y* is:

$$t_1t_2 + t_3t_4 + t_5t_6 - t_1t_2t_3t_4 - t_3t_4t_5t_6 + t_1t_2t_3t_4t_5t_6 .$$

One can extend this model to allow for a dynamic model in which trust is regularly updated, by using a trust-ranking algorithm similar to that used by Web search engines (e.g., PageRank of Google [PageRank, 1997]).

A Model Based on Observed Behavior

A natural way to acquire trust is through direct observation. At its most fundamental level, trust is a decision, subject to emotions and intuition. In this scenario, personal observation is preferred to second-hand methods because of hints, nuances, and feelings that can be garnered. Though feelings are not considered in computer trust systems, there are advantages in doing so. Not all actions give insight into trustworthiness. The challenge is to translate such observations into trust decisions.

A challenge to trust management systems is that trust relationships need to be constructed *before* they are exercised. There are four basic categories of activity that affect trust (Burmester & Yasinsac, 2004):

1. Trust earning actions over time
2. Trust earning actions by count
3. Trust earning actions by magnitude
4. Trust defeating actions

Combinations of the first three allow cautious parties to grant trust frugally. Untrustworthy parties will be challenged to conduct a sufficient quality and quantity of trustworthy actions to gain trust. On the other hand, observation of malicious, reckless, or otherwise unpredictable actions allows reduction or revocation of awarded trust.

A Model Based on the Internet Paradigm

The economic opportunity provided by the Internet has driven rapid establishment of many new trust models. Companies like eBay, Amazon, and Priceline conduct all of their business with customers with whom they have no personal relationship or interaction with. Early work on supporting trust models was from a business perspective (Pardue, 2000). Some work has been done more recently to identify models that support cryptographic protection of trust relationships. In Zhong, Chen, and Yang (2003), a token-based trust model is proposed in which parties accumulate trust, transaction-by-transaction. For trust-earning actions, parties are awarded tokens that can be retained and later presented to reflect the earned trust. If no additional trust information is gathered, tokens may be revoked or restricted. This novel approach to trust acquisition has many properties that are well-suited to mobile networks. Tokens can be created, awarded, and verified via distributed algorithms, allowing a global aspect to trust decisions. Conversely, if the trust algorithm is well understood, parties that desire to perform malicious acts can become sleepers, behaving perfectly until they acquire sufficient trust to allow successful mischief.

Transitive Trust

Transitivity is in many respects a natural attribute of trust and is encountered in some of the most used security systems (Steiner, Neuman, & Schiller, 1988; Zhong et al., 2003). With transitive trust models, trust must be explicit (i.e., parties must know that if they place their trust in one party, then they are automatically placing their trust in other potentially unknown parties as well). For example, if Alice trusts Bob and Bob trusts Carol, then Alice must trust Carol. Such models make

strong trust requirements on intermediaries or third parties. Unfortunately, there are inherent dangers in models with transitive trust (Christianson & Harbison, 1997).

A Model Based on Trust Classes

Trust may be considered as a two party relationship or there may be environments where nodes take on *class* trust properties, as in the Bell-LaPadula model (Bell & LaPadula, 1973). One way to form trust management functionality is to establish a trust promotion system. For example, consider a simple trust environment in which nodes can be categorized into the following five trust classes (from most to least trusted): *Highly trusted, Trusted, Unknown, Untrusted, Highly untrusted.* We can then establish a set of rules for promoting and demoting members between groups. These rules will be identified by the desired promotion rule. If promotion is not allowed for highly untrusted parties, then no rule is established for this class. The model may be further extended by designating a subset of the class of most trusted nodes as *promoters.* Promoters are responsible for determining if requestors meet the promotion requirements as designated in the promotion rules and in taking action to effect the justified group movement. While promotion is requested directly, demotion must be requested second hand.

A Financial Model

Trust can also be *contractually* secured. In this case, a Trusted Third Party guarantees the trust. As with secured loans, if the guaranteed trust is violated, the guarantor will deliver the promised security to the offended party. Secured trust is a pure form of transitive trust. It is unique in that its trust graph tree has height one and trust is secured by a contractually agreed value. As with secured financial interactions, the secured value may take many forms, including the following: a *co-signed trust certificate, a trust insurance policy, a trust bond and a trust collateral.*

These correspond to security mechanisms of the financial world. For a co-signed certificate, the co-signing party would have credentials that exceed those of the target and would assume liability for any adverse events that occur as a result of a trust breech. The insurance policy model is similar, except that the security is provided by a well recognized organization that promises benefits to the executor of the policy. The last two models are similar in that the trust target provides the value that secures the trust. The value can be monetary, property, or other items or issues of suitable value to the source.

CONCLUSION

We have considered several models that can be used to manage the trust in mobile wireless environments. These models are highly distributed and address many of the trust management properties that are needed to secure mobile environments.

Chapter 7.19
Quality of Service in Mobile Ad Hoc Networks

Winston K. G. Seah

INTRODUCTION

Mobile ad hoc networks (MANETs) form a class of multi-hop wireless networks that can easily be deployed on-the-fly. These are autonomous systems that do not require existing infrastructure; each participating node in the network acts as a host as well as a packet-forwarding router. In addition to the difficulties experienced by conventional wireless networks, such as wireless interference, noise and obstructions from the environment, hidden/exposed terminal problems, and limited physical security, MANETs are also characterized by dynamically changing network topology and energy constraints.

While MANETs were originally designed for use in disaster emergencies and defense-related applications, there are a number of potential applications of ad hoc networking that are commercially viable. Some of these applications include multimedia teleconferencing, home networking, embedded computing, electronic classrooms, sensor networks, and even underwater surveillance.

The increased interest in MANETs in recent years has led to intensive research efforts which aim to provide quality of service (QoS) support over such infrastructure-less networks with unpredictable behaviour. Generally, the QoS of any particular network can be defined as its ability to deliver a guaranteed level of service to its users and/or applications. These service requirements often include performance metrics such as throughput, delay, jitter (delay variance), bandwidth, reliability, etc., and different applications may have varying service requirements. The performance metrics can be computed in three different ways: (i) concave (e.g., minimum bandwidth along each link); (ii) additive (e.g., total delay along a path); and (iii) multiplicative (e.g., packet delivery ratio along the entire route).

While much effort has been invested in providing QoS in the Internet during the last decade, leading to the development of Internet QoS models such as integrated services (IntServ) (Braden, 1994) and differentiated services (DiffServ) (Blake, 1998), the Internet is currently able to provide only best effort (BE) QoS to its applications. In such networks with predictable resource availability, providing QoS beyond best effort is already a challenge. It is therefore even more difficult to achieve a BE-QoS similar to the Internet in networks like MANETs, which experience a vast spectrum of network dynamics (such as node mobility and link instability). In addition, QoS is only plausible in a MANET if it is combinatorially stable, i.e., topological changes occur slow enough to allow the successful propagation of updates throughout the network. As such, it is often debatable as to whether QoS in MANETs is just a myth or can become a reality.

BACKGROUND

The successful deployment of QoS in MANETs is a challenging task because it depends on the inherent properties of the network: node mobility, variable (and limited) capacity links, as well as rapid deployment and configuration. These factors lead to a network with dynamic topology, complex route maintenance, and unpredictable resource availability. It is difficult to implement existing Internet QoS models on MANETs because these mechanisms cannot be efficiently deployed in a network with unpredictable and varying resource availability.

A very critical assumption is made by most, if not all, MANET protocols, which is the willingness of all nodes to participate in the forwarding of packets for other nodes in the network. QoS provisioning in MANETs is therefore a multi-faceted problem which requires the cooperation and integration of the various network layers, which will be discussed in the following subsections.

1. **Physical layer:** The physical layer of any network is used to provide the means to transmit sequences of bits between any pair of nodes joined by a communication channel. In MANETs, the radio channel is used to provide wireless communication between the nodes in the network. In contrast with wired networks, which offer predictability and stability, radio channels are affected by the effects of reflection, diffraction, and scattering from environmental interferences. As such, the wireless medium is often unreliable and subject to drastic variations in signal strength, leading to higher bit rate errors (BER) at the physical layer. Due to node mobility and the erratic behaviour of the wireless channel, the link characteristics of the network experience rapid changes. The effects of large-scale/small-scale fading, shadowing, and path loss may also cause these communication links to be asymmetric. Hence, the physical mechanisms must be able to adapt to the changes and deterioration in link quality during data transmission and change their modulation scheme accordingly to suit the current channel state.
2. **Medium access control (MAC) layer:** The wireless channel in MANETs is a broadcast and shared medium where nodes are often subject to interference from neighbouring nodes within the transmission and interference ranges, and often suffer from hidden/exposed terminal problems. Although many solutions have been proposed to alleviate the exposed/hidden terminal problems, these problems are more pronounced in autonomous, mobile environments; wireless channels are also subjected to errors which are bursty, location-, and mobility-dependent. The MAC layer for MANETs has to cope with these problems, as well as the challenges of minimizing collisions, allowing fair ac-

cess, and providing reliable data transport under rapidly changing conditions.

3. **Network layer:** The main challenge of the network layer in a MANET is to determine and distribute routing information efficiently under changing link conditions and scarce bandwidth. In addition, it must be able to interoperate with traditional non-ad-hoc networks, such as the Internet and other wireless networks. Existing MANET routing protocols can be broadly grouped under reactive, proactive, or hybrid routing protocols. If the network topology changes too rapidly due to high node mobility, topology updates in these routing protocols may not propagate fast enough to form stable routes. Most of these protocols are also based on shortest-path algorithms, which may not result in routes that have the required resources to meet the requirements of the applications they support. An ideal QoS routing protocol should be able to adaptively select its paths based on the currently available resources to provide the service desired by a particular application.
4. **Transport layer:** In the wired Internet, there are two transport-layer protocols available to the application layer: (i) UDP (user datagram protocol), which provides unreliable and connectionless service; and (ii) TCP (transmission control protocol), which provides reliable, connection-oriented service to the invoking applications. Besides having to provide logical communication between applications running on mobile hosts, the transport layer in a MANET also needs to handle delay and packet loss arising from conditions unlike wired networks. In TCP (which is used for most applications in the Internet), packet losses are due to congestion, and a back-off mechanism will then be invoked to reduce the sending rate of data packets from the source nodes. However, in wireless media, packet loss is mainly due to transmission errors and current flow control or congestion control techniques that might lead to lowered throughput. There are also large variations in delay when the route changes, which is not addressed by the design of the existing transport layer protocols.
5. **Application layer:** According to Kurose (2003), the service requirements of an application can be broadly classified into data loss, bandwidth, and delay (which can be average end-to-end delay or delay variance). Loss-tolerant applications include multimedia applications such as real-time audio and video, which are not adversely affected by occasional loss of data but are highly sensitive to bandwidth and delay. Other applications involving sensitive data integrity, such as electronic mail and banking transactions, require fully reliable data transfer, but may not be time-sensitive and can work with elastic bandwidth. To cater for QoS in MANETs, the application layer must be designed to handle frequent disconnections and reconnections caused by the dynamic network topology and varying signal quality of the wireless channel. It must also be able to adapt to widely varying delay and packet losses.

DEVELOPMENTS IN MANET QoS

From the discussion above, we can see that hard QoS in MANET is unlikely to be plausible because of the inherent dynamic nature of a mobile ad hoc environment. It may be more feasible to implement soft QoS, whereby there may exist transient periods of time when the network is allowed to fall short of QoS requirements, up to a permitted threshold. The level of QoS satisfaction is thus quantified by the fraction of total disruption. We can then make QoS a function of the available network resources, and applications should ideally adapt to the quality of the network.

There have been many research efforts to provide QoS support in MANETs. Wu (2001) categorizes these efforts into QoS models, QoS resource reservation signaling, QoS routing, and QoS MAC, and provides an overview of how these different components can work together to deliver QoS in MANETs. In the following subsections, we describe some of the recent developments by the networking community and evaluate their effectiveness in providing QoS in MANET scenarios.

MANET QoS Models

A QoS model defines the methodology and architecture for providing certain types of service in the network, but it does not define the specific protocols, algorithms, or implementations to realize QoS provisioning. An ideal MANET QoS model should take into account the various network dynamics and constraints experienced by the nodes, such as mobility and varying link characteristics, and ensure that the architecture is able to provide some form of QoS guarantees.

Xiao (2000) proposes a flexible QoS model for MANETs (FQMM), which adopts a hybrid provisioning policy by dividing traffic into different classes and applying different QoS handling mechanisms to these classes. IntServ-like per flow provisioning is used for the class with highest priority, while DiffServ-like per aggregate is used for the remaining classes. FQMM is suited for relatively small-sized networks of up to 50 nodes; as in DiffServ, a node can be an ingress node (source node), egress node (destination node), or an interior node which forwards packets for other nodes. Depending on the topology and traffic pattern, the role that each node undertakes changes dynamically.

An integrated MANET QoS (iMAQ) model proposed by Chen (2002) defines a cross-layer architecture for multimedia traffic. The framework is comprised of: (i) an application layer that generates multimedia data, (ii) a middleware layer that uses location information from the network layer to predict network partitioning, and (iii) a network layer that uses predictive location-based routing to select a path to the future location of a node. Information is exchanged among the data advertising, lookup, replication services, and the QoS routing protocol in the form of system profiles, and this helps to achieve a higher quality in data access as well as enhances communications between the respective layers.

A two-layer QoS (2LQoS) model has also been proposed (Nikaein, 2002) which provides differentiated services and soft guarantees to network resources for admitted applications by using class-based weighted fair queuing (CB-WFQ) at the intermediate nodes. The model is comprised of two main phases: (i) path generation, in which the quality of the route is computed based on the network layer quality of intermediate nodes; and (ii) path selection based on the desired QoS class (which are mapped onto various application level metrics). In this architecture, network layer metrics (NLMs), which are used to determine the quality of individual nodes, are separated from the Application Layer Metrics (ALMs). NLMs refer to the hopcount, buffer level, and stability level, whereas ALMs comprise delay, throughput, and enhanced best-effort. The work is extended to include MAC Layer Metrics, such as the signal-to-noise-ratio (SNR) of the link and the coding scheme used.

QoS MAC for MANETs

Medium access control (MAC) protocols for MANETs are non-deterministic and distributed, with no base station of a centralized controller to coordinate the channel access. Therefore, mobile nodes have to contend for access to the shared medium in a random access manner. The industry standard MAC access scheme used in wireless networks is IEEE 802.11, which includes both the point coordination function (PCF) and distributed coordination function (DCF). However,

this base standard is not directly applicable to MANETs because of its lack of traffic prioritization mechanism.

A number of contention-based QoS MAC protocols have been proposed, some of which include: (i) priority queuing schemes such as IEEE 802.11e, (ii) multi-channel schemes with separate channels for data and control packets, and (iii) black-burst contention schemes with varying delay for traffic of different priorities.

The IEEE 802.11e MAC standard (and its enhanced distributed coordination function extension) is an enhancement to the original standard which aims to support QoS in wireless networks. Differentiated service is provided to nodes by having four queues with different access categories, each of which corresponds to a different set of channel access parameters. Traffic with higher priority can then contend for channel access more successfully than low priority traffic by modifying parameters such as inter-frame spacing (IFS) and contention window size (He, 2003).

Conventional MAC protocols, such as IEEE 802.11, are single-channel models which experience higher collisions and contention for channel access as the number of nodes in the network increases. Consequently, the network performance degrades significantly because the overall throughput is limited by the bandwidth of the channel. In contrast, multi-channel MAC schemes, such as those proposed by Tian (2003) and Wu (2002), have better throughput performance, decreased propagation delay per channel, and QoS provisioning in MANETs.

The black-burst (BB) contention scheme (Sobrinho, 1999) is a distributed MAC scheme that provides real-time access to ad hoc CSMA wireless networks. The real-time data traffic contend for access to the wireless channel by jamming the media with pulses of energy known as BBs, which have lengths that are functions of the delay being experienced by the nodes. Hence, the BB contention scheme gives priority to real-time traffic, enforces a round-robin discipline among real-time nodes, and results in bounded access delays to real-time packets.

Another MAC protocol that provides multiple priority levels is proposed by Sheu (2004). It adopts the black-burst mechanism, as described earlier, to differentiate between high and low priority stations. This helps to guarantee that the frames with higher priority, such as multimedia real-time traffic, will always be transmitted earlier than frames with lower priority. Furthermore, stations with the same priority will access the shared channel in a round-robin manner.

MANET QoS Routing

QoS routing is considered by Chakrabarti (2001) to be the most important element in the network because it specifies the process of selecting routes to be used by the packets of a logical connection in attaining the associated QoS guarantee. Crawley (1998) presents a framework for QoS-based routing in the Internet whereby paths for flows are determined based on some knowledge of resource availability in the network as well as the QoS requirements of the connection. There have been significant research efforts on QoS routing in MANETs, some of which include: (i) QoS extensions to existing routing protocols, (ii) AQOR (ad hoc QoS on-demand routing), (iii) CEDAR (core extraction distributed ad hoc routing), (iv) multi-path QoS routing, and (v) QoS-GRID, which uses topology management. Other QoS routing schemes for MANETs are discussed in Jawhar (2004).

As conventional MANET routing protocols implicitly select the shortest paths during route establishment and/or route maintenance, they are unable to offer QoS support to the nodes in the network. As such, many extensions for existing MANET protocols have been proposed to take into account the type of resources desired by the requesting application. Perkins (2003) proposes changes to AODV to provide QoS support by adding extensions to the messages used by the

route-discovery process. These extensions specify the service requirements, such as maximum delay and minimum bandwidth, in the route request (RREQ) and route reply (RREP) messages. Badis (2004) has also proposed QOLSR, an extension to the original OLSR. Instead of using the number of hops for route selection, metrics such as the available bandwidth, delay, jitter, loss probability, etc., are also added to the OLSR functionality and control messages format, to be used for multi-point relay (MPR) selection and routing table calculation.

The ad-hoc QoS on-demand routing (AQOR) protocol (Xue, 2003) is another QoS routing protocol that provides end-to-end QoS support in terms of bandwidth and delay. Besides performing accurate admission control and resource reservation via detailed computations, AQOR is also equipped with signaling capabilities to handle temporary reservation and destination-initiated recovery processes.

CEDAR (Sivakumar, 1999) performs QoS routing for small to medium-sized MANETs. It is comprised of three main components: (i) establishment and maintenance of a self-organizing routing infrastructure called the core, by approximating a minimum dominating set, (ii) propagation of the link state of high bandwidth and stable links in the core to all core nodes, and (iii) a QoS-route computation algorithm that is executed at the core nodes using only locally available states. The route is then selected from the dominator of the source node to the dominator of the destination that satisfies the required bandwidth.

In multi-path QoS routing protocols such as Liao (2002), Chen (2004), Leung (2001), and Chen (2004), the route discovery process selects multiple paths (ideally disjoint) from the source to destination. The multiple paths can be used collectively to satisfy the required QoS requirements (such as bandwidth), and in the event of link breakages along the main paths, the backup paths will then take over the routing immediately, thus reducing the time needed for another route-computation process.

QoS-GRID (Liu, 2003) is a location-based routing protocol with QoS provisioning. It uses a two-tier grid system to reduce the transmission power of each node so as to enhance the bandwidth utilization and provide stable bandwidth guarantees.

ALTERNATIVE QoS MECHANISMS

In the previous sections, we have offered a multi-layered overview of the problems and issues that surround QoS provisioning in MANETs. Despite numerous efforts to overcome these challenges and add guarantees to data delivery in autonomous, distributed, and ad hoc environments, it is inherently difficult to provide QoS support in MANETs due to the following factors: (i) unreliable and unpredictable wireless transmission media, (ii) node mobility induced topology and route changes, which lead to inaccurate locality information, and (iii) power control and energy constraints.

In addition, existing algorithms and mechanisms do not provide any form of assurance that routes will be found nor that broken routes will be recovered within a given time. To overcome these uncertainties, techniques like topology control and mobility prediction have been exploited.

In topology control, certain system parameters, such as the transmission radii of the nodes, can be varied using power control. However, this is not straightforward and may increase contention in the nodes. A QoS routing mechanism with mobility prediction has also been proposed by Wang (2001), which uses node movement patterns to determine the future location of nodes. It then selects the most stable path based on mobility prediction and QoS requirements on bandwidth and delay, but this does not eliminate the possibility that link breakages can still occur along the selected paths.

In the following, we propose some key alternatives to overcome the transient and unpredictable characteristics of MANETs and provision for QoS in MANETs.

- **Controlled node movement:** The system/protocols can be empowered with the ability to control the movement of a subset of nodes in the network. This can be done by making use of swarms of mobile robots with sensors and actuators (Seah, 2006), unmanned autonomous vehicles (UAVs), and public transportation (such as buses and trains), which have more predictable mobility patterns.
- **Clustering:** The ad-hoc nature of MANETs, along with their decentralized architecture, poses much difficulty in the coordination and functioning of the network. Clustering techniques enable dynamic hierarchical architectures to be formed and improve the network performance.
- **Vertical coupling (cross layer interactions):** Although traditional networking paradigms promote the usage of a multi-layered protocol stack in which the different layers have minimal impact on each other, this does not lead to optimal performance. Cross layered designs, such as that proposed by Chen (2002) can help to improve network performance by sharing information across the different layers, at the cost of interdependency between adjacent layers.
- **QoS adaptation:** Conventional network protocols have static behavior, i.e., they perform a fixed set of actions at all times, irrespective of the current network conditions. Since a MANET is generally dynamic in nature, QoS adaptation, whereby the protocols adapt to the network conditions at all times, may be able to produce better performance.

FUTURE TRENDS

Although there have been vast amounts of studies in the different aspects of QoS support in MANETs—QoS models, QoS MAC protocols, QoS routing protocols, and QoS signaling techniques, there are currently very few practical deployments of such networks. This is a consequence of the fact that the current research in MANETs is still unable to support the QoS requirements of the envisioned applications.

Future trends in QoS provisioning in MANETs appear to follow a cross-layered approach, with the different protocol layers working together to enhance the reliability, robustness, and overall performance of the network. The dynamic nature of MANETs also necessitates the need for the protocols to adapt their behaviors according to the prevailing network conditions–a mechanism that can generally be defined as QoS adaptation. In addition, the unpredictability and constraints of MANETs push the need for soft QoS to be considered as a compromising principle in MANETs. To provide QoS guarantees in the network, many other issues and assumptions have to be further studied. These include security, node reliability, node misbehaviors, node mobility, and the possible further interoperation of MANETs with the wired Internet.

CONCLUSION

The distributed architecture and autonomous nature of the nodes in MANETs contribute to its attractiveness as a communication network that can be easily deployed on-the-fly. However, the inherent characteristics of MANETs—node mobility, decentralized architecture, multi-hop communications, limited resources, and unstable link quality—contribute to the impediment of network performance. As such, it is difficult to provide QoS support in the network using

traditional network techniques (such as resource reservation and traffic differentiation) that are used in the wired Internet. As QoS provisioning in MANETs typically involve the collaboration of various layers of the networking protocol stack, researchers are increasingly considering the use of cross-layered designs, adaptivity, and mobility predictions to achieve QoS guarantees in the network. Nevertheless, there are still several outstanding QoS issues that must be addressed, and alternative forms of mechanisms must be studied in greater depth to facilitate the development of QoS in MANETs.

KEY TERMS

Clustering: A networking technique in which nodes in the network group themselves according to some network attributes to form hierarchical architectures.

Cross-Layer Design: A protocol design that leverages on the interactions and dependencies between different layers of the networking protocol stack to achieve better performance. MANET (mobile ad hoc network)—self-configuring and self-maintaining network in which nodes are autonomous and distributed in nature.

QoS (quality of service): The ability of a network to deliver a guaranteed level of service to its users and/or applications.

QoS Adaptation: The adaptation of the behavior of one or more network protocols according to the prevailing network conditions, so as to achieve QoS in the network.

Service Requirements: Performance metrics such as throughput, delay, jitter (delay variance), bandwidth, and reliability which are usually application-specific.

Soft QoS: A compromising principle of QoS support whereby there may exist transient periods of time when the network is allowed to fall short of QoS requirements, up to a permitted threshold. The level of QoS satisfaction is thus quantified by the fraction of total disruption.

UAV (Unmanned Autonomous Vehicle): A machine that can move through the terrain intelligently and autonomously without the need for any human intervention.

Chapter 7.20
Quality of Service Issues in Mobile Multimedia Transmission

Nalin Sharda
Victoria University, Australia

ABSTRACT

The focus of this chapter is on the quality of service (QoS) aspects involved in transmitting multimedia information via mobile systems. Multimedia content and applications require sophisticated QoS protocols. These protocols need to manage throughput, delay, delay variance, error rate, and cost. How errors are handled in a multimedia session can have significant impact on the delay and delay variance. Coding and compression techniques also influence how the final presentation is transformed by the impediments encountered on a mobile network. Providing the user with the ability to negotiate between cost, quality, and temporal aspects is important, as this allows the user to strike a balance between these factors. In moving from 2G to 3G, and, over the next decade to 4G mobile networks, the ability to transmit multimedia information is going to improve constantly. Nonetheless, providers must develop viable economic models and user interfaces for providing differentiated QoS to the users.

INTRODUCTION

Transmission of multimedia information over mobile networks to portable devices, such as laptops, mobile phones, and PDAs (personal digital assistants), is leading to the development of new applications. However, successful transmission of multimedia information over mobile networks cannot be taken for granted. Understating the impediments to successful transmission of multimedia information is of paramount importance. This chapter focuses on multimedia applications that use mobile networks, and issues involved in the delivery of multimedia content with the desired quality of service (QoS). Current and future challenges in achieving successful mobile multimedia information transmission are also discussed.

Multimedia applications require more sophisticated QoS protocols than those for simple data transmission. The main parameters that underpin QoS are throughput, delay, delay variance, error rate, human perception of quality, and cost (Sharda, 1999). The interplay between these factors is rather complex, therefore, some simplifying assumptions must be made in developing methodologies for delivering multimedia content with the desired QoS.

For the delivery of desired QoS, one of the most promising concepts developed over the last few years is that of resource reservation. This entails reserving resources such as bandwidth on interconnects, and buffer space and processing power on switching nodes.

Packet switching networks embody the idea of statistical time division multiplexing (STDM); that is, resources are allocated to a communication session based on the demands of the traffic. This leads to more efficient, and therefore, more economical usage of the resources. However, the need to allocate resources dynamically adds complexity to the communication system's operation and management. Mobile multimedia communications are further complicated due to their variable transmission quality, the need to keep track of end system location, restrictions placed due to limited battery life, reduced screen size, and the cost of the connection.

Over the last decade, some progress has been made in establishing mobile multimedia transmission systems. However, much research and development is still required before we can take it for granted that a multimedia application, such as videoconferencing, would run with the desired QoS over a mobile communication infrastructure on a hand-held device as we zoom down a freeway at high speed, and, all this at a reasonable cost.

The next section of this chapter presents the challenges introduced by the mobile multimedia content, applications, and communication systems. It begins with an overview of mobile multimedia systems, and then presents the implications of coding and compression techniques for transmitting multimedia. Requirements of various multimedia applications and their relationship to mobile communication systems are also presented.

The third section presents QoS issues in transmitting multimedia content over mobile systems. Fundamentals of QoS concepts and different QoS models are introduced, and a novel model for managing QoS in real time is presented.

The fourth section presents directions for future research, and the final section gives the conclusions.

MOBILE MULTIMEDIA SYSTEMS

Overview

This section presents an overview of coding methods used for various media types, multimedia applications, and current mobile communication systems. QoS issues related to each of these are also discussed.

Multimedia communication systems combine different types of media contents, such as text, audio, still images, and moving images, to achieve the overall objective of a communication session. Therefore, the network needs to provide a service which works well for all media types.

The requirements for successfully transmitting a particular media type depend upon its coding and compression techniques, and the application in which it is being used. Media content that must be transmitted live, or processed in real time, poses more stringent requirements. Consequently, live video conferencing is one of the most challenging multimedia applications.

The network infrastructure and the communications protocols used for transmission play a vital role in satisfying the demands of a given application. In general, multimedia transmission requires high bandwidth, low error rate, low delay, and very low delay variance. To date, we have

not solved all of these challenges for even wired media. Fulfilling these requirements for achieving high-quality multimedia transmission over wireless connections is even more challenging.

The transition from the 2nd generation (2G) mobile systems to the 3rd generation (3G) mobile communication infrastructure presents new opportunities; however, still there are many challenging problems that need to be overcome. One of the key features missing in the current systems is the facility for the user to negotiate with the system and strike a compromise between the three key service aspects—quality, cost, and time—just as any market-oriented goods or services have to strike a balance between the quality, cost, and its delivery time.

Errors encountered in any transmission system can be either ignored, or detected and corrected. Errors can be ignored only if the received message is usable even with some errors. If errors in the received message are not acceptable, then these errors must be detected and corrected. Reverse error correction protocol requests retransmission of packets received with errors. This not only adds delay to the final reception of packets, it also adds delay jitter, as different packets encounter different delays. Forward error correction protocols include additional error correction bits, so that some of the errors can be corrected from the received data; this adds to the total data traffic. The choice of error handling method depends upon the type of data, its coding methodology, and the application.

Multimedia Content

By definition, a multimedia system combines different media types: text, audio, still and moving images. Each of these content types can be further categorised into sub-types. For example, still images can be bi-tonal, greyscale, or full-colour; furthermore, these can have continuous variation in tone—as in a photograph, or have sudden variation in the intensity—as in a printed page. A variety of techniques are used for digitally coding still images, depending upon the image type and application. Similarly, many text representation techniques and associated digital coding techniques are used. Audio and video are even more complex, as these are time varying quantities and involve continuous sampling over time. Errors and delays introduced at any stage of sampling, encoding, transmitting, and decoding of audio and video can lead to reduction in the quality of the final presentation.

Most multimedia content needs to be compressed to reduce the storage space and transmission bandwidth. Uncompressed multimedia content has in-built redundancy, and a few corrupted bits do not change the contents dramatically. Conversely, compressed media is compact, and has much less redundancy. Consequently, any errors during transmission affect compressed content more severely.

Mobile transmission systems are inherently more error-prone than wired transmission systems. The requirements for successfully transmitting a particular media type over a network depend not only on its coding and compression techniques, but on its application as well. However, all multimedia content is for human consumption, therefore, the criteria for acceptable quality of presentation ultimately depends upon human perception. For example, streamed video can accept a few seconds of delay, but live video conferencing becomes rather ineffective if the round-trip delay exceeds even a tenth of a second.

Text Coding

Despite the move towards graphical information, text remains a vital part of any multimedia presentation. One of the most enduring text codes is the American Standard Code for Information Interchange (ASCII). ASCII began its life as a 7-bit code designed for use with teletypes. Today, if

someone talks of an ASCII document, they essentially refer to a text document with no formatting. Applications such as Notepad create ASCII text, and word processors can save a file as "text only". Extended ASCII codes were designed for computers to be able to handle additional characters from other languages. It took some time to get a single standard for these additional characters, and there are a few Extended ASCII sets.

Unicode provides a text code that is independent of platform, program, or language. In Unicode, a unique 16-bit number is reserved for every character. The Unicode standard aims to provide a universal repertoire with logical ordering that is efficient. The latest version of Unicode Standard is Unicode 4.0.1, and supports around a hundred international scripts.

ASCII and Unicode have been used extensively over wire-line communication systems, and can be used over wireless media as well. In general, transmission of text codes does not require high bandwidth or stringent limits on delay and delay variance. Hence maintaining QoS in transmitting text is often not much of a problem. Nonetheless, a new code set was designed for sending short text messages over mobile systems.

Short message service (SMS) uses a 7-bit code set that enables one to send and receive text messages of up to 160 characters on mobile phones. Some 8-bit messages are used for sending smart messages (such as images and ring tones) and for changing protocol settings. For Unicode-based text messages, 16-bit codes of maximum 70 characters can be used. These are viewable by most phones, and some appear as a flash SMS, that is, appear on the screen immediately upon arrival, without pressing any button. The SMS code was originally developed for the 2G technology, and therefore works well with 2G as well as 3G systems. The only possible issue with respect to QoS can be errors; bandwidth, delay, and delay jitter do not impede the transmission of SMS messages.

Non-Textual Information

The standard developed to transmit multimedia information over the Internet is the multipurpose Internet mail extensions (MIME). This standard was developed by the Internet Engineering Task Force (IETF) to support the transmission of mixed-media messages across TCP/IP networks. This also became the standard for transmitting foreign language text which the ASCII code could not represent.

Multimedia messaging service (MMS) provides the ability to send messages that combine text, sounds, images, and video over wireless networks. This requires handsets that are MMS capable. MMS is an open wireless standard specified by the WAP (wireless application protocol) forum—which has now been consolidated into the Open Mobile Alliance (OMA). In the WAP protocol, a notification message triggers the receiving terminal to start retrieving the message automatically using the WAP GET command. This retrieval may be modified by applying filters defined by the user. The content that can be transmitted with the WAP protocol can use a variety of media types and encoding standards.

Audio Coding

The basic technique for digitising analog audio signals is called pulse code modulation (PCM). In this technique, an analog audio signal is sampled at a rate double that of the maximum frequency that needs to be captured, and each sample is stored using 8-bit or 16-bit words.

Phone quality audio signals are sampled at 8,000 samples per second, and stored with 8-bit resolution; this generates 64 Kbps data rate. CD quality audio has two channels; it is sampled at 44,000 samples per second and saved with 16-bit resolution, giving a 1.4 Mbps data rate. A variety of compression techniques are used to reduce the bandwidth required to transmit audio signals.

Compression becomes particularly important for CD quality stereo music, as the required 1.4 Mbps bandwidth is not economically available even in wire-line networks, much less so in wireless networks.

The MP3 (MPEG audio Layer 3) compression format has become one of the most widely used standards for transmitting high quality stereo audio. MP3 is one of three audio coding schemes associated with the MPEG video compression standard. The MP3 standard provides the highest level of compression and uses perceptual audio coding and psychoacoustic compression to remove all redundant and irrelevant parts of a sound signal that the human ear does not hear. MP3 uses modified discrete cosine transform (MDCT) and improves the frequency resolution 18 times with respect to that of the MPEG audio Layer 2 coding scheme. It manages to reduce the CD bit rate of 1.4 Mbps down to 112-128 Kbps (a factor of 12) without sacrificing sound quality. Since MP3 files are small, they are easily transferred across the Internet, and are also suitable for transmission over wireless networks.

The next generation of MP3 standard is called mp3PRO. It is fully compatible with MP3, while halving the storage and bandwidth requirements. With this standard CD quality stereo can be transmitted at 64 Kbps. Furthermore, it can be used with digital rights management software, and can be ported transparently to any MP3-friendly application.

Advanced audio coding (AAC) is a wideband audio coding algorithm that exploits two main coding strategies to reduce the amount of data needed to encode high-quality digital audio. First, it removes signal components that are not important from a human perception point of view, and second, it eliminates redundancies in the coded audio signal. The MPEG-4 AAC standard incorporates MPEG-2 AAC, for data rates above 32 Kbps per channel. Additional techniques increase the effectiveness of the AAC technique at lower bit rates, and are able to add scalability and/or error resilience. (These techniques extend AAC into its MPEG-4 version: ISO/IEC 14496-3, Subpart 4.) The MPEG-4 aacPlus standard combines advanced audio coding techniques such as spectral band replication (SBR), and parametric stereo (PS). The SBR techniques deliver the same audio quality at half the bit rate, while the PS techniques (optimised for the 16-40 Kbps range) provide high audio quality at bit rates as low as 24 Kbps (Dietz & Meltzer, 2002).

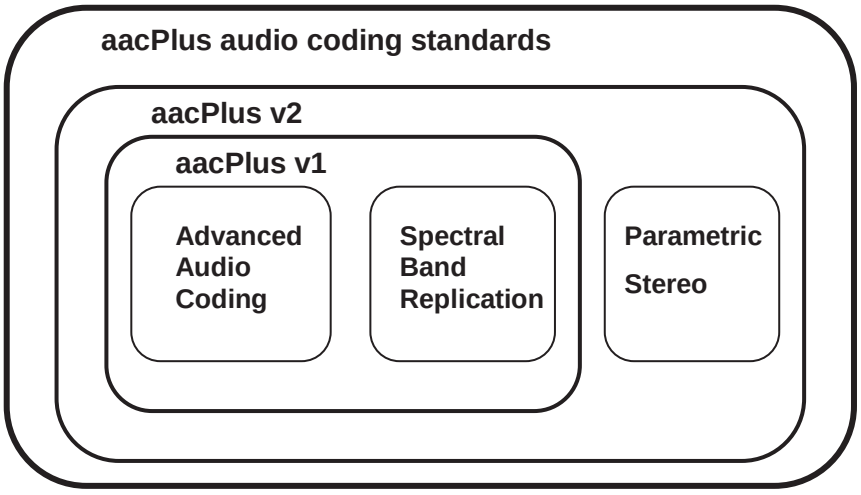
The aacPlus codec family includes two versions. Version 2 of aacPlus is the high quality audio codec targeted for use in the 3GPP (3rd Generation Partnership Project). The aacPlus version 1 standard is adopted by 3GPP2 and ISMA (Internet Streaming Media Alliance) for digital video broadcasting (DVB).

The relationship between the aacPlus codec family members is shown in Figure 1 (Dietz & Meltzer, 2002). To compress the incoming stereo audio, the encoder extracts parametric representation of the stereo aspect of the audio. The stereo parametric information takes 2-3 Kbps and is transmitted along with the mono signal. Based on the parametric representation of the stereo information, the decoder regenerates the stereo signal from the received mono audio signal.

To be able to transmit high quality stereo audio, it is necessary to compress it to reduce the bandwidth, otherwise it may not be possible to obtain the desired QoS, especially over wireless networks. However, high level of compression makes the transmitted signal highly susceptible to errors, especially if the audio is being transmitted in real time. Any loss in the parametric information will severely degrade the quality of the reproduced stereo signal. Stereo is often used for music, and the slightest imperfection in music gets noticed by even non-experts.

Human ears are more sensitive to errors than human eyes. Human hearing faculties behave like differentiators, accentuating any variations, while

Figure 1. Relationship between aacPlus audio codecs v1 and v2 (Dietz & Meltzer, 2002)



human eyes behave like integrators, smoothening out variations (Sharda, 1999). Therefore, an audio stream should be given higher priority as compared to text or an image data stream.

Still Image Coding

Still image coding depends upon the type of image and its compression algorithm. Standards such as JPEG (Joint Photographic Experts Group), GIF (Graphics Interchange Format), and PNG (Portable Network Graphics) have dominated the field so far. JPEG is generally used for lossy compression of continuous tone images, such as photographs. GIF is a bitmap image format for pictures with 256 colours. PNG is a lossless bitmap image format. PNG improves upon the GIF format and is freely available.

The newer JPEG 2000 image compression standard uses a wavelet transform instead of the discrete cosine transform used in JPEG (Taubman & Marcellin, 2002). Therefore, JPEG 2000 can give higher compression ratio without generating the blocky and blurry artefacts introduced by the original JPEG standard. It also allows progressive downloads to extract various image resolutions, qualities, components, or spatial regions, without having to decompress the entire image. Distortion performance is also improved over the original JPEG standard, especially at low bit rates and at extremely high quality settings. JPEG 2000 is more error resilient as compared to the original JPEG standard (Secker & Taubman, 2004). This makes JPEG 2000 much better suited for applications requiring image transmission over wireless networks, as errors and delays introduce fewer observable artefacts in the displayed image.

Wireless networks experience higher error rates, and have lower bandwidth. Therefore, they are more severely challenged when transmitting digital images. Since the JPEG 2000 standard provides higher compression ratios, it is more

suitable for the low bandwidth wireless networks; however, some additional issues need to be addressed (Santa-Cruz, Grosbois, & Ebrahimi, 2002). Issues such as error resilience over wireless networks are being addressed by the JPEG 2000 Wireless (JPWL) team. Their aim is to standardise tools and methods for efficient transmission of JPEG 2000 images over error-prone wireless networks. One of the techniques being developed by JPWL make the code stream more error resilient by adding redundancy, or by interleaving data (Dufaux & Nicholson, 2004). The decoder not only detects errors, but also corrects some, where possible. Another technique changes the sensitivity of different parts of the code stream to errors. More sensitive sections of the code stream are more heavily protected than the less sensitive sections. The third technique describes the locations of the remaining errors in the code stream; the decoder then uses this information to exclude the corrupted parts of the code stream from the decoding process.

By standardising these techniques in JPWL, JPEG 2000 is being made more resilient to transmission errors, making it an ideal choice for the transmission of digital images and video over wireless media.

Moving Image Coding

Moving image coding can entail storing up to 20-30 image frames in every second. This demands very high bandwidth for high quality uncompressed video. Development of video coding standards that provide low resolution and low frame rate video suitable for transmission over networks began with the H.261 standard published by the ITU (International Telecom Union) in 1990, with data rates in multiples of 64 Kbps. The H.263 version provided a replacement for H.261 (in 1995) to work at all bit rates. It was further enhanced as H.263v2 (in 1998) and H.263v3 (in 2000). H.263 is similar to H.261, with improved performance and error recovery, and supports CIF,[1] QCIF, SQCIF, 4CIF, and 16CIF images. As these standards are designed for multiples of 64Kbps rates these are sometimes called px64 (where p can be 1-30). Originally these data rates were expected to suit ISDN (integrated services digital network) lines, nonetheless, these standards are useful in transmitting video over other wire-line and wireless networks also. H.263 is the baseline standard for the new 3G-324M standard, which targets the 3G wireless networks (Smith & Jabri, 2004).

Another option within the 3G-324M specification is the next generation video coding standard MPEG-4 AVC. It was approved in 2003 and called MPEG-4 AVC or ITU-T H.264, or simply advanced video coding (AVC).

MPEG-4 AVC doubles the compression efficiency of earlier standards for the same picture quality, which leads to 50% lower bandwidth (Navakitkanok & Aramvith, 2004). Therefore, it is far better than the earlier standards for wireless transmission. It offers improved resilience to transport errors, improved bit rate scalability, and stream switching for transmission over less reliable network infrastructure, such as wireless networks.

Motion JPEG 2000 (like Motion JPEG) can perform video compression applying only intra-frame compression. This makes Motion JPEG 2000 well suited for video transmission over wireless networks. It has been demonstrated that Motion JPEG 2000 outperforms MPEG-4 in terms of coding efficiency, error resilience, complexity, scalability, and coding delay (Tabesh, Bilgin, Krishnan, & Marcellin, 2005).

The JPWL work has taken into consideration the general principle underpinning networking protocols, with particular attention given to 3G networks (3GPP/3GPP2), wireless LANs (WLAN based on the IEEE 802.11 standards family), and Digital Radio Mondiale (DRM), making motion JPEG 2000 particularly suitable for wireless networks.

Multimedia Applications

Applications which have so far been bound to wire-line networks and desktop computers, now want to be let loose. The only option is to use wireless networks and portable devices. Areas for such mobile multimedia applications include both personal and business communications. E-learning, marketing, travel, and tourism are just a few of the burgeoning application areas that can make good use of mobile multimedia systems. Some of the potential killer applications based on the JPEG 2000 Wireless (JPWL) methods include video streaming and video conferencing (Liu & Choudary, 2004).

Mobile systems offer new opportunities and challenges as they become capable of transmitting multimedia information. Such applications need to transmit not only the core information, but also some associated meta-information. Most electronic systems use multi-tier information transmission processes, which include: intimation of arrival (bell, ring, beep, and vibrate); abbreviated information (subject, caller ID); textual information (text message, SMS); multimedia information, and meta-information for layered retrieval of the information.

How a particular information type and associated meta-information is used depends upon the application, the user preference, user device, and the required QoS (Cheng & Shang, 2005).

Text Applications

Text is very useful for communication. It is often said that a picture is worth a thousand words; nonetheless, we should not forget that a few well chosen words can be worth scores of pictures. Additionally, text requires much lower bandwidth, and has greater certainty of meaning. It is more reliable in the face of transmission errors, especially if we use either reverse or forward error correction protocols.

Text is easy to transmit asynchronously or synchronously. One can send an SMS to a friend during work, without the fear of disturbing her in an import meeting. The receiver can reply in her own time, or the two can engage in a brief chat session to fix their evening rendezvous. The runaway success of SMS follows the predicate that "brevity is the soul of wit," as SMS allows succinct messages that convey the meaning quickly. Coded messages based on SMS have also become prevalent, further reducing the time taken to enter and read the message.

Some commonly used SMS codes include: *ATB—All the best; BRB—Be right back; GR8—Great; LUV—Love; PCM—Please call me; TTYL—Talk to you later; 2DAY—Today; and WER R U—Where are you?* SMS codes are also being used to download information to mobile phones, such as snow photos to check the condition on ski slopes.

In Japan, codes called Emoji have been developed. These are colourful, and often animated inline graphics used for mobile messaging. However, these are not standardised or interoperable between carriers. Emonji's are treated as characters, and each carrier has its own set.

In conclusion, text or text-like messages are, and will remain, an important aspect of mobile communications, especially because these are inexpensive, highly expressive, and are least problematic with respect to delivery with the desired QoS.

Audio Applications

Transmission of voice was the original motivation for developing the mobile communications technology. However, digital radio is also coming online, and integrating digital radio in mobile phones is in the offing. An Austrian company Livetunes has developed UMTS-enabled handset with digital radio. SIRIUS Satellite Radio can transmit commercial-free music and other audio

entertainment to cars and homes. Mobile audio commercials over such digital radio channels allow advertisers to send audio commercials to their customers' mobile phone. The customer receives a phone call; upon answering the call, the audio commercial is played. It can include new offers, promotions, and announcements. To avoid spamming, companies have to provide their own subscriber database and the audio clip.

The QoS requirements for audio are different for bi-directional conversation than those for uni-directional digital radio transmission. For digital radio, buffering can be used to remove any delay jitter; however, excessive buffering can add unacceptable delay to conversational applications (Sharda, 1999).

Human hearing is very sensitive to any distortion in audio. For conversational audio, we can tolerate some errors, as long as the meaning of the spoken words is clear. If there is a problem in understanding the meaning, then the listener can always ask the speaker to repeat what was said. This is like reverse error correction working at the highest communication layer, that is, the user layer. However, this cannot work for stereo music; as human hearing works like a differentiator, and any distortion gets accentuated. Furthermore, our hearing is capable of picking slightest variation between the two channels of stereo music. Therefore, QoS issues are very important when high quality stereo music is transmitted, but not so important for conversational audio.

Still Image Applications

Applications needing still image transmission can use multimedia messaging service (MMS). Examples of MMS based applications include: weather reports giving images, stock prices displayed as graphs, football goals displayed as a slide show, and many more. An extension of still image transmission is animated text messages. The main QoS factor that affects still images is delay. As delay jitter does not effect still image transmission, any errors can be overcome by using reverse error correction protocols. If such additional delays are not acceptable, then images can be displayed with errors. Uncompressed images can tolerate a high level of errors; however, the ability to tolerate errors reduces for compressed images. The original JPEG type compression techniques lead to blocky images when errors occur, as they use discrete cosine transform. However, JPEG 2000 compression standard overcomes this problem by using wavelet transform. Images compressed with JPEG 2000 degrade "gracefully" in face of errors. As wireless communication systems are inherently more error prone, image-based applications will benefit from the use of JPEG 2000 standard for their compression (Dufaux & Nicholson, 2004).

Content repurposing is also becoming important, so that the content creator can compile content only once, and the system can vary image size and resolution depending upon the display screen size and the communications channel bandwidth (Rokou & Rokos, 2004)

The aim of content repurposing is to push the content with the most appropriate resolution, so that it can be transmitted over the available network to meet the QoS goals. In general, this would imply pushing lower resolution images over wireless networks. However, with JPEG 2000 and JPWL, the system can push a rough image to begin with, which keeps improving as more data bits are transmitted.

Video Applications

Video phones are a natural extension of the current audio telephony. Wire-line based video phones were demonstrated decades ago, however, these never became popular. Mobile video telephony is likely to become popular once the cost of transmitting acceptable quality video becomes affordable. In the meanwhile, look-at-this (LAT) applications

will generate demand for mobile Internet and 3G wireless networks, as these will create large amount of real-time mobile video. Some possible LAT application areas include:

a. **Retail:** Before purchasing an item, the consumer sends an image of the item to their partner for comment or approval.
b. **Real Estate:** An agent sends images of the building and its surrounding areas to the prospective customer.
c. **General Business:** A worker sends live video to colleague(s) at other location(s) while holding a voice conversation. This could be applied to developing new ideas; designing new products; repairing faulty equipment; maintaining, installing, or inspecting a system.

QoS is of great importance in video transmission. Video conferencing is the most challenging multimedia application for transmission over mobile systems. Much effort has gone in to migrating from 2G networks to 3G networks to provide the desired QoS for video transmission. However, the cost of transmission is still high enough for it to be an impediment in its large-scale adoption.

Mobile Communication Systems

The desire to communicate over long distances has been an innate need for human beings since time immemorial. We can reflect that the earliest telecommunications systems devised by human beings were wireless systems, namely, smoke signals, semaphore flags, drums, and yodelling and so forth. Therefore, it is not surprising that electronic communications are also moving towards wireless systems.

Evolution of Telecommunications

Electric telecommunications began with the telegraph demonstrated by Morse in 1837 and the telephone developed by Bell in 1876. Marconi began his experiment with radio transmission in 1895. Automation of circuit switching systems began in 1919 with the Strowger exchange. The era of satellite communications dawned with the Telstar satellite in 1950. Saber became the first major data network in 1962.

Evolution of Mobile Systems

An early landmark in the development of wireless communications was the patent for the spread spectrum concept, proposed in 1941 by Hedy Lamarr. The first mobile telephone service was setup in St. Louis by AT&T as far back as 1946. Some theoretical breakthroughs also occurred around this time. In 1948, Claude Shannon published the Shannon-Hartley equation, and in 1949 Claude Shannon and Robert Pierce develop the underlying concepts for CDMA (code-division multiple access). In 1950, Sture Lauhrén made the world's first cellphone call, and by 1956, Swedish PTT Televerket operated a mobile telephone service. In 1969, the Nordic Mobile Telephone Group started a mobile service. CDMA was deployed for military systems in the 1970s. In 1973, Motorola vice presidents Marty Cooper and John Mitchell demonstrated the first public call from a handheld wireless phone.

Evolution of Digital Mobile Systems

First Global System for Mobile Communications (GSM) technology based networks were implemented by Radiolinja in Finland in 1991. In 1992, the Japanese Digital Cellular (JDC) system was introduced. By 1993, the IS-95 CDMA standard got finalised. First meetings of the 3GPP (3rd Generation Partnership Project) Technical Specification Group was held in December 1998. In 2000, Siemens demonstrated the world's first 3G/UMTS (3rd Generation Universal Mobile Telecommunications System) call over a TD-CDMA (time division-CDMA) network.

In 2000, commercial GPRS (general packet radio service) networks were launched. These networks supported data rates up to 115 Kbps, as compared to GSM systems with 9.6 Kbps data rates. In 2001 NTT (Nippon Telegraph & Telephone Corp.) produced commercial WCDMA (wide-band CDMA) 3G mobile network. In 2003, Ericsson demonstrated the transmission of IPv6 traffic over 3G UMTS using WCDMA technology.

Fixed Wireless vs. Mobile Communications

We need to distinguish between fixed wireless communication systems and mobile communication systems. A mobile communication system frees the end systems from the tyranny of being connected to a wall socket, and provides the ability to communicate anytime and anywhere. It allows the freedom to roam outside the home or the office.

Fixed wireless communication systems are local alternatives to wired communication systems. These do not provide mobility outside the home or the office, nonetheless, they provide a cost effective telecommunications connection for a given location with the ability to move around within a specified boundary.

For remote locations, satellite-based communication systems may be the only means of establishing a connection; however, these can be expensive. Satellite connections add about half a second round trip delay, making full-duplex audio or video connections rather difficult. While there is appreciable delay in a satellite connection, the delay variance is not very high, as the number of hops is fixed at two—transmitter to the satellite, and satellite to the transmitter. Error rates can be high on a satellite connection, especially burst errors—in case of atmospheric disturbances.

Universal Mobile Telecommunications System (UMTS)

Today, there are more than 60 3G/UMTS networks using WCDMA technology. Over 25 countries have adopted this technology, and there is a choice of over 100 terminal designs in Asia, Europe, and the U.S. The 3G mobile technologies identified by ITU for 3G/UMTS offer broadband capabilities to support a large number of voice and data customers, and offer much higher data rates at a lower incremental cost than the 2G technologies (Myers, 2004).

One of the issues driving the development and proliferation of 3G technologies is the recognition that there is a need for guaranteeing the QoS for multimedia traffic. Without guaranteed QoS, many applications fail to perform as per the users' expectations. Until the users are confident of getting the quality they need for running mobile multimedia applications effectively, they will not shift from their current mode of operation and adopt the new wireless networking technologies for multimedia information transmission.

QUALITY OF SERVICE IN MOBILE SYSTEMS

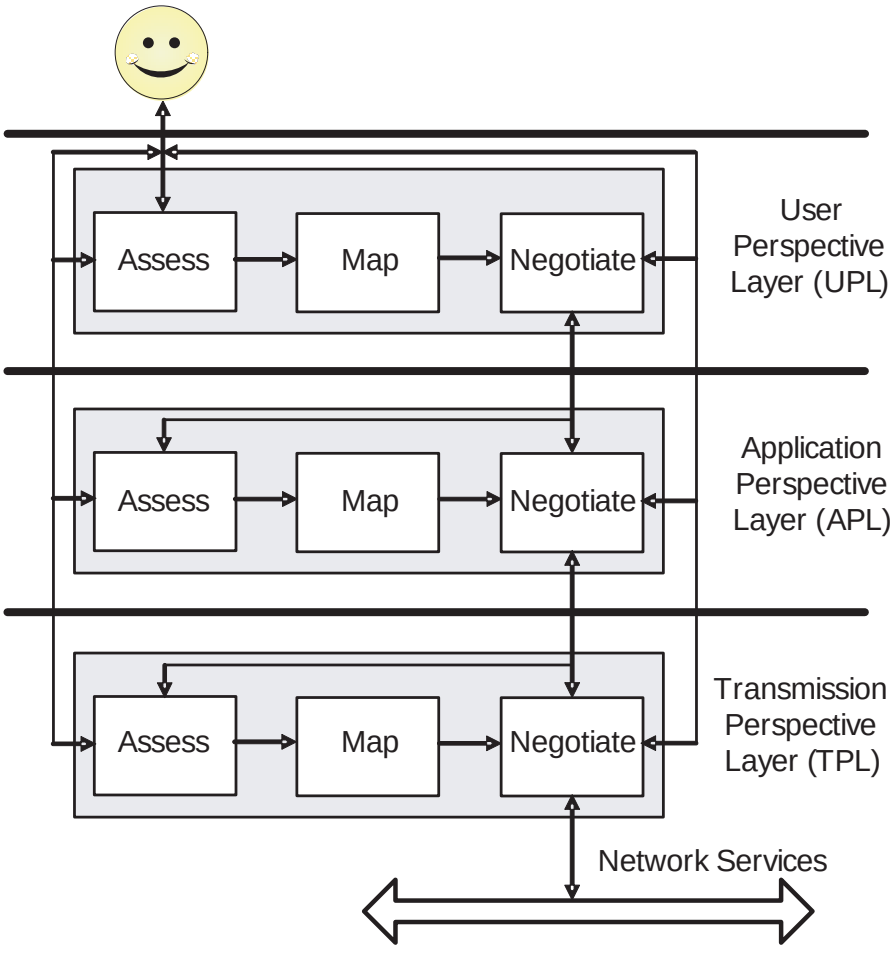
This section gives an overview of the various approaches being trailed for the provision of QoS in mobile networks. While much work has been done in providing QoS guarantees at the network infrastructure level, a holistic approach to providing end-to-end QoS has been missing to some extent. We begin by presenting a QoS model that focuses on the user, and develops a methodology for allowing the user to negotiate with the system to find a compromise between cost, quality, and temporal aspects.

QoS Concepts and Models

The three layer quality of service (TRAQS) model shown in Figure 2 comprises three layers for QoS management in multimedia communications (Sharda & Georgievski, 2002). These three layers are: user perspective layer, application perspective layer, and transmission perspective layer. Each layer performs QoS processing for a set of QoS parameters that are related to the specific perspective. The main functions of the three perspective layers are:

- **User Perspective Layer (UPL)** interacts and performs QoS negotiations with the user and then transfer the QoS request to the APL.
- **Application Perspective Layer (APL)** first assesses the QoS request received from the UPL, and aims to satisfy the needs of the

Figure 2. Three layer QoS (TRAQS) model (Sharda, 1999)



multimedia application by requesting the required services from the TPL.

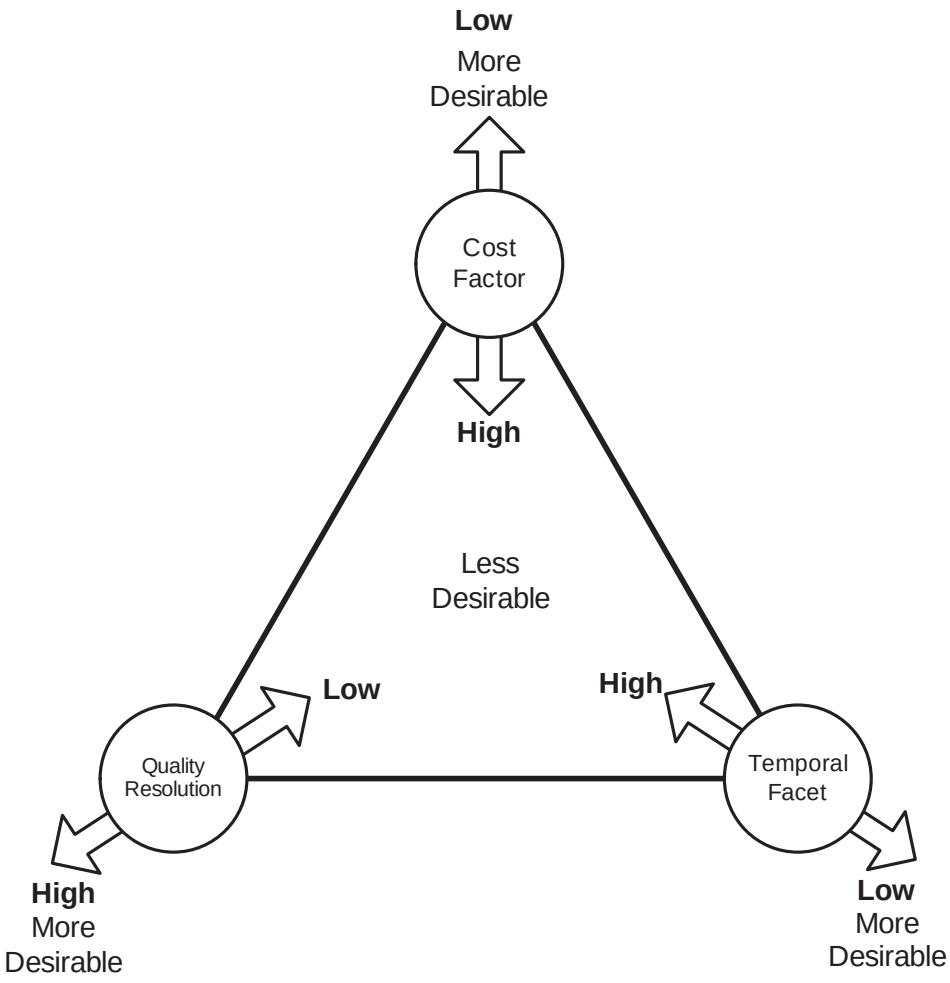
- **Transmission Perspective Layer (TPL)** is responsible for negotiating with the network infrastructure to obtain appropriate communication services that can guarantee QoS.

Similarly, the various QoS protocols developed at the network infrastructure level need to be able to communicate with the TPL to allow the user to specify the desired compromise between cost, quality, and temporal issues such as delay and jitter.

Quality, Cost, Temporal Triangle (QCTT)

In purchasing any goods or services one needs to find a compromise between three important factors: cost, quality, and time. While one would

Figure 3. Quality, cost, temporal triangle (QCTT) model (Georgievski & Sharda, 2005a)



like to get the best quality at the least cost and in the shortest time, in practice, this is not possible. One must strike a compromise between these three factors. So far mobile communications systems have not come to grips with this reality. Future communication systems must provide users the ability to specify what quality and temporal aspects (such as delay and jitter) they want, and then systems should respond with the cost it would charge to provide that quality.

Only with a differentiated cost can the telecommunications service providers afford to deliver the required QoS. If the cost is too low, the network may be overwhelmed with traffic, and none of the users can then obtain the desired QoS. Over and above this, the network services provider may not be able to make profit. On the other hand, if the cost is too high, there will not be enough consumers using the service, once again making it difficult for the service provider to get return on investment. Whereas, by providing the user the ability to negotiate, the consumer and the service provider can both have a win-win situation; some consumers pay high cost as they need higher quality, while other consumers can pay lower cost, as they have lower QoS requirements.

In the following sections, we first explain the concepts involved in the quality, cost, temporal triangle (QCTT), and then present an implementation of the same (Georgievski & Sharda, 2005a).

The three performance aspects—quality, cost, and time—are bound by a tri-partite dependency and thus can be modelled as a triangular relationship, as shown in Figure 3. The QCTT model embodies an inherent restriction on the delivery of QoS, that is, it is possible to achieve the more desirable parameter values only for two of the three performance aspects, while the third aspect must be forced to the less desirable value (Georgievski & Sharda, 2005b).

For example, if a user chooses to have high quality resolution (e.g., large image size, high frame rate), and, the more desirable, low temporal facet (e.g., low delay and jitter), then the cost factor has got to be high. By embedding the quality, cost temporal (QCTT) model in a user interface, we can provide the ability to dynamically manage QoS even while a multimedia session is in progress.

A multimedia communication session first needs to enter static QoS specifications, and then carry out dynamic QoS management as the session proceeds. An interface based on the QCTT model provides the ability to dynamically manage QoS. Such interfaces are described in the following sections.

Static QoS Specification

Figure 4 shows the user interface developed for negotiating static QoS prior to initiating a multimedia communication session. Using this interface, the user is able to specify the desired QoS, and then interactively negotiate with the system. It uses intuitive GUI elements such as a four colour system, a user status response, and a system status signalling system. These GUI elements allow the user to request the desired QoS, and get feedback if the network can deliver the same (Georgievski & Sharda, 2005a).

Dynamic QoS Management with QCTT

A dynamic QoS management interface is shown in Figure 5. This interface uses the QCTT model for re-negotiating QoS while a communication session is taking place. This is achieved by using three GUI elements: three sliders, buttons, and pivot point displacement. The system feedback GUI elements include: system QoS provision ring and values, and QCT threshold line (Georgievski & Sharda, 2005a).

To specify the desired QoS, the user moves the pivot point in the QCT triangle to a location which indicates the desired values for quality, cost, and temporal parameters.

The system provides visual feedback as follows:

Figure 4. Static QoS negotiation user interface (Georgievski & Sharda, 2005a)

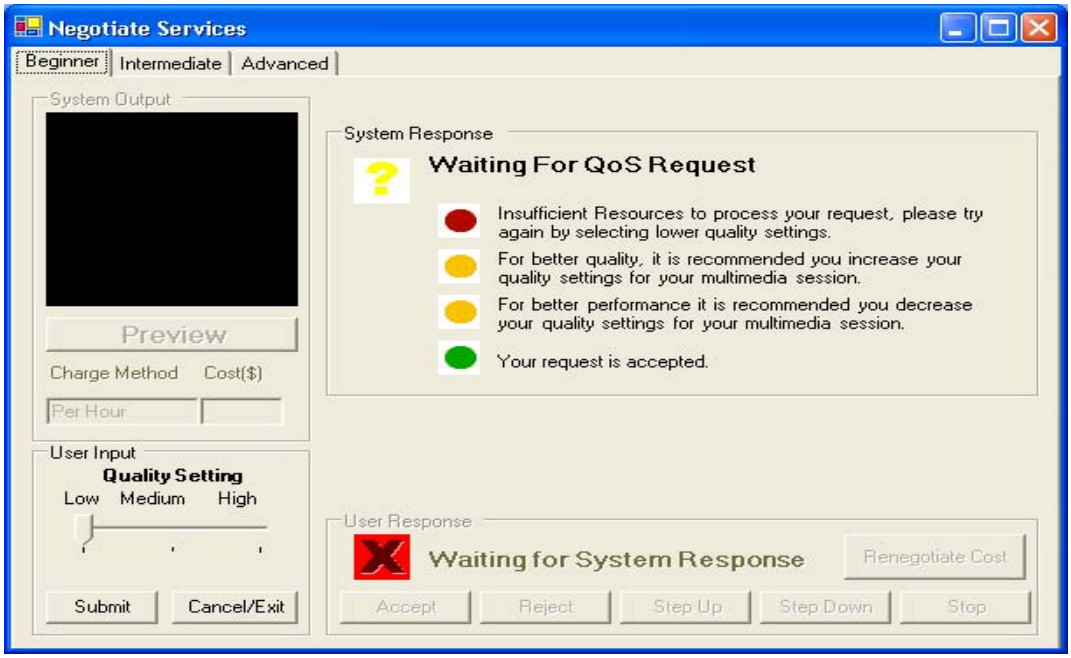


Figure 5. Dynamic QoS management user interface (Georgievski & Sharda, 2005a)

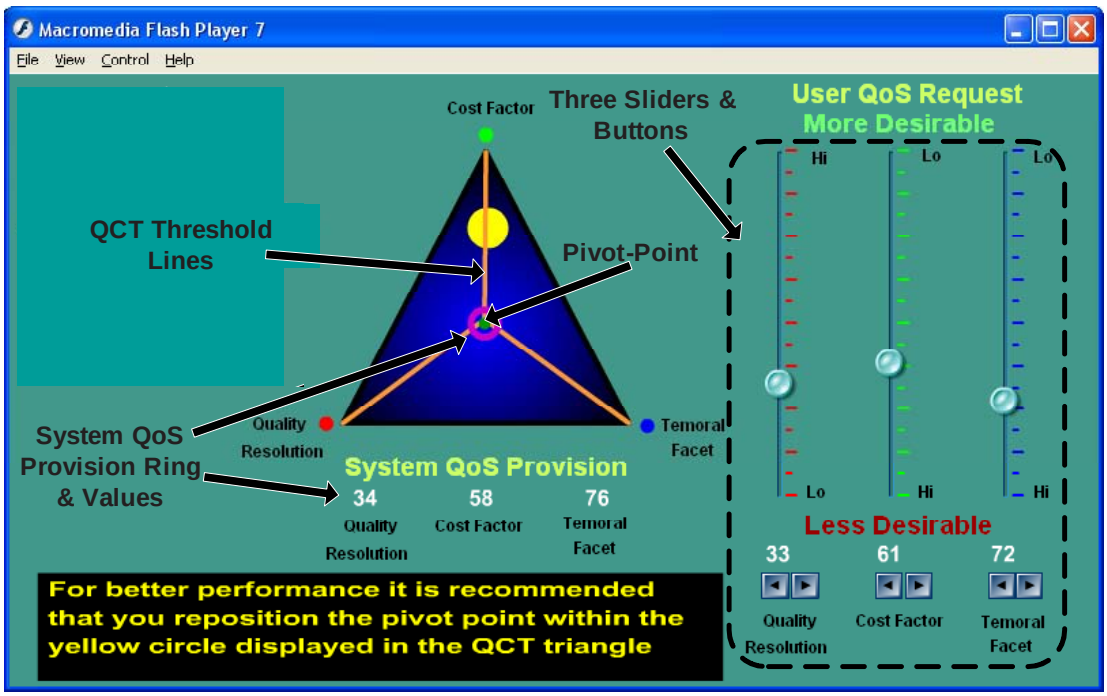

1. **QoS Provision Ring** displays the current QoS parameter values that the system is able to provide.
2. **QoS Provision** values display the current numerical values set for QoS parameters.
3. **QCT Threshold Line** uses a three-colour scheme to provide feedback for displaying desirable and non-desirable values for each aspect.

This system has been tested and a usability analysis has been carried out on the same. While some improvements have been stipulated in the current implementation, overall, it received good assessment from the users (Georgievski & Sharda, 2005a).

Quality of Service on the Move

The ability to provide the requested QoS while roaming will be an important aspect in differentiating various mobile operators. This will determine their ability to hold on to their customers and therefore their revenue stream.

Providing QoS to a customer on the move is highly complex. Factors such as continuous handover, variable quality, dropout, and environmental factors make delivery of consistent QoS highly problematic. QoS provisioning has three main aspects: (1) resource reservation, (2) QoS routing protocol, and (3) Call admission control policy.

The integrated services (IntServ) framework developed under the RFC 1633 aims to provide customised QoS to individual applications (Aggélou, 2003). This is based on two aspects:

1. **Resource Reservation:** Each router needs to know the amount of buffer space and link bandwidth it needs to reserve for a session.
2. **Call Admission:** Each router determines the resources already committed to current sessions it is serving, before accepting the request from a new session.

QoS routing is the most important protocol for mobile networks, the main objective specified for this protocol in the RFC 2386 are:

1. **Dynamic Determination of Feasible Paths:** This is based on policy and cost constraints.
2. **Optimisation of Resource Usage:** This requires state-dependent routing schemes.
3. **Graceful Performance Degradation:** This aspect compensates for transient inadequacies using the state-dependent routing scheme.

In summary, a mobile network needs the ability to reserve resources, ensure that a new call is admitted only if enough resources are available, choose the most suitable path to optimise the utilisation of resources, and provide graceful degradation in performance as resources become overloaded.

Quality of Services in Mobile Ad-Hoc Networks

Mobile ad-hoc networks are becoming an important area of investigation. As routing paths are not fixed in an ad-hoc network, QoS routing becomes an even more dynamic problem (Aggélou, 2004). In any ad-hoc network, a variety of routes with differing node capacity and power may be available to transmit data to the destination.

In general, not all routes are capable of providing the required QoS to satisfy the needs of the mobile users. Even when a route is selected that initially meets the user requirements, its error characteristics will not remain constant with time, due to the dynamic nature of routing and node placement in mobile ad-hoc networks. Therefore, ongoing re-routing will be required in an ad-hoc mobile network.

MOSQUITO: Mobile Quality of Service Provision in the Multi-Service Network

The MOSQUITO project, at the University College London, explored a microeconomic approach to resource allocation for providing QoS over multi-service network.

In this protocol, a base station sells bandwidth and QoS guarantees in small auctions to mobile terminals. A simple price setting / bidding function is used to determine the outcome of the auction. This research project aims to explore if:

- Microeconomics can be used for resource allocation.
- The performance of such a system can be measured.
- The algorithm creates a stable system or a chaotic one.
- Chaos can be characterised and controlled.

To use microeconomics for QoS provisioning, such questions need to be answered. Additionally, pricing functions need to be established using some simplifying assumptions; because, without simplifying heuristics, the juxtaposition of a myriad of factors such as pricing, routing, and quality selection will make real-time negotiations impossible.

FUTURE DIRECTIONS

There is no doubt that the future is heading towards mobile communications. And multimedia information will increasingly become the main traffic being transmitted, or blocked, on these networks. One solution to this problem is the so called "brute force" method: that is, "throwing" more bandwidth at the multimedia applications. However, experience shows that as more resources are made available without a viable economic model, the system ultimately gets overloaded. Therefore, developing QoS systems that provide the user with the ability to negotiate with the network infrastructure are going to be of paramount importance.

Some of the developments in this area point to the following:

1. In the near future, mobile computing and communication systems will suffer from low bandwidth and low performance due to battery limitations.
2. Increasingly, mobile systems will provide higher bandwidth and combine different wireless technologies, such as high performance local wireless networks and wide area networks.
3. Third generation mobile systems will combine IP-traffic with traditional voice traffic.

The next generation of mobile networking technology is called 4G, or "3G and beyond" by IEEE (Aggélou & Tafazolli, 2001). In Japan, NTT DoCoMo is conducting tests under the 4G banner for 100 Mbps speeds with moving terminals, and 1 Gbps for stationary terminals. The first commercial release by NTT DoCoMo is expected in 2010. This technology aims to provide on demand high quality video and audio. 4G will use OFDM (orthogonal frequency division multiplexing), and also OFDMA (orthogonal frequency division multiple access) to better allocate network resources, and service multiple users simultaneously. Unlike the 3G networks, which use both circuit switching and packet switching, 4G will use packet switching only. Additionally, many QoS issues will be handled by developing new protocols. Nonetheless, the author contends that providing the ability to negotiate a compromise between cost, quality, and temporal aspects will remain an important issue.

CONCLUSION

Transmission of multimedia information over mobile networks is becoming increasingly important. New applications are in the offing if such multimedia information can be transmitted with the desired QoS. Text and still images do not pose much problem when transmitting these over mobile networks, as delay and delay variance do not adversely effect the operation of applications using text or still images. JPEG 2000 standard provides a marked improvement over the current standards such as JPEG, GIF, and PNG for still image transmission. Audio and video transmission, especially for full-duplex applications requiring real-time operation, poses the most demanding requirements for providing the desired QoS. While 3G networks, and 4G networks of the future, are capable of providing the required infrastructure for delivering multimedia content with the desired QoS, their user interfaces need to provide the ability to strike the desired balance between quality, cost, and temporal aspects.

ABSTRACT

In this article we discuss how we have predicted the third generation (3G) customers using logistic regression analysis and statistical tools like Classification and Regression Tree (CART), Multivariate Adaptive Regression Splines (MARS), and other variables derived from the raw variables. The basic idea reflected in this paper is that the performance of logistic regression using raw variables standalone can be improved upon, by the use for various functions of the raw variables and dummies representing potential segments of the population.

INTRODUCTION

An Asian telecommunication operator which has successfully launched a 3G mobile telecommunications network would like to make use of existing customer usage and demographic data to identify which customers are likely to switch to using their 3G network.

The objective of this competition was to develop a prioritization mechanism that will accurately predict as many current 3G customers as possible from the "holdout" sample provided. It also involved identifying the profiles of 3G customers that can be used in identifying potential 3G customers among the existing second generation (2G) base.

The competition organizers were provided with a sample of 24,000 mobile phone subscribers, out of which customer type was provided for 18,000 subscribers, 15,000 being 2G and the rest 3G. Around 250 variables describing call and usage-related information was provided for all of the 18,000 subscribers. A holdout sample of another 6,000 subscribers was provided with the same set of variables, but without the 2G/3G flag. The task was to accurately predict as many 3G customers as possible from the holdout sample.

The organization of the article is as follows: We discuss the methodology approach taken and the modeling techniques used to develop the logistic model. Then we discuss the model results and the cutoff we have selected to generate the predictions. Finally, we discuss an alternative approach that we have tried.

METHODOLOGY APPROACH MODELING METHODOLOGY

The modeling approach used for determining the 3G customers is a combination of logistic regression, CART, MARS, and other derived variables. The CART and MARS are modeling tools of Salford Systems. This combination is an improvement over the logistic regression model with raw variables only. The potential segments of the population are identified by CART, and potential splines for various important variables obtained by MARS are used along with the other variables. Logistic regression is used as the dependent variable is dichotomous (reference Hosmer W. David, Stanley Lemeshow: Applied Logistic Regression, Wiley, New York (1989) Chapter 1 Pages 8-10, Chapter 2 Pages 25-29). In addition, we have selected specific segments of some of the raw variables, which have very high or low event rates.

The variables obtained from CART are indicators of potential segments of the population. By potential segments, we mean segments of population with very high or low event rates. These indicators are used in the logistic model as independent variables. MARS, on the other hand, generates splines from variables, thereby capturing important segments of a variable. These splines, termed as basis functions, are then used in the logistic model. Some variables have a very high or low event rate in a particular range. We have analyzed these ranges and created segments to be used as independent variables in the model. The CART, MARS, and other derived variables, when included in the model, show a higher predictive power than what is obtained from the raw variables standalone.

Once the CART and MARS variables have been included, a stepwise logistic regression is used to reach an optimum model. The stepwise regression is used for the sake of parsimony as the number of variables (raw, CART, MARS, and derived variables combined) is large, thereby creating a scope of overfitting. Moreover, by using a stepwise procedure it is ensured that the variables in the model are all significant at the desired level. The variance inflation factors of each of the variables entering the model are scrutinized in order to prevent multi-collinearity.

MODELING TECHNIQUES USED: MISSING IMPUTATION AND OUTLIER TREATMENT

In order to prepare the population for building the model, missing values had to be imputed and outliers had to be smoothed out. Missing imputation is done on variables which have less than 70% missing values. Variables with more than 70% missing values are omitted. The respective medians of the variables are used for the missing imputation.

Outlier treatment is done for variables with high and/or low extreme values. Variables with maximum/99th percentile ratio greater than 5, and those with 1st percentile/minimum ratio greater than 5 are considered for outlier treatment. The outlier treatment is done using exponential smoothing. The higher outliers are treated as follows:

If observation > 99th percentile then observation = (99th percentile)$^{(4/5)}$* (observation)$^{(1/5)}$

The lower outlier is treated as follows:

If observation < 1st percentile then observation = (1st percentile)$^{(4/5)}$* (observation)$^{(1/5)}$

For variables with 1st percentile as 0 and minimum less than 0, all observations less than 0 are set to 0.

CART

The CART is used to build a classification tree on the population to find segments with very high and low event rates. The modeling population selected for building the CART tree is a 66.67% simple random sample without replacement of the overall population, on which missing imputation and outlier treatment have been done. The remaining 33.33% is used as a validation sample. The target variable is 0 if the customer is 2G and 1 if 3G. CART trees are built on this modeling sample (see Figure 1).

Figure 1. A typical snapshot of a CART run

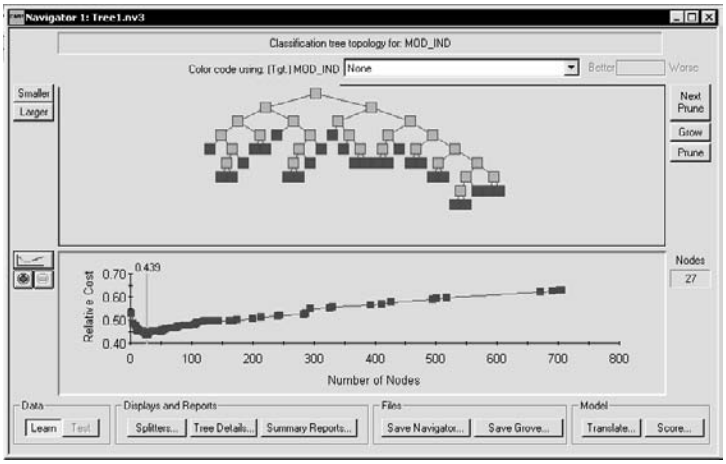

Figure 2. An example of a terminal node

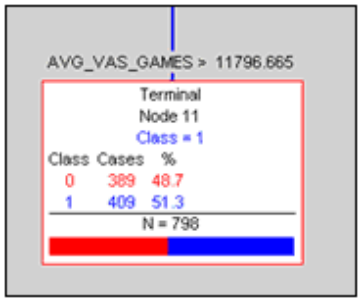


Each node of the CART tree would give a segment of the population. The terminal nodes together would divide the population into a set of mutually exclusive and exhaustive segments (see Figure 2).

The modeling population has an event rate of 16.7%, but the population segment captured by this terminal node has an event rate of 51.3%. Terminal nodes with very high (as in the previous case) or very low event rates would be used in the logistic model as independent variables. For this purpose, indicator variables are created using the logic that CART has used to arrive at the terminal node. The translation generated by CART is a sas code that creates nodes and terminal nodes and is used to make these indicator variables.

MARS

MARS is used to create spline transformations of variables for use in the model, hence improving their accuracy. The core building block of a MARS model is the basis function transformation of a predictor variable X:

Basis function = Max(0, X-C) *where c is a constant discovered by the algorithm*

The value of this basis function is equal to 0 for all values of x up to a threshold c and equal to X-C for all values of x greater than c. The basis function defines a knot (c) where a regression changes slope.

The same modeling population that is used to build CART was used for MARS. The target variable was 0 if the customer is 2G and 1 if 3G.

A typical basis function would be

BF1 = max(0, HS_AGE - 4.000);

The basis functions are used in the logistic model as independent variables.

OTHER DERIVED VARIABLES

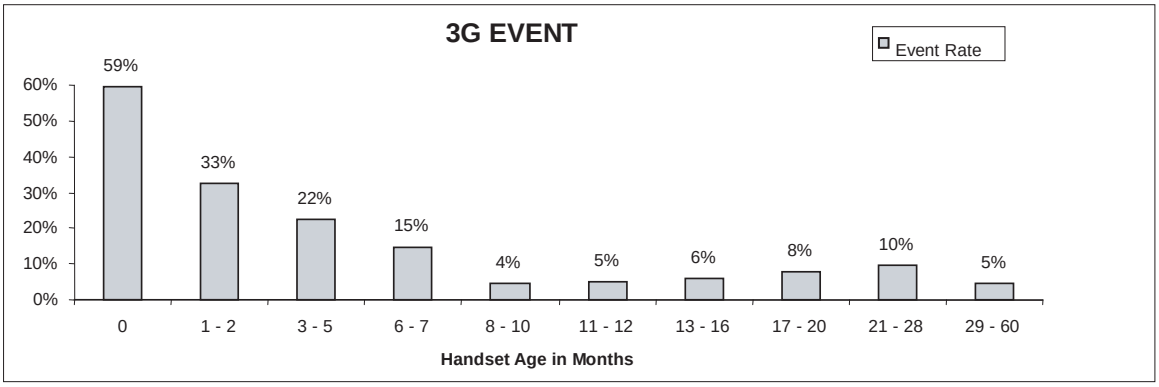
Some variables are derived by analyzing bivariate plots of various variables with the dependent variable. The plots are created by dividing the range of a variable into 10 to 20 bins and computing the event rates at each of those bins. Indicator variables are created for bins with very high or very low event rates. A typical example of such a derived variable is shown in Figure 3.

From the plot in Figure 3 we see that the event rate is very high when the handset age is 0 months. Hence, we can create an indicator variable for the 0 bin and use it in the model.

MODEL RESULTS MODEL PERFORMANCE

A logistic model is built on the modeling population to predict whether a given customer is 3G or 2G. The model consists of nine variables. All the variables are accepted at 99.95% level of significance. The concordance is becoming as high as 90.6%. The variables showed negligible multi-collinearity among themselves, which is reflected by the fact that the highest variance inflation factor is 1.74. The Ks statistic is becom-

Figure 3. Bivariate plot for handset age in months



ing 68% at the 25th percentile for the modeling population and 65% at the 20th percentile for the validation population. The Hosmer-Lemeshow statistic is 6.7852 with 0.56 p-value.

MODEL VARIABLES AND SIGNIFICANCE

The most important variable appearing in the model is the *handset model.* Three subsegments of the population with a high 3G rate appeared in the model, of which, two were becoming the most important variables, in terms of percentage variation explained. Subsegments with a low average billing amount over the last 6 months, low variation in usage of games, and low handset age are also becoming important. The ongoing hypotheses and results for the variables entering the model are stated as follows:

Handset model. Customers who have bought 3G-enabled handsets have a higher chance of making a 3G connection. Indicator variables for three segments based on handset age are entering the model. All of these variables show a high positive effect on 3G enrollment and together they capture 53% of the variance in the model.

Low average bill amount over the last 6 months. Customers with lower usage have a lower chance of making a 3G connection. This variable shows a small negative effect on 3G enrollment and captures 11% of the variance in the model.

Low handset age. Customers who have bought a handset very recently have a higher chance of making a 3G connection. As discussed in section 2.2.4, low handset age shows a positive effect on 3G enrollment and captures 10% of the variance in the model.

Low variation in usage of games. Customers who are not used to accessing games on mobiles have a lower chance of making a 3G connection. This variable shows a very small negative effect on 3G enrollment and captures 8% of the variance in the model.

High number of retention campaigns in the last 6 months. Customers who have received a higher number of retention campaigns have

a higher chance of making a 3G connection. This variable shows a negative effect on 3G enrollment and captured 7% of the variance in the model.

Segments with a high usage of games and subscription plans with a high 3G rate. Customers accessing games on mobiles and those that have certain subscription plans have a higher chance of switching to the 3G connection. The indicator variable created for this segment shows a considerably higher positive effect on 3G enrollment and captures 6% of the variance in the model.

Low variation in usage of GPRS. Customers who do not use GPRS are less likely to use the 3G connection. This variable shows a very small negative effect on 3G enrollment and captures 5% of the variance in the model.

MODEL CUTOFF

The model accuracy is maximized at a 90th percentile cutoff, but it captures only around 53% of the 3G customers. There is a steep increase in sensitivity up to the 75% percentile of the predicted probabilities, after which it plateaus. Specificity falls steeply after the 80th percentile of the predicted probabilities. The sensitivity, specificity, and accuracy are shown in Figures 4 to 6.

From Figures 4, 5, and 6 we find that the best results for specificity, sensitivity, and accuracy are obtained in the 75th - 80th percentile of the scores. Given the fact that the event rate is 16.7% we choose to go with the 80th percentile. Hence, customers who are falling in the top 20% of the model score have been assigned as potential 3G customers. The lift at the top of the 20% cutoff is becoming 76% for the modeling population and 74% for the validation population.

CONTINGENCY TABLE OF THE CUTOFF

The modeling population consists of 11,955 records. Based on the top 20% score cutoff we get 481 3G customers misclassified as 2G, 867 2G

Figure 4.

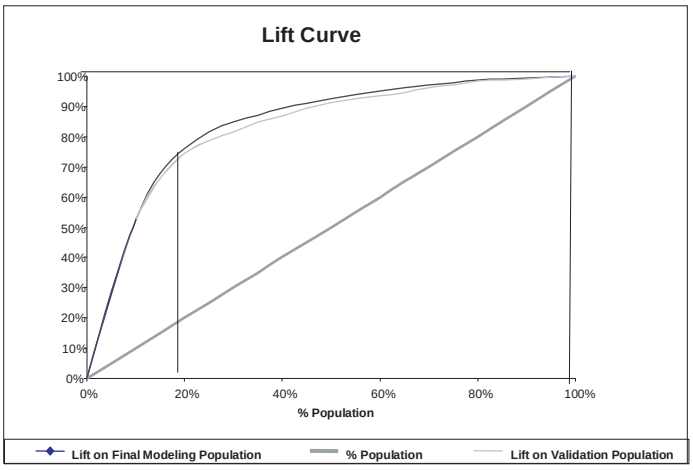


Figure 5.

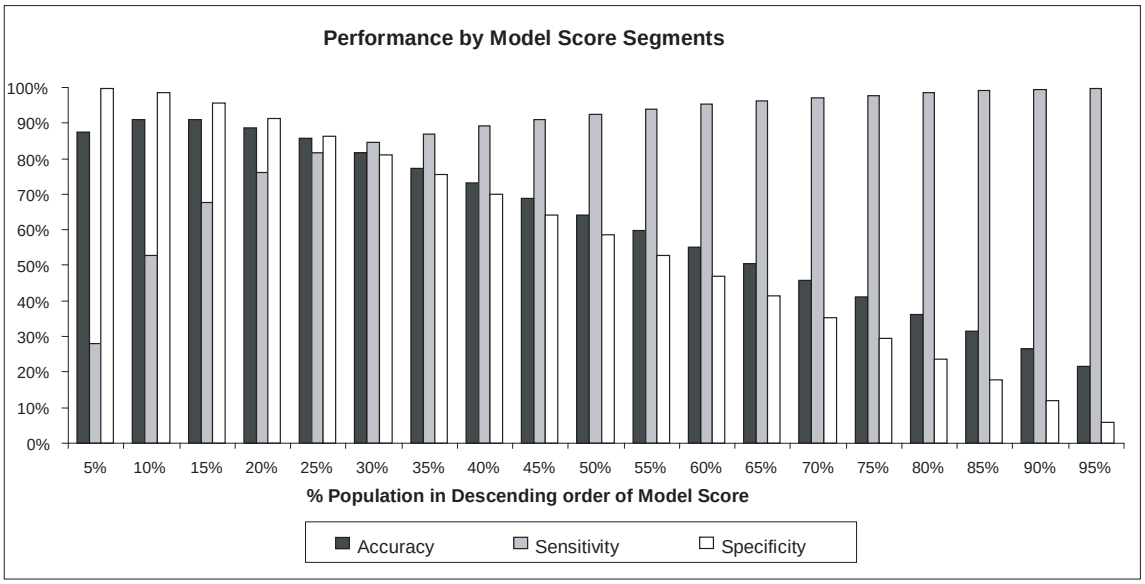

Figure 6.

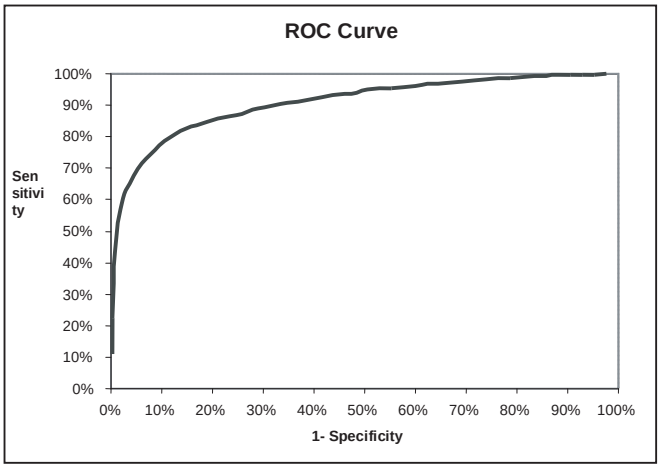

customers misclassified as 3G, 9,088 customers correctly classified as 2G and 1,519 customers correctly classified as 3G. The predictions on the modeling population have an accuracy of 89%, a sensitivity of 76%, and a specificity of 91%. The definitions of accuracy, sensitivity, and specificity are shown in Table 1.

Table 1.

	Actual Event (1)	Actual Non-Event (0)
Predicted Event (1)	True Positive (TP)	False Positive (FP)
Predicted Non-Event (0)	False Negative (FN)	True Negative (TN)

Sensitivity = TP / (TP + FN)
Specificity = TN / (TN + FP)
Accuracy = (TP + TN) / (TP + TN + FP + FN)

The validation population consists of 6,045 records. Based on the same score cutoff as the modeling population, we get 266 3G customers misclassified as 2G, 434 2G customers misclassified as 3G, 4,611 customers correctly classified as 2G, and 734 customers correctly classified as 3G. The predictions on the validation population have an accuracy of 88%, a sensitivity of 73%, and a specificity of 91%.

COMPARISON WITH MODEL USING RAW VARIABLES

The model using CART dummies, MARS basis functions, and other derived variables along with the raw variables (MODEL 1) is performing better than the best model obtained using raw variables standalone (MODEL 2).

MODEL 2 is a 10-variable model with a concordance of 84.3% where as MODEL 1 is a 9 variable model with a concordance of 90.6%. Moreover, MODEL 1 gives a lift of 76% for the modeling population, as compared to a 63% lift achieved from MODEL 2.

ALTERNATIVE APPROACH

An alternative approach is tried while building the model after creating all the derived variables that are discussed in earlier sections. Instead of building a single logistic model on the entire modeling population, various subsegments of the population are taken and a separate logistic model is built on each of them. The ongoing hypothesis behind this approach is that the population may show more homogeneity within proper subsegments and hence a model based on a particular subsegment may have more predictive power as compared to the overall model.

The subsegments are derived using CART. The final segmentation chosen for this approach is based on average billing amount in the last 6 months. Based on this variable the modeling population is segmented into two parts. One part (PART A) contains 44.5% of the population and has a 3G event rate of 28.46%, and the other part (PART B) contains 55.5% of the population and has a 3G event rate of 7.32%.

The model built on PART A consists of 9 variables and had a concordance of 88.30%, whereas the model built on PART B consists of

10 variables and had a concordance of 87.20%. The combination of these two models gives an overall lift of 75.05% at a top 20% cutoff on the modeling population. The overall summary of classification is as follows:

Accuracy = 88%
Sensitivity = 75%
Specificity = 91%

The combined model using this approach shows a slightly inferior predictive power as compared to the overall model. Hence, we have decided to use the overall model.

CONCLUSION

In this article we have discussed the various techniques used to improve upon the predictive power of a logistic regression model by implementing various types of variables.

We have discussed how the raw data is cleaned by imputing missing values and treating for lower and upper outliers. We have then discussed how to create indicator variables for potential segments of the population that are captured by CART and use these variables in the logistic model. We have also discussed how basis functions derived from MARS are used in the model. Furthermore, we have other derived variables that are obtained by analyzing the bivariate plots of various important variables with the dependent variable.

After this, we have discussed the ongoing hypotheses and the effect on 3G enrollment of various independent variables that appear in the final logistic model. We have discussed the cutoff used for this model and the various analyses like lift curve and receiver operating characteristic (ROC) curve that have guided us to the cutoff point. We have looked at the various results like sensitivity, specificity, and accuracy, from the contingency table of the cutoff, for both the modeling and the validation population.

We have concluded our discussion by showing that the model we have built is indeed better as compared to the model using raw variables.

Chapter 7.22
Mobile Phone Customer Type Discrimination via Stochastic Gradient Boosting

Dan Steinberg

Nicholas Scott Cardell
Salford Systems, USA

ABSTRACT

Mobile phone customers face many choices regarding handset hardware, add-on services, and features to subscribe to from their service providers. Mobile phone companies are now increasingly interested in the drivers of migration to third generation (3G) hardware and services. Using real world data provided to the 10th Pacific-Asia Conference on Knowledge Discovery and Data Mining (PAKDD) 2006 Data Mining Competition we explore the effectiveness of Friedman's stochastic gradient boosting (Multiple Additive Regression Trees [MART]) for the rapid development of a high performance predictive model.

INTRODUCTION

The PAKDD 2006 Data Mining Competition required the analysis of real world data from an industry that includes people of all ages and walks of life. In economically developed regions it is increasingly common for elementary school children to have their own mobile phones, and mobile communication is now preferred over fixed lines for undeveloped regions. Evolving 3G technologies offer a considerable expansion of the communication services routinely supported by mobile phone networks to include multi-player games, video conferencing, and enhanced Web browsing. Excitement over 3G technology has

waxed and waned since 2000 as the early promises were not fulfilled, but 3G is now becoming a fixture of the global mobile marketplace. Thus, a competition focused on analysis of 3G mobile phone customers is both topical and readily understood by data analysts, modelers, and business decision makers from all industries.

This Salford Systems report is organized as follows. In the first sections we offer our understanding of the competitive challenge, the data available, and how we framed the modeling objectives. The competition organizers have provided their own description of the nature of the modeling challenge and the data, but we believe that our perspective on these topics is somewhat different and is thus needed to explain our strategy. In the second section we provide a summary of the key descriptive statistics that gave us our initial picture of the nature of the data and its adequacy for modeling purposes. The third section describes our modeling methods and reports our results and performance based on the labeled data. The fourth section delves further into the results to examine specific findings at the predictor level. Finally, the last section summarizes our results and offers conclusions.

THE MODELING CONTEXT

The data provided for the PAKDD 2006 modeling competition consisted of summary data for each of 18,000 customers of an Asian mobile phone service provider. The data included customer demographics, a calling plan indicator, 6-month summaries of calling behavior, handset characteristics, summaries of billing amounts and late payment patterns, and other communication-related behavior, including Web, e-mail, and game usage. The training data came in the form of a flat file containing 252 columns, with 15,000 rows drawn from second generation (2G) customers and 3,000 rows drawn from 3G customers. In addition, a further 6,000 rows of prediction set data were provided in the same format, but with the 2G/3G flag suppressed. Essentially, the competition required the development of a classification model learned from the training set able to predict the 2G/3G class membership of the customers in the prediction set. However, some fine points regarding the competition require elaboration.

In predictive modeling of a binary (2 class) outcome, a number of performance criteria have been discussed extensively in the literature. For example, Caruana (2004) discusses cross-entropy (likelihood), the area under the receiver operating characteristic (ROC) curve, and classification accuracy in the context of the KDD2004 competition, and lift in a specified percentile was used as one performance criterion in the Duke/NCR Teradata 2002 churn modeling competition. In the PAKDD 2006 competition, the stated performance measure was classification accuracy, a metric that by itself appears to take no account of the ability of a model to properly rank order data from most probable to least probable 3G class membership. This competition had an important wrinkle, however. Classification accuracy was to be measured for the 3G class only. The competition organizers wanted to rule out the degenerate solution (all customers are 3G) as uninteresting, and also rule out what they termed "manipulated" solutions. A successful manipulated solution can be extracted from a model "that has strong rank ordering performance" by assigning the least probable customer to the 2G class and all others to the 3G class. This "solution" would have a high probability of yielding a perfect score on the 3G class, because even a moderately good model should be able to successfully identify a single 2G customer to place in the 2G class. Such a solution would presumably be disqualified as manipulated.

Less obviously manipulated solutions are possible, however. Given a good rank ordering of the customers by the probability of being 3G, a decision rule that assigns relatively few records to the 2G class should exhibit a high classifica-

tion accuracy rate for the 3G class. If the objective were average classification accuracy in the two classes, then the optimal decision boundary would be at P* = Prob(3G) = 1/6, assigning all customers with estimated Prob(3G)<1/6 to the 2G class, on the assumption that the population fraction of 3G is the same as observed in the training data, or 1/6. Finding a rationale to shift the decision boundary towards 0 would improve an entrant's chance of winning, provided that the solution did not strike the judges as manipulated. Possible rationales include weighting the costs of misclassification more heavily for 3G errors, perhaps on the basis of customer expenditures. We decided not to attempt this, however, because it is a form of manipulation. Instead, we used our classification tools employing unit costs and chose a decision threshold intended to maximize average within-class classification accuracy.

We were concerned that a competition entrant might successfully find and openly defend or even silently and surreptitiously deploy a "quasi-manipulated" winning strategy. Indeed, in the absence of a step-by-step review of winning entries, it would not be possible to tell if such hidden manipulation had been employed. (However, the top three winning outcomes were so close that it is reasonable to assume that all submitted nonmanipulated results.) Given these concerns as we prepared to enter the competition, we elected to make this competition into a speed contest. Our goal was to develop the best possible average accuracy classifier in a very short period of time. We managed to complete our data analysis in a single concentrated working day.

The organizers of this competition are to be commended for acquiring a substantial volume of real world customer data for public release. Such data can rarely be acquired without limitation. In this instance, the limitations pertain to the data fields made available, and to the descriptive information characterizing the data. We know that the data were drawn from the customer records of an Asian mobile phone provider, but we were not given the time period from which the data were drawn, and several valuable fields are provided with partial information only. For example, the nationality of the customer is listed as an uninformative numerical code, and similarly the countries most often called are also limited to numeric codes. We are provided with no information regarding the competitive landscape, the nature of the marketing campaigns for either 2G or 3G services, the pervasiveness of mobile phone use, or the overall 3G market share in the country or for the provider in question. These informational limitations severely restrict both the business value of any models developed and our ability to extract real-world insight into the workings of the marketplace or into consumer behavior.

What Can Be Learned from the Data?

The formal description of the competition data was confined to two pages. Therefore, we resorted to making plausible assumptions about its nature. We assumed that the data were gathered from a short time window. With 24,000 customers in total, such a sample could easily have been extracted from a single month's worth of retrospective account data. Our tests (reported hereafter) establish that the train and prediction sets were very likely drawn from the same customer population and from the same time period. From a business perspective the effort to predict 2G versus 3G in this context is of limited value. We would naturally expect that someone who goes to the trouble of acquiring a 3G handset and subscribing to a 3G plan would behave differently than someone who is content to use 2G hardware and services. Indeed, a powerful predictor of a customer being 3G is that they own a 3G-capable handset! From a business and marketing point of view, more valuable insights would be generated by studying the phone records of all customers at a point in time when 3G was not available with the goal of predicting

which 2G customers eventually migrated to 3G. However, the data available were gathered after the decision to go to 3G had been made. Thus, the modeling exercise is more properly thought of as a profiling effort in which a multivariate portrait of the behavioral differences between these two groups is extracted. We would agree that 2G customers who look like 3G customers (i.e., have a high estimated probability of being 3G) are prime candidates for an up-sell marketing campaign, but we would also want the service provider to investigate the primary reasons such customers have not already switched. The data made available for this competition have been generated via a classic self-selection process that can strongly bias the results of a model intended to predict the future probability of a 2G customer's migration to 3G. Extensive literature in statistics has been devoted to the selection bias topic, but is not one that can be addressed within the confines of this report (see, for example, Rosenbaum & Rubin, 1983).

DATA OVERVIEW

To get a better grasp of the data we grouped the available predictors into the following illustrative categories (not all variables are listed here):

Basic demographics: age, nationality, marital status, occupation

Handset related: model, manufacturer, duration owned, times changed

Calling plan related: plan ID, high end status, number of lines, line tenure

Payment behavior: delinquency, blacklisted, suspended, amount overdue

Special features: games, e-mail notification, WAP, GPRS, citiguide, picture xmit

Call behavior/bill detail: SMS, voice/data, inbound/outbound, 900 numbers,

peak/off-peak, roaming, forward, extranet, fixed/mobile, countries called

For the call behavior and bill detail variables, statistical measures summarizing the last 6 months were provided, including total, average, and standard deviations, and counts of certain events such as payment delinquency were included. While this represents substantial information it should be clear from this listing that a great deal of information was suppressed for both convenience and confidentiality. In a real-world consulting environment, a modeler would also have had access to postcode, as well as to month-by-month account details from which trends, minima, maxima, and other statistics could be extracted.

Conventional inspection of the data revealed no obvious errors or problems requiring repair prior to productive analysis. Missing values were evidently not a problem, either. While the variables recording the three most frequently called countries were heavily missing, this simply reflected the fact that most customers did not use their mobile phones to call out of country at all; therefore, we added new predictors to capture this information. The occupational code is missing in 63.41% of the training data, a genuine lack of information. The 11 remaining variables with missing values are listed in Table 1; certainly there

Table 1. Missing value prevalence by variable

Variable	%Missing
MARITAL_STATUS$	5.79%
CONTRACT_FLAG	5.07%
DAYS_TO_CONTRACT_EXPIRY	5.07%
PAY_METD$	4.92%
PAY_METD_PREV$	4.92%
HS_MODEL	2.94%
HS_MANUFACTURER	2.89%
AGE	2.71%
TOT_DEBIT_SHARE	1.51%
NATIONALITY	0.11%
GENDER	0.02%

is no reason to be concerned about the prevalence of missing values.

To ascertain the elementary predictive power in the data we conducted variable-by-variable statistical tests, using difference of means *t*-tests for continuous and binary flag variables, and chi-square tests for multi-level categorical predictors. The *t*-statistics for the difference of means tested are displayed in Figure 1, sorted in descending order with the X-axis listing the variable rank. (This diagram was inspired by Tusher, Tibshirani, & Chu, 2001.)

Conducting a simple *t*-test for each continuous or binary flag variable shows that almost all variables exhibit a *t*-statistic greater than two, and that 169 variables exhibit a *t*-statistic greater than three. Among the categorical predictors we find two overwhelmingly powerful predictors in handset type, (HS_MODEL, df=332 , Chi-square=6657.72), and calling plan (SUBPLAN, df=65, Chi-square=2002.33). Thus, we have an abundance of apparently useful predictors and should expect our final model to be quite accurate.

From a business decision support perspective we would find some of these predictors painfully obvious: a person who elects to purchase a 3G handset is probably (but not certainly) a 3G customer; a person who elects a 3G calling plan is probably (but not certainly) a 3G customer; a person who makes heavy use of interactive gaming is probably a 3G customer. While not surprising, these factors turn out to be key components of 2G/3G discrimination in the models that follow.

Train Set Versus Prediction Set Data

When a prediction set is made available along with training set data we always find it useful to ascertain the degree of similarity or difference between

Figure 1. Distribution of difference of means t-statistics: 2G versus 3G customers

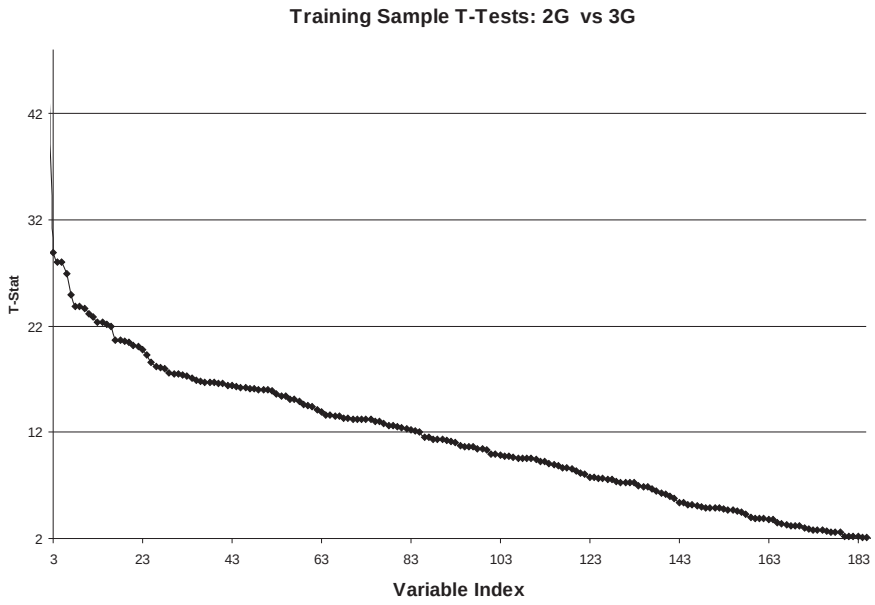

Figure 2. Distribution of difference of means t-statistics: Train versus prediction data

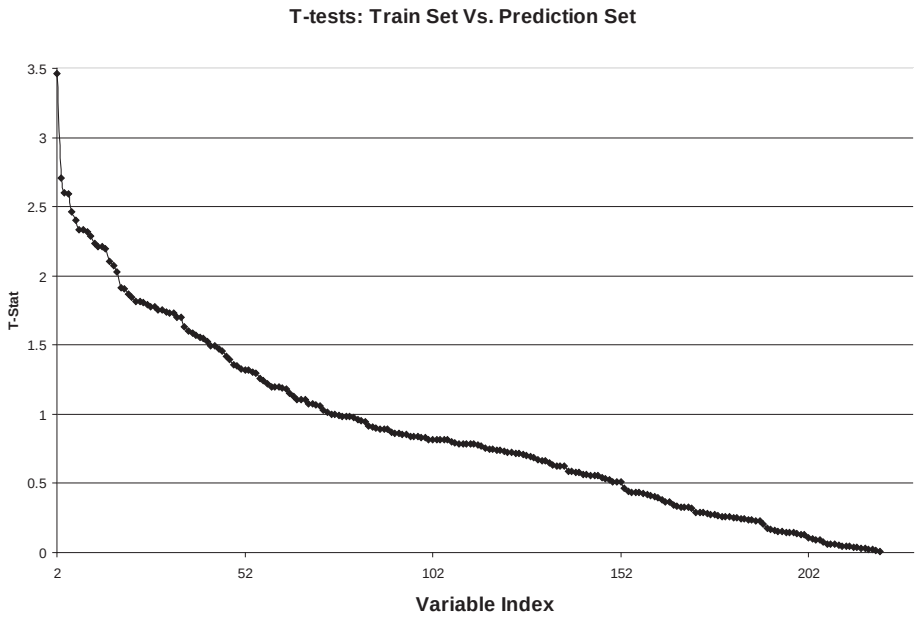

the two data sets. Comparisons can be conducted variable by variable and in a multivariate predictive model. Figure 2 displays the *t*-statistics from a test of train versus prediction set, where again the *t*-statistics are sorted in descending order and the X-axis lists the variable rank.

The good news here is that few substantial differences exist between the two samples. Only 16 variables display a *t*-statistic greater than 2, with the largest being 3.47. Given sample sizes of 18,000 train and 6,000 prediction set customers and 220 variables to test, one would expect to find 11 *t*-ratios greater than 2 due to chance alone. Among the categorical predictors only PAY_METD shows a marginally significant between-sample difference, with a *p*-value of .0458 Our conclusion is that there is no evidence that the train and prediction sets differ in any meaningful way.

Comparing Train and Prediction Sets via Modeling

For this test we concatenated the two data sets and used the sample indicator (Train_Predict) as the target in a multivariate modeling exercise. We used the Classification and Regression Tree (CART) (Breiman, Friedman, Olshen, & Stone, 1984; Steinberg & Colla, 1995) to automatically build this model and found virtual unpredictability: If we choose a record at random from one of these two sets it is not possible to predict which set the record came from. Figure 3 displays the results of the CART analysis. The upper panel contains

Figure 3. CART test of ability to discriminate between train and prediction data

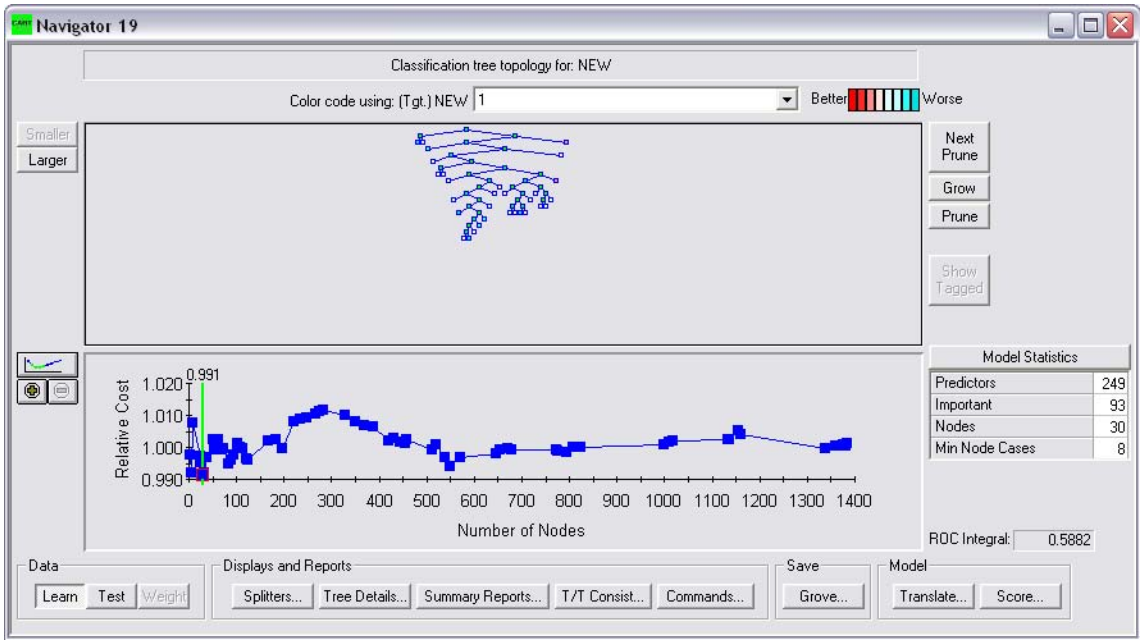

Table 2. Confusion matrix: CART model to discriminate between train and prediction data

Actual Class	Total Cases	Percent Correct	0 N=6084	1 N=5869
1	3,032	49.77	1,523	1,509
0	8,921	51.13	4,561	4,360
Total:	11,953.00			
Average:		**50.45**		
Overall % Correct:		**50.78**		

the tree topography for the optimal tree and the lower panel graphs the relative test error for the train versus predict set discrimination problem. The relative error never dips below .991, indicating an inability to discriminate between the two data sets. Table 2 contains the confusion matrix for the best of these models.

Confusion Matrix—Test Data—Count

Testing was conducted by dividing the data into equal-sized train and test partitions. The CART model shows negligible predictability at the optimal tree size, strongly supporting our hypothesis that both datasets come from the same population of customers.

Data Preparation: Compressing Categorical Variables

As we noted previously, the categorical predictors HS-MODEL and SUBPLAN are highly predictive of CUSTOMER_TYPE all by themselves. These predictors are somewhat awkward to use in their raw form because of the large number of levels in each, many of which have relatively low representation in the data. The HS_MODEL lists 332 different handset models in the training set, 60 of which contain only a single customer, and 182 of which list fewer than 10 customers each. Similarly, SUBPLAN lists 66 plans, 22 of which have fewer than 10 customers each. For convenience, interpretability, and reliability we elected to compress these predictors into new variables with substantially fewer levels.

To compress HS_MODEL and SUBPLAN we grew CART *probability* trees, using CUSTOMER_TYPE as the target and the variable to be compressed as the sole predictor. (Supervised binning via decision trees, for continuous predictors, is discussed by Dougherty, Kohavi, & Shamai, 1995—the extension to categorical predictors is quite natural.) We divided the data into equal learn/test partitions to assess model performance. Such a supervised compression group levels with similar mixes of 2G/3G customers. In

Figure 4. CART model to compress HS_MODEL

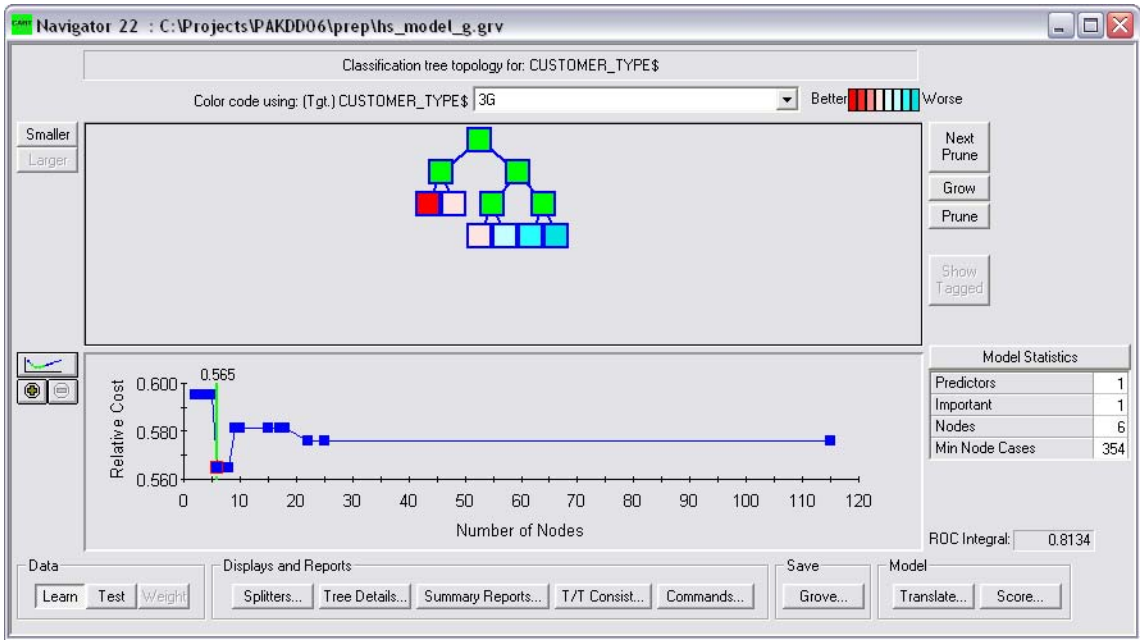

Figure 5. Lift ratios in CART terminal nodes for compressing HS_MODEL

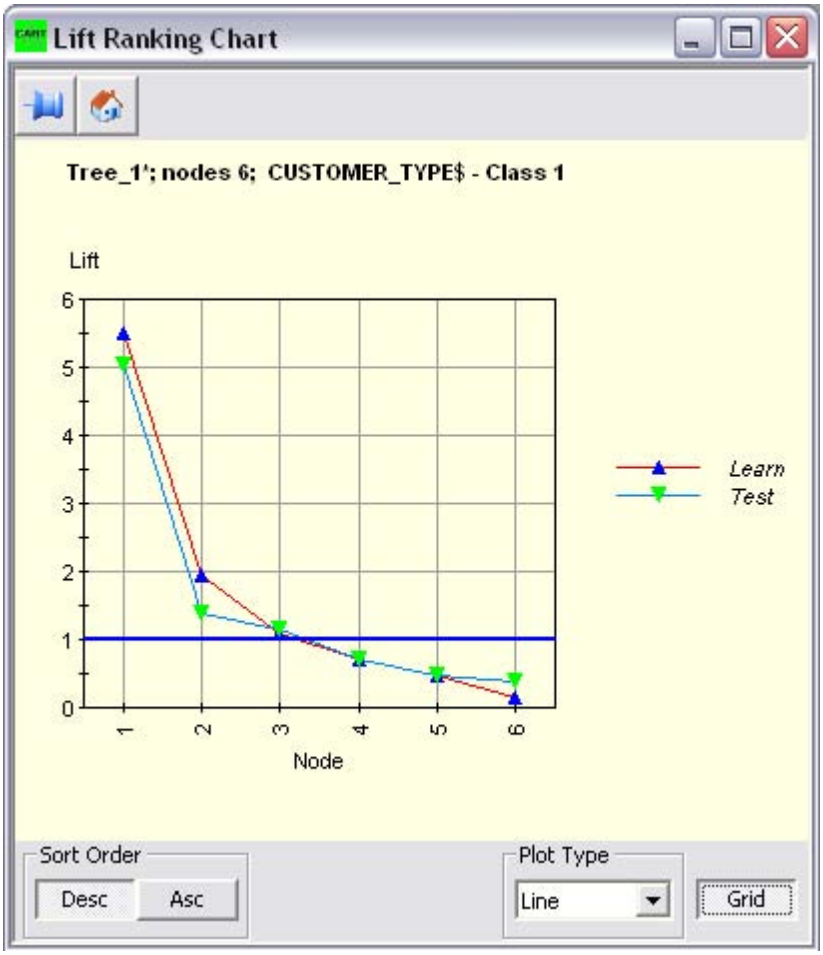

Figure 4 we see that HS_MODEL compresses nicely to just six groups; the 3G/2G lift ratios in each group (relative to the population baseline) are displayed in Figure 5.

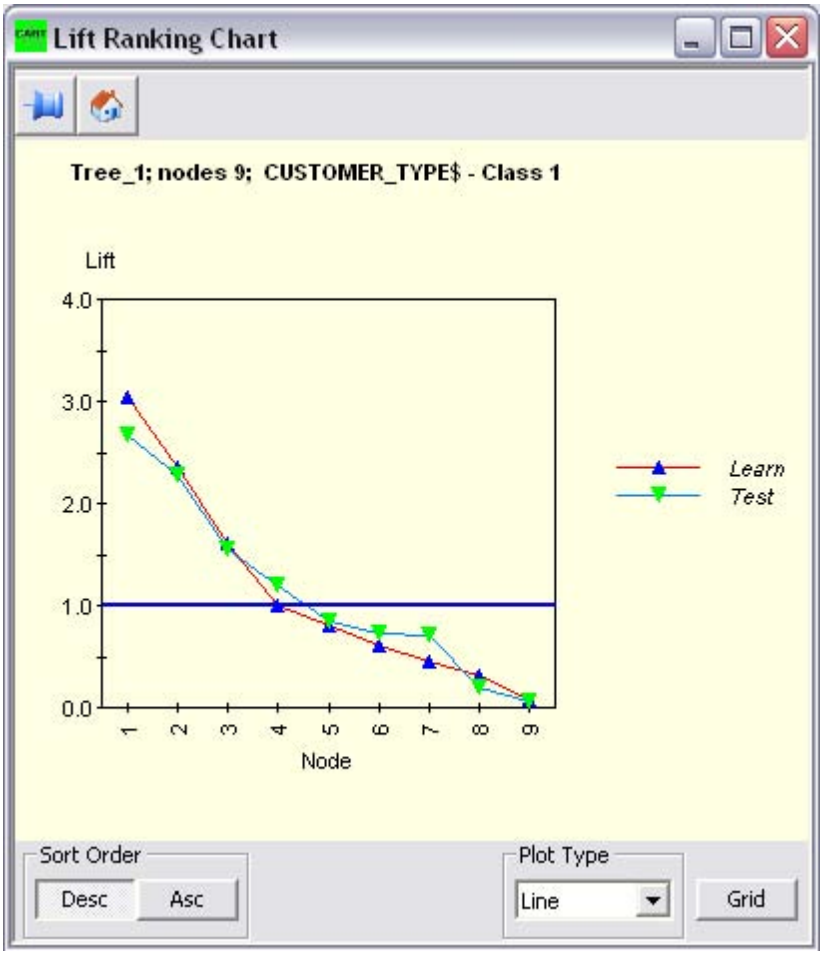
The same procedure was used to compress the SUBPLAN variable into nine separate groups. The lift ratios are presented in Figure 6.

MODELING

Single Tree CART Models

We began our analysis with CART trees to obtain a quick initial insight into the data via its visual displays and variable importance rankings. A display of the tree pruned back to seven nodes is

Figure 6. Lift ratios in CART terminal nodes for compressing SUBPLAN



shown in Figure 7, where a *black* terminal node indicates above-average probability of 3G (and thus assignment to the class 3G) and a *gray* terminal node indicates below-average 3G probability (and thus assignment to class 2G). The tree reveals that customers with older handsets tend to be 2G, as do those with more recent contracts (having longer durations before expiry). More game time is also associated with greater probability of 3G. While none of this is surprising, it is always reassuring to have core expectations ratified before moving on to more complex modeling methods.

The first CART models yielded cross-validated average class accuracies of about 81.28%, as shown in Table 3. The CART cross-validated area under the ROC curve was 0.8581.

Figure 7. Primary splitters in single CART tree to predict 2G/3G

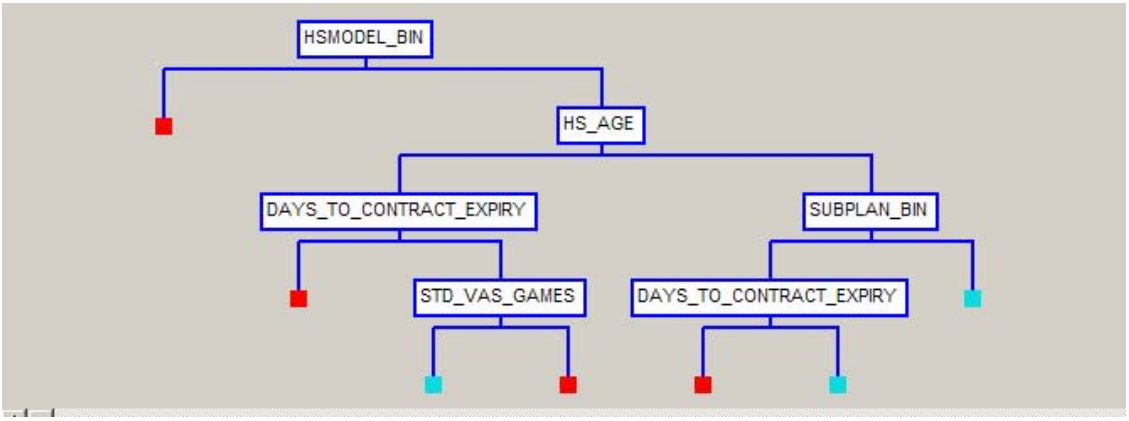


Table 3. Confusion matrix: CART model to discriminate between 2G and 3G customers. Cross-validation estimates

Actual Class	Total Cases	Percent Correct	2G N=13763	3G N=4237
2G	15,000	86.89	13,033	1,967
3G	3,000	75.67	730	2,270
Total:	18,000.00			
Average:		81.28		
Overall % Correct:		85.02		

CART Model Confusion Matrix—CV Test—Count

Splitting the data into 80% learn and 20% test partitions yields a similar class average accuracy of 80.12%, and an area under the ROC curve of .8451.

The most important variables as ranked by CART appear in Table 4.

Boosted Trees: TreeNet Models

We next moved on to stochastic gradient boosting models (Friedman, 2001), using the TreeNet™ (Salford Systems, 2005) commercial release of Friedman's MART™. Our primary reason for doing so was that tree ensembles often outperform single trees, and TreeNet in particular is able to extract small amounts of predictive information

Table 4. Variable importance rankings for CART model to discriminate between 2G and 3G customers where we see HS_MODEL ranked most important and SUBPLAN ranked third

Variable	Score
HS_MODEL	100.00
HS_AGE	69.17
SUBPLAN	22.95

AVG_MINS_MOB	8.73
AVG_MINS_OBPK	8.64
AVG_CALL_OB	8.60

from a large collection of predictors such as we have in this challenge. Also TreeNet tends to yield stable results in its variable importance rankings and predictive scores.

Using a slow learn rate, 241 predictors, and tuning the model to optimize for average class accuracy, we obtained the TreeNet summary report of Figure 8.

Figure 8. Summary report for TreeNet model displaying model performance versus number of trees

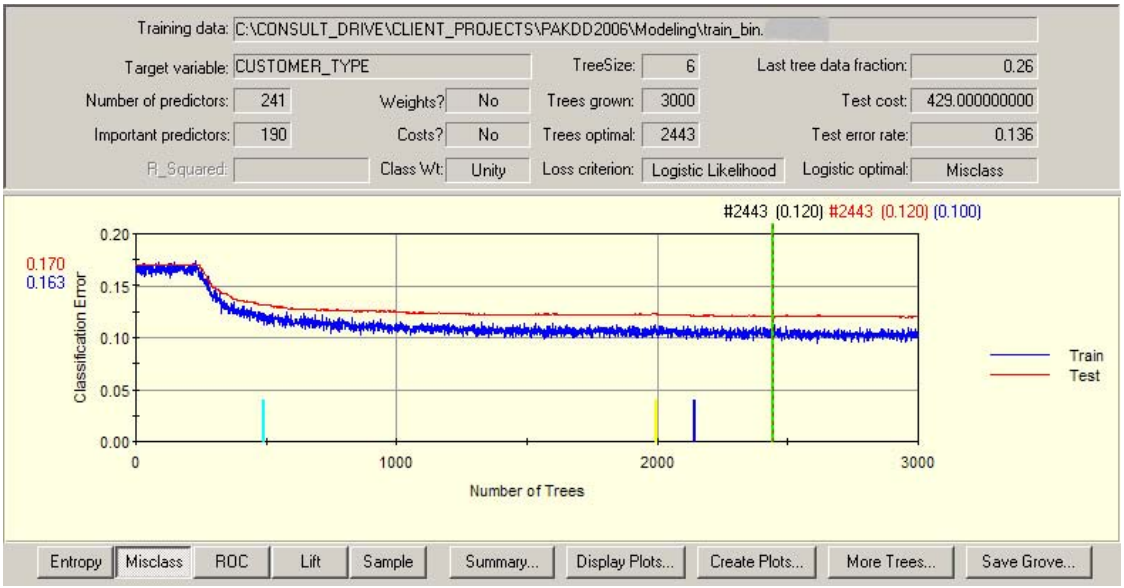

Table 5. Confusion matrix: TreeNet 6-node model for 2G versus 3G

Actual Class	Total Cases	Percent Correct	2G N=13763	3G N=4237
2G	2975	84.24	2506	469
3G	611	79.71	124	487
Total:	3586			
Average:		81.98		
Overall%Correct		83.46		

The default tree size of six nodes is adequate for capturing 3-way (and possibly some 4- and 5-way) interactions and yields in an area under the ROC curve of .907 on test data. Because this result is a good deal better than our best single CART tree, we were persuaded to use TreeNet scores as the basis of our classification scheme. In terms of average classification accuracy (Table 5) the model is only slightly better than the single CART tree.

TreeNet Confusion Matrix—20% Test—6-node Trees

To test whether interactions are needed at all in this model we re-ran our model restricting the tree

Figure 9. TreeNet Confusion Matrix—20% Test—2-node trees

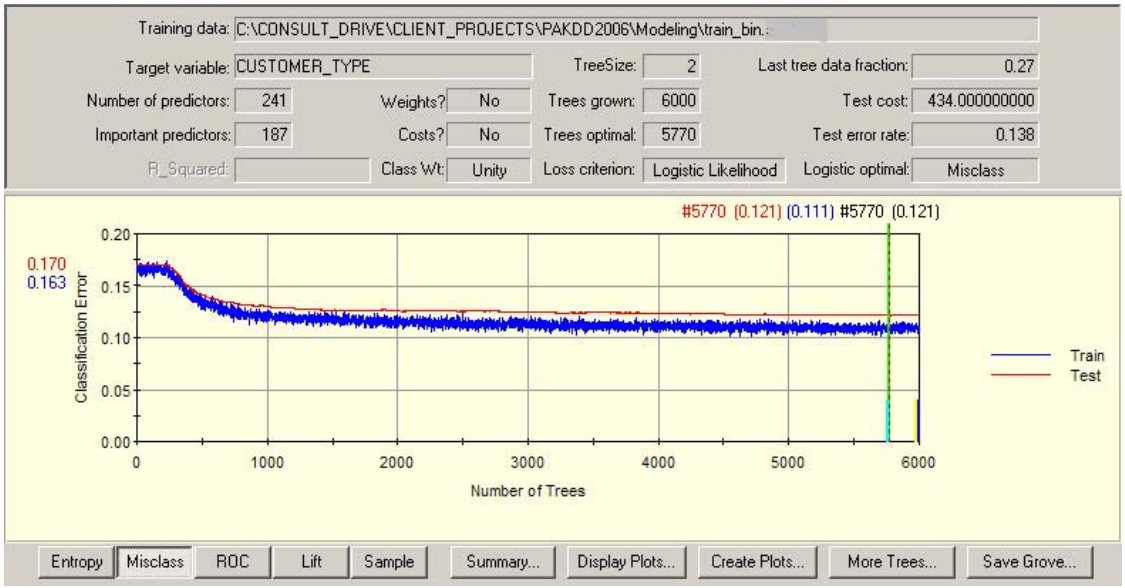

Table 6. Confusion matrix: TreeNet 2-node model for 2G versus 3G

Actual Class	Total Cases	Percent Correct	2G N=13763	3G N=4237

Total:	3586			
Average:		81.68		
Overall%Correct		82.01		

size to two nodes, or "stumps" models. Because each tree can involve, at most, one predictor, and because the final prediction is based on a sum of scores across all trees, the stumps model is constrained to be additive in the predictors. The model summary is shown in Figure 9. The confusion matrix appears in Table 6.

TreeNet Confusion Matrix—20% Test—2-node Trees

While this performance is not as good as those obtained from the 6-node trees, it is close enough to suggest that interactions are not playing a major role in this model. Nevertheless, we ran Friedman and Popescu's (2005) interaction tests to determine that DAYS_TO_CONTRACT_EXPIRY and HS_AGE are the only serious interaction candidates among the predictors.

To delve further into the details of the model it is worth looking at the distribution of model scores on the train dataset where CUSTOMER_TYPE is known. When the objective function is the logistic regression, TreeNet scores are literally predicted logits and a 0.0 score corresponds to a predicted probability of being a 3G of 0.50. The greater the score, the greater the predicted probability of 3G is (see Figure 10).

The heavy black curve with the highest peak represents 2G customers, the medium gray curve represents 3G customers, and the dark gray curve represents all customers.

The graph suggests reasonably good separation between the two target classes. The area of overlap mostly occurs in a narrow middle range of scores between -2.0 and -1.0, and the graph can be used to guide a trade-off between the true positive and false positive rates. For example, a decision threshold of –3.2 yields a 100% accuracy in predicting 3G customers and still isolates several hundred 2G customers in the leftmost spike. On the other hand, a threshold set at –1.7 keeps the true positive rate above 99% while still separating a very large group of 2G users on the left.

On the prediction set where the target is unknown the score distribution is seen in Figure 11.

As expected from our previous analysis of training and prediction set differences, the overall distribution of scores is virtually identical across the two data sets. From the prediction set scores graph one might conclude that the optimal score threshold to maximize the true positive 3G rate should be around –2.0. However, because such a low threshold would produce an unreasonably high false positive rate, our submitted predic-

Figure 10. Distribution of TreeNet scores among 2G and 3G customers in train data

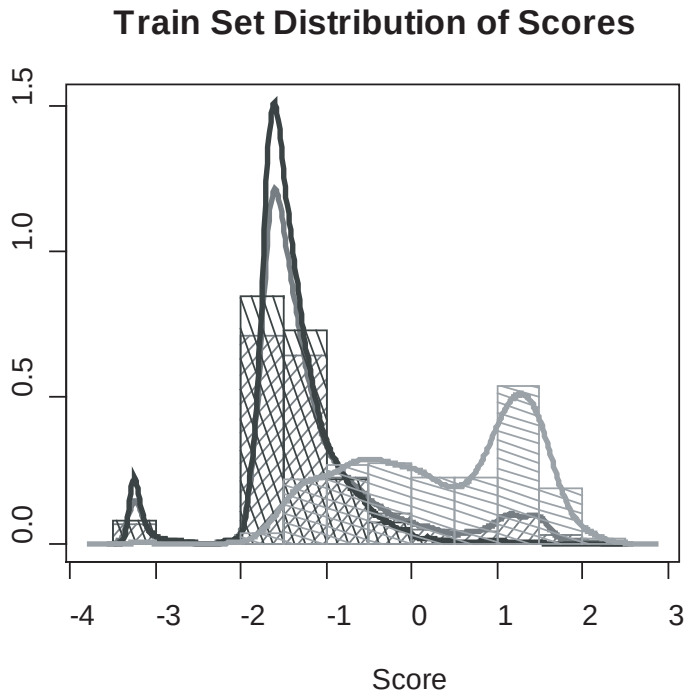

Figure 11. Distribution of TreeNet scores in prediction set for unlabeled customers

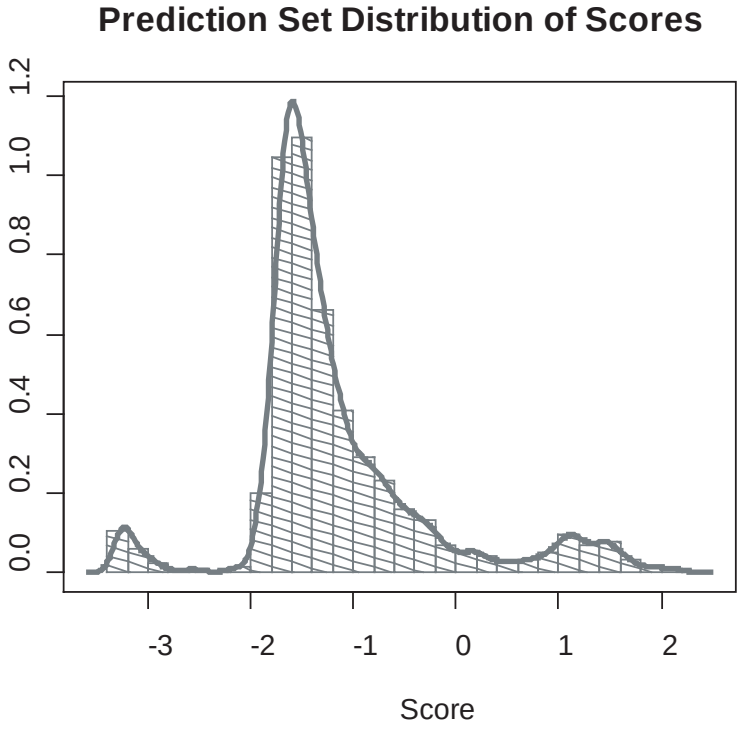

tions were based on the threshold of –1.1, which equalizes both true positive and true negative classification rates.

Model Simplification

For interpretation purposes, it is often useful to try to reduce the number of predictors that appear in the model. We used *variable shaving* to accomplish model simplification, fitting a series of progressively smaller models to the data. Each new model is specified by dropping the least important predictor from the previous model in a pattern similar to backwards stepwise regression.Figure 12 provides the results of the shaving process.

The graph indexes each model by the number of predictors, while the model accuracy is reported in terms of the area under the ROC curve. We observe that a model with eight predictors is sufficient to achieve an ROC not far below that of our "large scale" model.

Model Insights

Table 7 lists the relative importance of the eight predictors in the shaved TreeNet model (The larger 241 predictor model was used in our competitive submission.):

TreeNet Variable Importance

The grouped version of the HS_MODEL variable appears to be the most influential. Its additive contribution plot is shown in Figure 13.

Not surprisingly, the relative contribution of individual groups agrees with the results of the CART model used for grouping. It is clear that, on average, the phone models that appear in the first group are heavily favored by 3G customers, whereas phones appearing in the sixth group are on average favored by 2G customers.

Next on the importance list is the age of the handset and its impact on the probability of a customer being 3G, as illustrated in Figure 14.

Figure 12. ROC as a function of the number of variables removed. The integers superimposed over the curve represent the number of predictors left in the model.

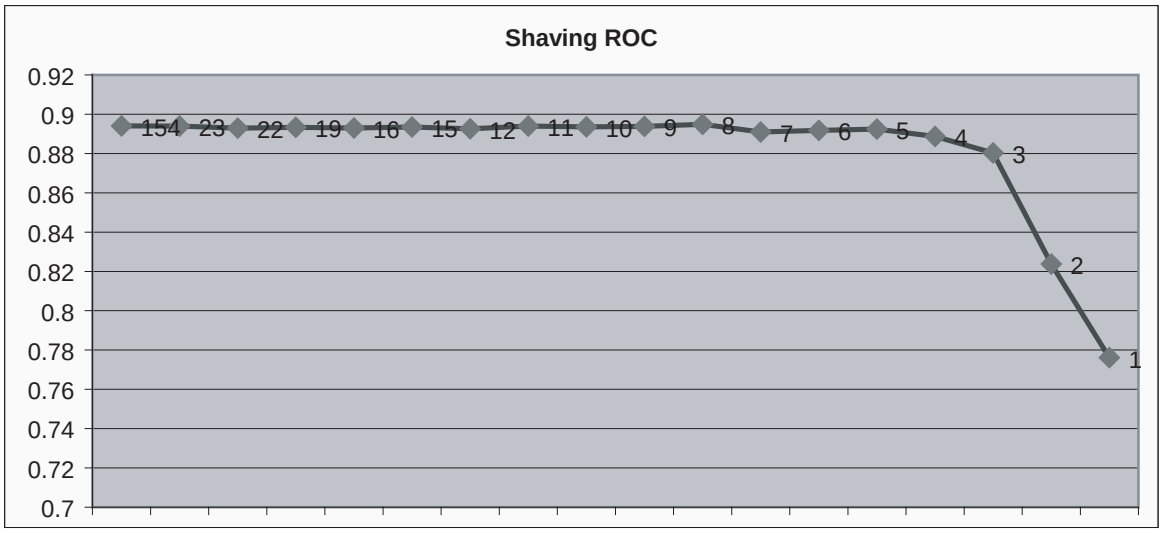

Table 7. TreeNet variable importance rankings for 2G versus 3G model

Variable	Score
HS_MODEL	100.00
SUBPLAN	23.90
HS_AGE	23.55
AVG_VAS_GAMES	13.84
AVG_VAS_GPRS	8.71
AVG_BILL_AMT	6.95
AVG_MINS_INTRAN	5.67
TOT_RETENTION_CAMP	4.02

Figure 13. TreeNet partial dependency plot: Contribution of HS_MODEL_G to predicted probability of 3G

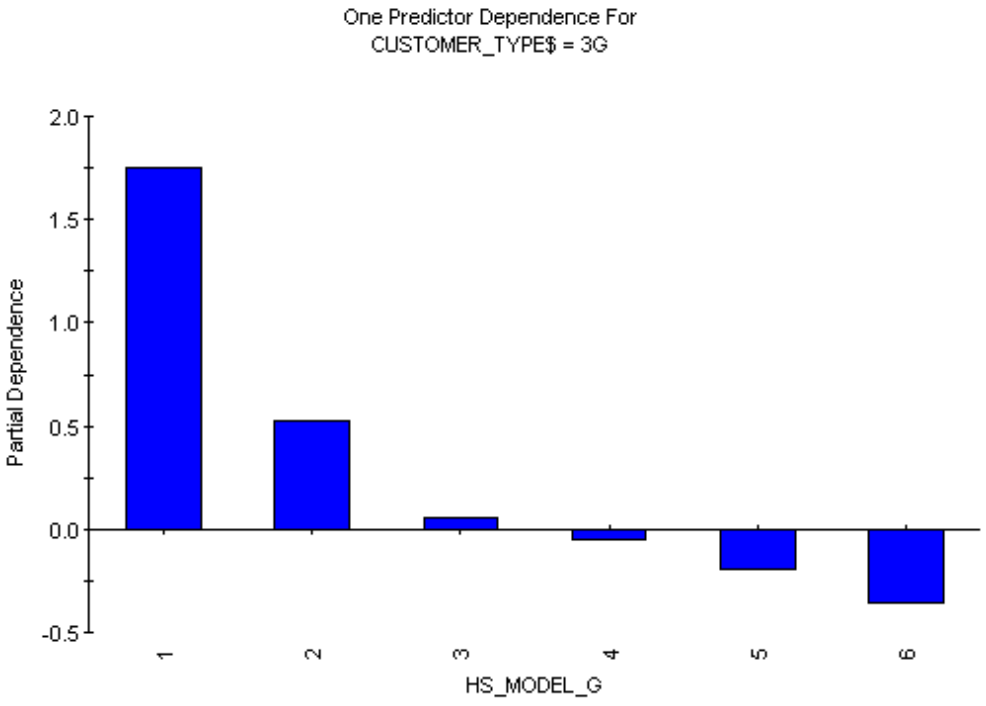

Figure 14. TreeNet partial dependency plot: Contribution of HS_AGE to predicted probability of 3G

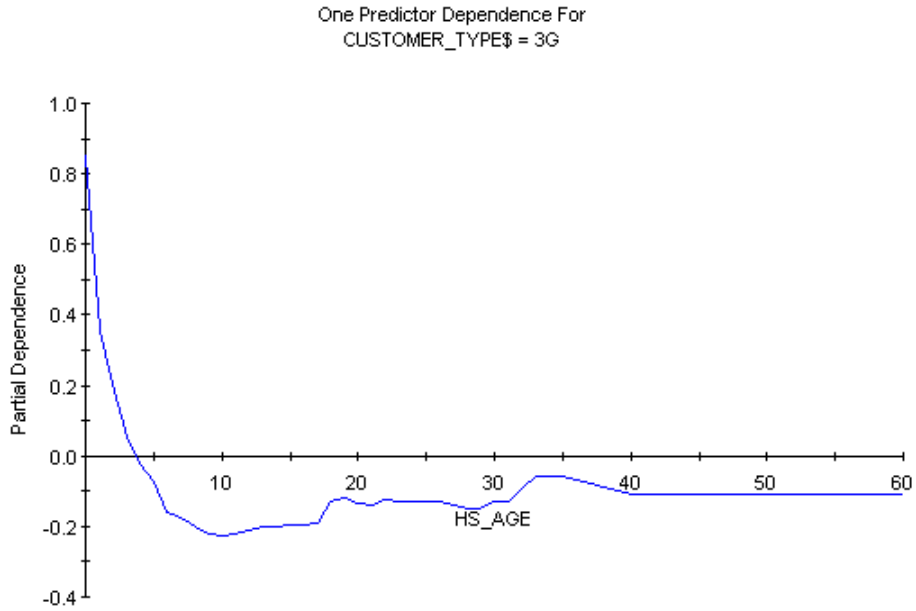

This "partial dependency" plot is a standard TreeNet output and helps us understand the workings of key predictors. The newest handsets (with an age of near zero) are very likely to be owned by 3G customers, and the probability that a customer is 3G drops rapidly with every month that the handset has been owned. Once a handset is older than 10 months its age does not matter much as far as discrimination between 2G and 3G is concerned.

The next important predictor measures gaming activity AVG_VAS_GAMES (Average Games Utilization [Kb]) for the last 6 months (Figure 15).

This is essentially a step function, with anyone downloading more than 1 MB being far more likely to be 3G.

The next variable is a grouped version of the SUBPLAN (Figure 16; see the CART model described earlier).

Again, the relative contribution of each group agrees with the one suggested by the relevant CART model. Subplans comprising group 1 are more associated with 3G users whereas groups 8 and 9 are "closer" to 2G customers.

Not surprisingly, the next variable tells us that 3G customers are associated with larger monthly bills with a steep ramp rising from about 100 to about 275 units per month (Figure 17).

Figure 18 illustrates the importance of retention campaigns for 3G users. It appears that 3G users have been subjected to many more retention campaigns, though it is not possible to tell whether the retention campaigns induce 3G subscribership or that 3G status attracts campaigns.

Figure 15. TreeNet partial dependency plot: Contribution of AVG_VAS_GAMES to predicted probability of 3G

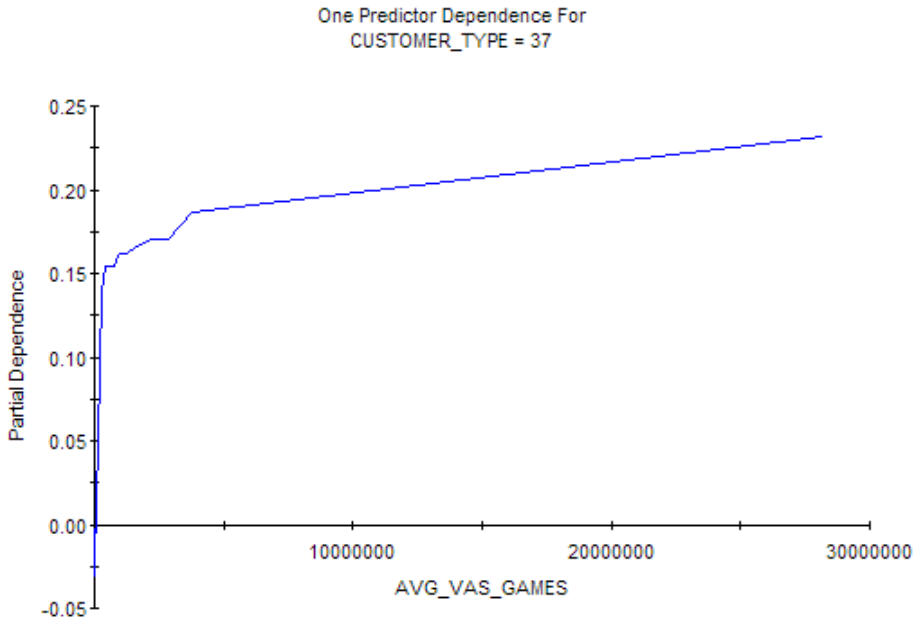

Figure 16. TreeNet partial dependency plot: Contribution of SUBGROUP_G to predicted probability of 3G

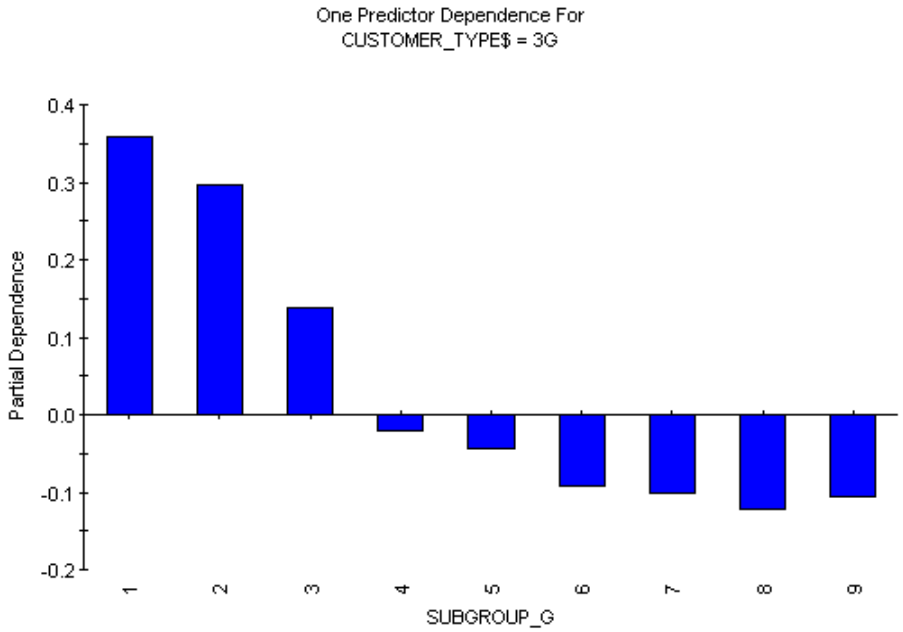

Figure 17. TreeNet partial dependency plot: Contribution of AVG_BILL_AMT to predicted probability of 3G

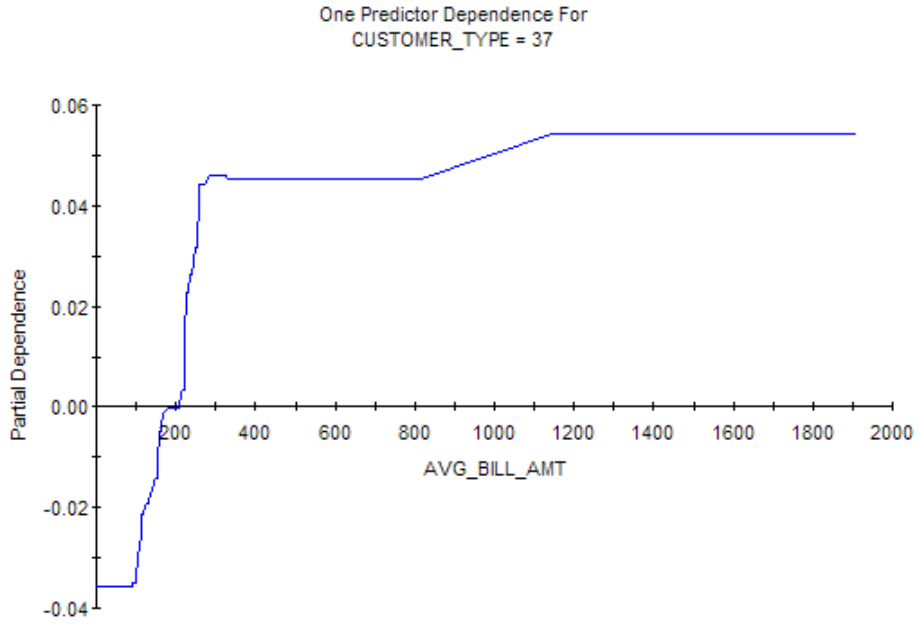

Figure 18. TreeNet partial dependency plot: Contribution of TOT_RETENTION_CAMP to predicted probability of 3G

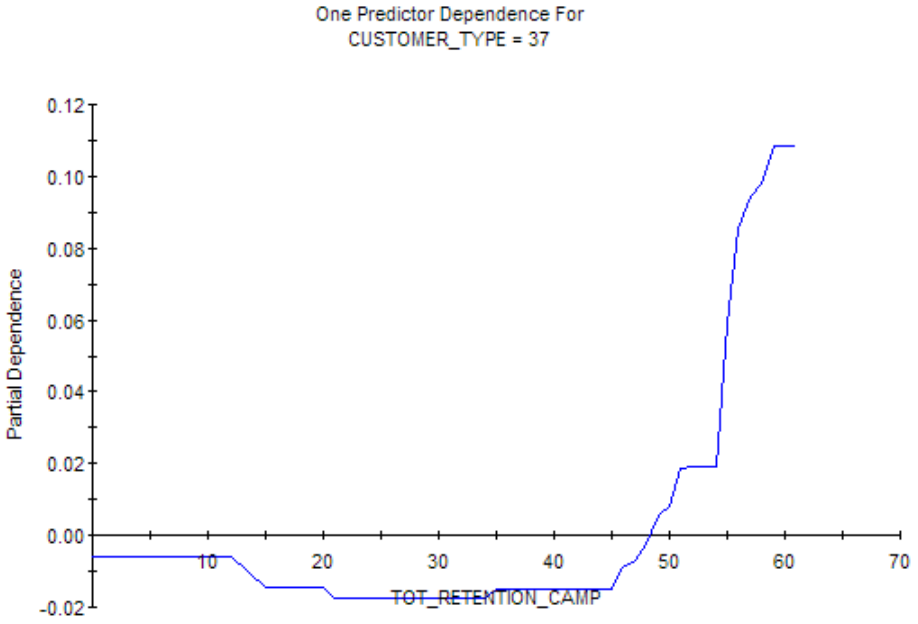

Figure 19. TreeNet partial dependency plot: Contribution of AVG_VAS_GPRS to predicted probability of 3G

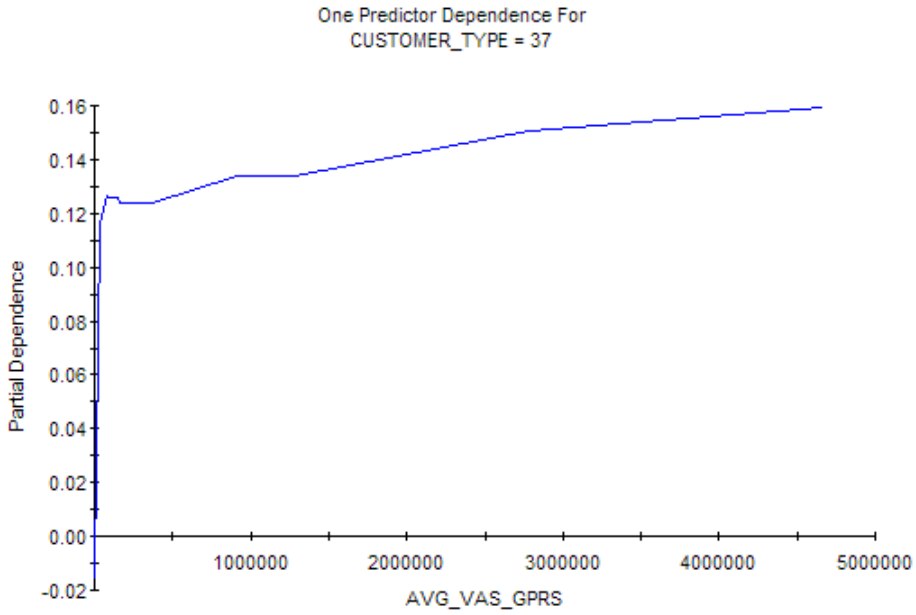

Figure 20. TreeNet partial dependency plot: Contribution of AVG_MINS_INTRAN to predicted probability of 3G

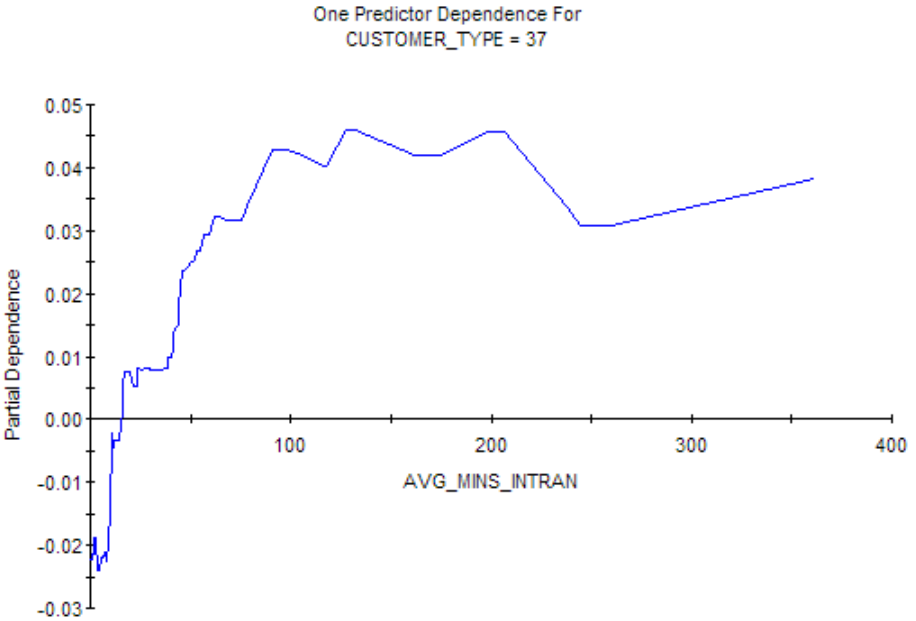

Similarly, GRPS utilization characterizes 3G consumers (Figure 19),again with a cutoff around 100 KB.

Finally, average intranet minutes are weakly associated with 3G users. Although the slope of the ramp is steep, the difference between the highest and lowest points on this curve is less than .07 (Figure 20).

A MODEL WITHOUT HS_MODEL OR SUBPLAN

Given the overwhelming importance of the HS_MODEL and SUBPLAN, along with the fact that these two predictors so closely proxy the customer's decision to subscribe to 3G services, we fit a model without these variables. We also suppressed other predictors that are obviously associated with 3G services, such as GAMES usage, and concentrated on predictors that have relevance to customers of all types, such as minutes used. One such model has a test area under the ROC of 0.78 and the following variable importance list (see Table 8).

TreeNet Variable Importance

The collection of graphs in Figure 21 illustrate how these variables help us discriminate between

Table 8. TreeNet variable importance rankings for model excluding HS_MODEL and SUBPLAN

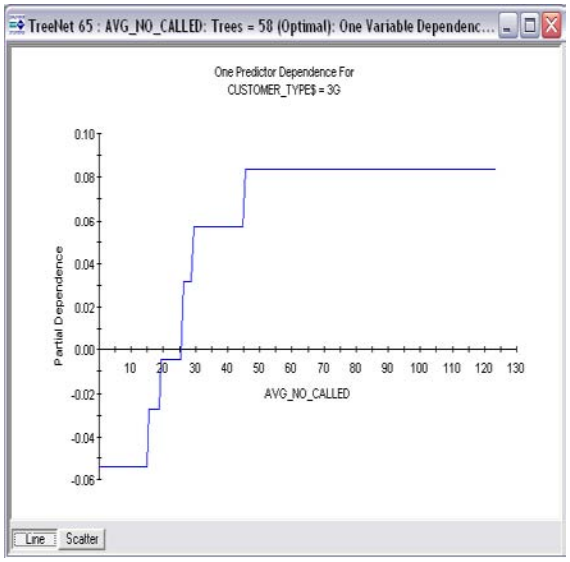

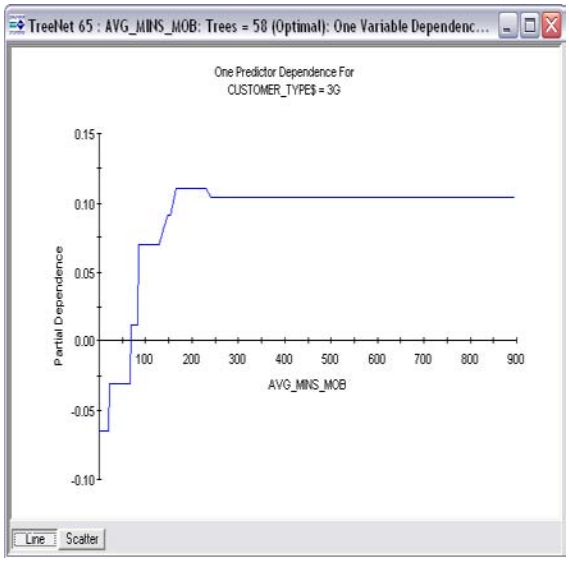

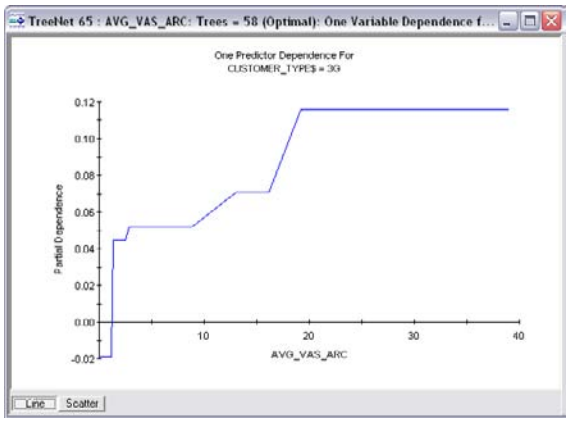

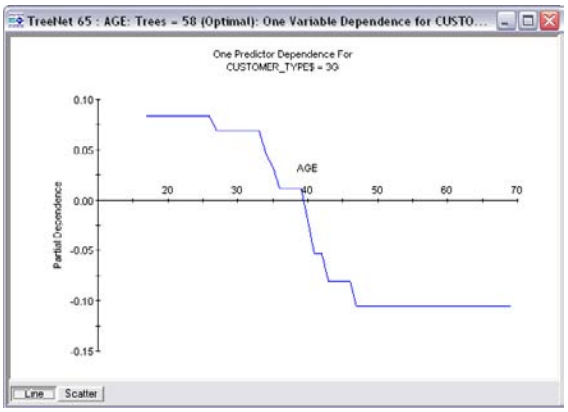

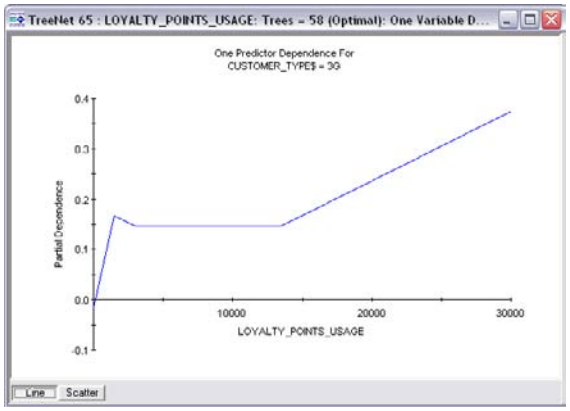

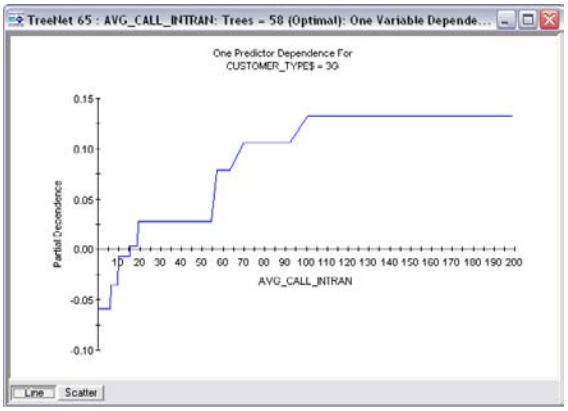

Figure 21. continued

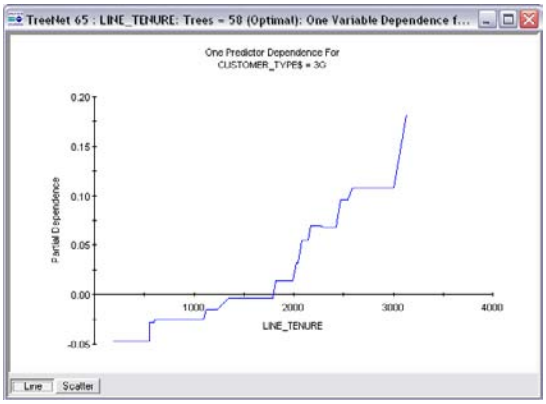

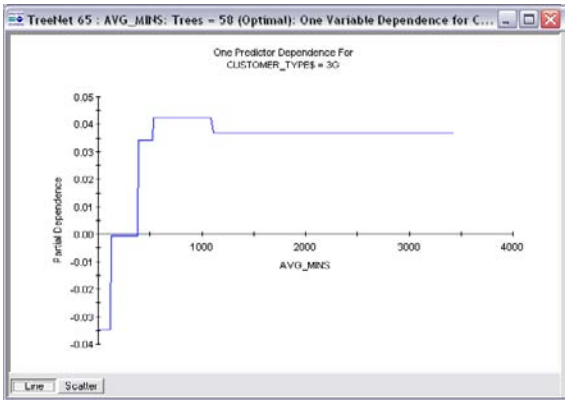

the behavior of 2G and 3G customers (see Figure 21).

These suggest that all the top important variables (except for AGE) are positively associated with the 3G-user group.

DISCUSSION AND CONCLUSION

Data mining competitions are inherently limited by the data and information that the proprietary data owners are prepared to release. In the PAKDD 2006 competition, the limitations permitted a discrimination task to profile the differences between existing 2G and 3G customers at a given point in time. While some of these differences, such as the handset used, are relatively obvious, it was still possible to extract useful and nonobvious insights into the differences between these two customer segments. For example, it was surprising to see that 2G and 3G customers differ strongly along almost all 250 dimensions of the available data. At the same time, it was possible to produce a highly accurate discriminator between the two classes using only eight predictors. Given that the data correspond to historical choices customers have already made regarding which service plan to subscribe to, it is much harder to draw firm conclusions regarding the propensity of a 2G customer to switch to a 3G service. While existing 2G customers who behave very much like 3G customers in terms of their account profile seem likely candidates for a service upgrade, the data contain no information that might help us understand why they have elected to stay with a 2G service plan. Data tracking 2G customers over time and recording which of them switch to 3G eventually would provide more direct evidence on this question.

Chapter 7.23
An Immune Systems Approach for Classifying Mobile Phone Usage

ABSTRACT

With the recent introduction of third generation (3G) technology in the field of mobile communications, mobile phone service providers will have to find an effective strategy to market this new technology. One approach is to analyze the current profile of existing 3G subscribers to discover common patterns in their usage of mobile phones. With these usage patterns, the service provider can effectively target certain classes of customers who are more likely to purchase their subscription plans. To discover these patterns, we use a novel algorithm called Artificial Immune Recognition System (AIRS) that is based on the specificity of the human immune system. In our experiment, the algorithm performs well, achieving an accuracy rate in the range of 80% to 90%, depending on the set of parameter values used.

INTRODUCTION

A sample dataset of 24,000 mobile phone subscribers is used for this study, in which 20,000 records are known to be second generation (2G) network customers and the remaining are 3G network customers. The target field is the customer type (2G/3G). About 75% of the dataset have the target field available and are used for training purposes; while the remaining quarter of the dataset has a missing target field and are meant for prediction.

The objective of the classification is to correctly predict as many 3G customers as possible from the prediction set and obtain insights on the characteristics of the existing 3G customers to be used as reference for their marketing strategy.

To perform this task, we use a novel algorithm called the Artificial Immune Recognition System (AIRS) proposed by Watkins, Timmis, and Boggess (2004), which is based on the processes in biological immune systems.

OVERVIEW OF AIRS

The Human Immune System

The function of the human immune system is to identify and destroy foreign invaders (antigens) which are possibly harmful to the body. It does this through an innate and nonspecific response (mediated by macrophages) and also with an adaptive and specific response (mediated by lymphocytes). An innate response is not directed towards any specific antigens, but against any invaders that enter the body. The adaptive response is mediated mainly by two types of lymphocytes, B-cells and T-cells. The AIRS approach is modeled based on the behavior of B-cells, hence only the behavior of B-cells will be described here. On the surface of each B-cell are receptors that are capable of recognizing proteins of a specific antigen. Through costimulation and suppression of each other, similar B-cells form networks that can recognize similar antigens.

When antibodies on a B-cell bind with an antigen, the B-cell becomes activated and begins to proliferate. Thus, it means that only B-cells which are able to recognize the invading antigen will proliferate and produce clones (a process known as clonal selection). New B-cell clones are produced which are exact copies of the selected B-cells, but then undergo somatic hyper-mutation to generate a wider range of antibodies, so as to be able to remove the antigens from the body. A small quantity of B-cells remains in the system after the invading antigens have been removed. These B-cells act as an immunological memory to allow the immune system to produce a faster response to similar antigens that might re-infect the body in the future.

The AIRS Algorithm

Processes in biological immune systems have inspired the design of AIRS. An artificial recognition ball (ARB) is used to represent a set of *identical* B-cells. The ARBs in the system will compete for B-cells in order to survive (in the evolutionary sense); therefore an ARB with no B-cell will be removed from the system. A fixed number of B-cells are allowed in the system, so the least stimulated ARB will not be able to get any B-cells, and will therefore be removed from the system. We will at times refer to a B-cell as an ARB, only because an ARB is simply a representation of many B-cells of the same specification. When a new training data record (antigen) is presented to the system, each B-cell is cloned in proportion to how well it has matched the antigen according to the principle of clonal selection. The mutation rate used in the cloning process is *inversely* proportional to how well it matches the antigen. During the mutation process, new clones undergo a process of somatic hyper-mutation, where each attribute of the clones is varied slightly to provide a wider range of response to the training data record. Eventually, the clone with the best fit to the presented antigen will be retained as a memory cell. The memory cells are retained in the system to provide faster response should the system become re-infected with similar antigens.

AIRS relies heavily on finding the similarity (or difference) between a pair of customer records, therefore a proper distance measure needs to be defined. Hamaker and Boggess (2004) conducted a survey of distance measures that can be used in conjunction with AIRS. Based on this survey, we use the *heterogeneous value difference metric*

(HVDM) as our distance measure. The HVDM measure uses the *Euclidean distance* measure for numerical data fields and a *value difference metric* (VDM) for categorical data fields. Consider *x* and *y* as two customer records that are going to be compared, each having *G* data fields and having one of *C* possible classifications (where *C* = 2, either being 2G or 3G). All numerical fields are normalized to the range of [0, 1]. The function *HVDM*(*x*, *y*) returns the HVDM distance of *x* and *y* according to the formulas:

$$HVDM(x,y) = \frac{1}{\sqrt{G}}\sqrt{\sum_{g=1}^{G} hvdm(x_g, y_g)^2}$$

$$hvdm(x_g, y_g) = \begin{cases} \sqrt{vdm(x_g, y_g)} \\ \left| x_g - y_g \right| \end{cases}$$

g is categorical field
g is numerical field

$$vdm(x_g, y_g) = \sum_{c=1}^{C} (P(c \mid x_g) - P(c \mid y_g))^2$$

where $P(c|x_g)$ denotes the probability that a customer record has class *c* given the value x_g.

Based on our judgment, VDM is the most effective measure for categorical fields compared to other distance measures as presented in Hamaker and Boggess (2004) because it relies on the statistics observed in the training data, which more likely reflects the real-world situation. We will now present the algorithm (full details may be found inWatkins et al., 2004). The symbols that we will be using to define the algorithm are explained as follows:

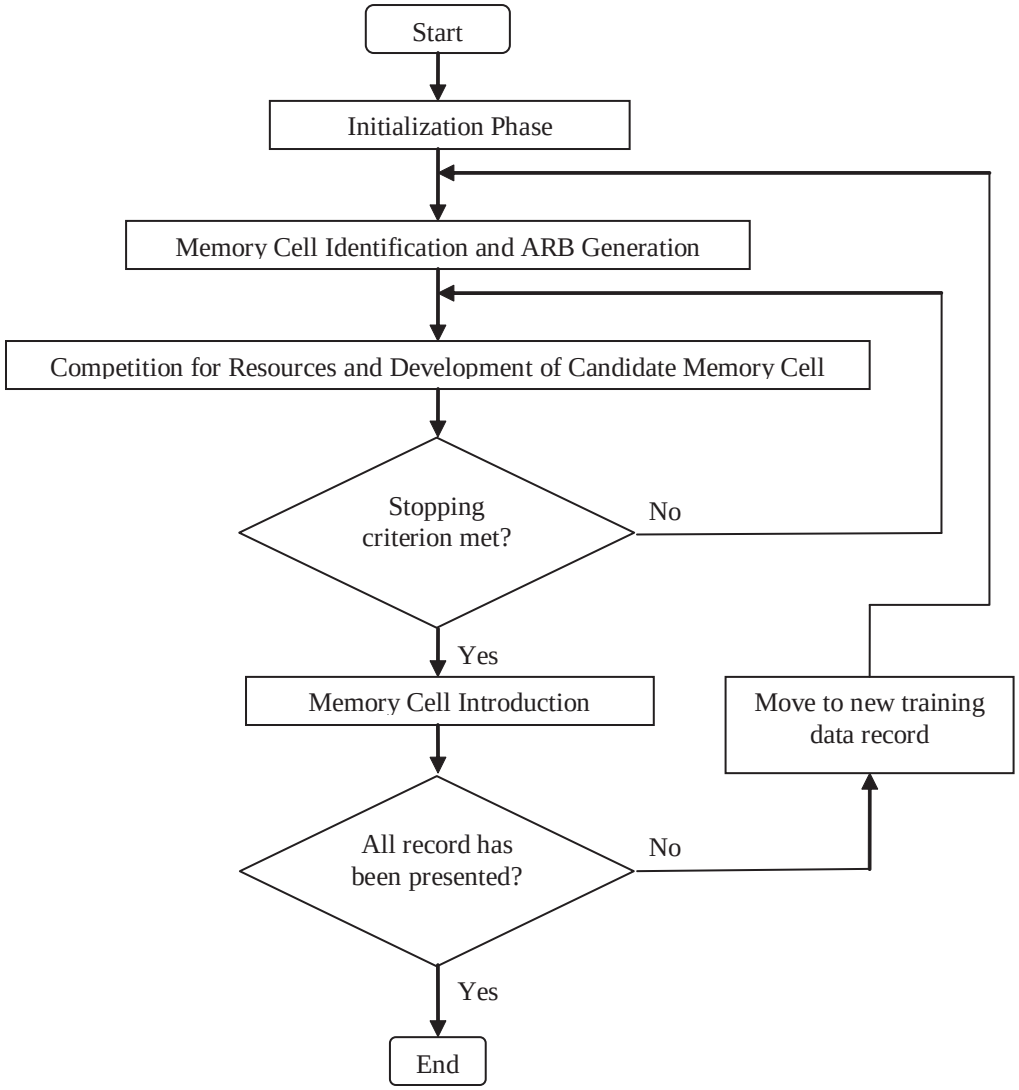
- There are *n* antigens, and there are *G* data fields and *one categorical* class in each antigen. The class of the antigen may take the value of $\{1, 2, \ldots, nc\}$, where *nc* is the number of possible values in the target class.
- *MC* denotes the set of memory cells. *mc* represents an individual member of *MC* and *mc.c* represents the class of the memory cell, while $mc.f_i$ represents the value of the i^{th} feature (data field) in the memory cell.
- *AB* denotes the set of ARBs and *ab* represents a single ARB. *ab.c* denotes the class and the i^{th} feature of an *ab* respectively.
- *ag* represents an antigen (training data record), and *ag.c* and $ag.f_i$ represent the class and value of the i^{th} feature (training data field) in the antigen, respectively.
- $MC_c \subseteq MC$ denotes the set of memory cells with the class *c*.
- *ab.stim* denotes the stimulation level of an ARB *ab*.
- *ab.resources* denotes the number of resources (B-cells) currently held by an ARB *ab*.

The user-defined parameter values we used in our experiments to control the behavior of the algorithm are presented as follows:

- *numEpochs*: Number of passes through the training data (= **3**);
- *numResources*: number of B-cells (resources) allowed in the system (= **200**);
- *clonalRate*: Number of mutated clones that a given ARB is allowed to produce. An ARB *ab* is allowed to produce at most (*clonalRate* * *ab.stim*) new clones. This product is also used to control how many B-cells will be allocated to an ARB (= **10**);
- *mutationRate*: A value between [0, 1] that determines the likelihood that a given feature or class of an ARB will be mutated (= **0.1**);
- *hypermutationRate*: number of mutated clones that a given memory cell is allowed to inject into the system. A memory cell *mc* injects at least (*hypermutationRate* * *clonalRate* * *mc.stim*) mutated clones (= **10**);

- *distance*: The distance metric used (= ***Heterogeneous Value Difference Metric***);
- *ATS*: affinity threshold scalar, a value between [0, 1] that will be multiplied with the affinity threshold (*AT*) to produce the cutoff value for memory cell replacement (= **0.2**);
- *stimThreshold*: a value between [0, 1] used as a stopping criterion for training on specific antigen (= **0.95**); and
- *k*: The parameters that specify how many nearest neighbors participate in the classification process (using *k*-nearest neighbor) (**= 15**);

Figure 1. Process flow of the AIRS training process



These parameter values were determined by performing multiple tests on the training data (using 10-fold cross validation) to verify their effectiveness. The training process of the algorithm is shown in Figure 1. Each phase will be discussed separately followed by the classification process.

The Initialization Phase

During this phase, all data preprocessing that is needed will be performed. Details of the data preprocessing involved will be elaborated in a later section. After the preprocessing, the affinity threshold (AT) of the system is calculated by averaging the distance between all training data. It should be noted that the affinity between two antigens should always be between 0 and 1, therefore

$$AT = \frac{\sum_{i=1}^{n}\sum_{j=i+1}^{n} affinity(ag_i, ag_j)}{{}^{n}C_2}$$

where *affinity*(*x*, *y*) will return the distance of the two antigens *x* and *y*, depending on which distance metric is used (HVDM for this specific case). Seeding of memory cells, when desirable, will also be performed in this phase.

Memory Cell Identification and ARB Generation

In this phase, the best matched memory cell is identified and ARBs are generated from the best matched memory cell that is identified. The first step is to identify the memory cell mc_{match} from $MC_{ag.c}$ (the set of memory cells with the same class label as the presented antigen *ag*) which has the highest stimulation. The level of stimulation between two records (antigens) *x* and *y* is defined as *stimulation*(*x*, *y*) = 1 – *affinity*(*x*, *y*). If $MC_{ag.c}$ = {} then mc_{match} = *ag* and *ag* is added to $MC_{ag.c}$.

After mc_{match} has been identified, *NumClones* number of clones of mc_{match} will be produced as ARBs. The number of clones is *NumClones* = (*hypermutationRate* * *clonalRate* * mc_{match}.*stim*) where *stim* denotes the current stimulation level. It should be noted that *NumClones* is proportional to the stimulation value of mc_{match} to the antigen. Each numerical feature in mc_{match} can only mutate in a constrained range centered at the original value. The width of the range is inversely proportional to the stimulation value *stim*. This implies that a heavily stimulated mc_{match} will produce clones that are closer to it because it has a limited range for mutation, which is reasonable since the original mc_{match} already matches well with the antigen; hence it is very likely that best-fitted B-cell can be found in the neighborhood of mc_{match}. A categorical feature does not have this constraint and can be mutated freely. All of the produced clones are added into the system as ARBs and will have the same class label as the original mc_{match}.

The pseudo code for this phase is shown in Figure 2. maxStim($MC_{ag.c}$, *ag*) returns a memory cell in the set of $MC_{ag.c}$ with the maximum stimulation to the antigen *ag*. mutate(mc_{clone}) mutates the clone of a memory cell according to the rule described previously. *AB* represents the set of ARBs (or set of representative B-cells) in the system, and |*AB*| denotes the size of the set *AB*.

Competition for Resources and Development of a Candidate Memory Cell

The objective of this phase is to find the ARB in the system (which is produced from the previous phase) which is the most stimulated when presented with an antigen. This ARB may then be retained as a memory cell. Recall that an ARB is a set of *identical* B-cells, therefore its characteristics can also be represented by a single cell. To find the most stimulated ARB, we allocate resources (B-cells) to all ARBs in the system based on their

Figure 2. Memory cell identification and ARB generation

```
if (MC_ag.c = {})
        mc_match = ag
        MC_ag.c = {mc_match}
else
        mc_match = maxStim(MC_ag.c, ag)
endif
mc_match.stim = stimulation(ag, mc_match)
NumClones = hypermutationRate * clonalRate * mc_match.stim
AB = {}
while ( |AB| < NumClones) do
        mc_clone = mc_match
        mc_clone = mutate(mc_clone)
        AB = AB ⋃ mc_clone
endwhile
```

stimulation level to the current antigen. An ARB *ab* is given (*ab.stim * clonalRate*) B-cells.

However, as B-cells allowed in the system are limited (set by the value of *numResources*), if the number of allocated B-cells exceeds the allowed number of B-cells; some B-cells need to be removed from the system. B-cells will be removed starting from the ARBs with the weakest stimulation, until the number of B-cells in the system equals to or are less than *numResources.* In this way, ARBs which are weakly stimulated by the antigen will be removed from the system. The surviving ARBs are examined by the algorithm to test whether they are stimulated enough by the antigen to cease further training. The average stimulation level *s* is computed by averaging the stimulation level of all surviving ARBs. If $s \geq stimThreshold$ then the stopping criteria is met.

Regardless of whether the stopping criterion is met or not, the surviving ARBs are then allowed to produce (*stim * clonalRate*) clones which undergo somatic hyper-mutation. The mutation rule is the same as the rule described in the previous section where numerical fields have constrained ranges for mutation. If the stopping criterion is met, the most stimulated ARB in the system is chosen as the candidate memory cell $mc_{candidate}$. The algorithm then proceeds to the next training phase, otherwise this phase is repeated.

The pseudo code for this training process is shown in Figure 3. minStim(*AB*) returns an ARB with minimum stimulation from the set of ARBs *AB.* avgStim(*AB*) returns the average stimulation value of ARBs in *AB. newAB* and *MU* are temporary storage locations for newly created ARBs.

Figure 3. Competition for resources and development of a candidate memory cell

```
resAlloc = 0
foreach (ab . AB) do
        ab.resources = ab.stim * clonalRate
        resAlloc = resAlloc + ab.resources
endfor
while (resAlloc > numResources) do
        numRemove = resAlloc – numResources
        ab_remove = minStim(AB)
        if (ab_remove.resources≤ numRemove)
                AB = AB – {ab_remove}
                resAlloc = resAlloc – ab_remove.resources
        else
                ab_remove.resources = ab_remove.resources – numRemove
                resAlloc = resAlloc – numRemove
        endif
endwhile
s = avgStim(AB)
newAB = AB
foreach (ab . AB) do
        NumClones = clonalRate * ab.stim
        MU = {}
        while ( |MU| < NumClones) do
                ab_clone = ab
                ab_clone = mutate(ab_clone)
                MU = MU ⋃ ab_clone
        endwhile
        newAB = newAB ⋃ MU
endfor
AB = newAB
if (s < stimThreshold)
        // repeat this phase
else
        //continue to next phase
endif
```

Memory Cell Introduction

In this phase, we will decide whether $mc_{candidate}$, identified in the previous phase as the ARB with highest stimulation, should be retained as a memory cell and whether $mc_{candidate}$ should replace mc_{match}. $mc_{candidate}$ is retained as memory cell if it is more stimulated compared to mc_{match} with respect to the current antigen. Furthermore, if the affinity between $mc_{candidate}$ and mc_{match} is less than the threshold ($AT * ATS$), mc_{match} is going to be replaced by $mc_{candidate}$. It means that if $\underline{mc}_{candidate}$ and mc_{match} have strong affinities (the distance between the two is sufficiently large), one memory cell cannot be used as a substitute for the other. If the affinity is weak, one memory cell can be regarded as a substitute of the other, and since $mc_{candidate}$ is more stimulated than mc_{match}, $mc_{candidate}$ is used as the memory cell.

Once the process is finished, the algorithm completes training for one antigen. If there are any other antigens (other data records) that need to be trained, the algorithm returns to train the new antigen. If all antigens have been trained, the training phase is finished and the produced memory cells can be used for classification.

Produced Classification Model

The algorithm produces a set of memory cells as a result of the training. In a clustering algorithm, each of the memory cells may be visualized as a cluster center. Using the parameter values specified before, we observed that the number of memory cells produced is only around 10% of the number of training data records.

Classification is performed using a weighted *k*-nearest neighbor approach; where *k* most stimulated memory cells have the right to vote for the presented antigen class. Since we have an imbalanced training data (3,000 3G customers against 15,000 2G customers), we can expect that there will be more memory cells representing the 2G customers compared to 3G customers; hence unweighted voting puts the 3G customers at a high probability of being incorrectly classified as 2G customers. To compensate for this, we set the ratio for a vote of 3G:2G = 5:1 (proportional to the ratio of training data available). Testing has shown that a weighted *k*-nearest neighbor approach performs more effectively compared to the unweighted approach.

As for the *k* value used to determine how many neighbors get to participate in the voting process, we used $k = 15$. By experimentation, we vary the value of *k* from $k = 1$ to 15 and observe that the solution quality increases. When *k* is higher than 15, there are some cases where the solution quality is reduced.

EXPERIMENTAL DESIGN

We are provided with 24,000 customer records, from which 18,000 records are to be used for training purposes, while the remaining 6,000 are for prediction. There is one categorical target field, which is customer type (2G/3G). Of the 18,000 training data records, 15,000 are 2G customers, and 3,000 are 3G customers. Each record in the dataset consists of 250 data fields. The data field can be categorized into two types; *numerical* and *categorical.*

Data Preprocessing

Before we supply the data into the AIRS algorithm, we need to preprocess the data. The data preprocessing that is done are normalizing numerical value, handling missing values, and converting categorical variables from literal strings to integer indices for easier processing.

For each numerical data field, we perform min-max normalization. First, we scan the data to find the minimum and maximum value of the field, then we normalize each value in this field to the

range of [0,1] by converting it to $\frac{val - \min}{\max - \min}$, where *val* is the value to be converted, *min* is the minimum value, and *max* is the maximum value.

For missing values that occur in the dataset, we simply replace them with a global value "MISSING," however, other strategies such as statistical regression might be more effective in handling the missing value.

For categorical data fields, we give an index to each possible value that might appear in the data and change the values from literal strings to indices. This has the advantage of more efficient processing because the algorithm only needs to deal with numbers instead of strings.

In addition, we also need to compute the conditional probability value $P(c|x_g)$ which is needed if we use HVDM distance measure. $P(c|x_g)$ denotes the probability that a customer record has class c given the value x_g.

We also note that in the dataset, there are some data fields in which only *one* value would appear in all customer records for the entire training data (e.g., **HS_CHANGE**, **TOT_PAS_DEMAND** for a numerical data field, and **VAS_SN_STATUS** for a categorical data field). We would not get any useful information from these fields since there is only *one* value that appears in the data and no other value to compare it to. Therefore, for these data fields, they can be safely removed from the data.

Training, Validation, and Parameter Tuning

To decide on which parameter values would yield the best results, we try several sets of parameter values. Validation is performed using 10-fold cross validation. We divide the training data randomly into 10 equal parts. For every run of the algorithm, nine parts will be used for training, and the remaining part will be used for validation purposes. We train the system with the training data, and we analyze the accuracy of the prediction on the validation set. By performing the validation methods repeatedly with different sets of parameter values, we can pick the set of parameter values which yield the best results. This is further illustrated in the next section.

RESULTS AND DISCUSSIONS

Obtained Results and Analysis

To perform the experiment, we perform a 10-fold cross validation method 10 times for each set of parameter values. The result shown in Table 1 is the average of the obtained values. Due to the time constraint, we only modify the number of training passes (*numEpochs*) and the value of *k* for classification using *k*-nearest neighbor.

As we can see from Table 1, as *k* increases, the accuracy rate generally increases, however, we also observe that sometimes, for *k* value higher than 15, the accuracy rate decreases. Therefore, we set the *k* value to 15. The same can be observed in the number of training passes, when the number of training passes is greater than 3, sometimes, the accuracy decreases. In addition, too many training passes increases the time involved in training the algorithm. Hence, we set the number of training passes to 3. Other values, such as the clonal rate, hyper-mutation rate, and number of allowed B-cells in the system are the default values for the algorithm which are initially used in the original source code by Hamaker and Watkins (2003).

Dataset Analysis

The discussion in this section will be based only on the training data, since we will need to know whether a record is incorrectly classified as false positive (classified as 3G although the actual class is 2G). Since our algorithm does not produce the characteristics of 3G customers, therefore the

Table 1. Accuracy rate of AIRS with varying sets of parameters

Number of training passes	*k* value for k-nearest neighbor			
	1	7	11	15
1	85.53%	86.54%	86.98%	87.22%
2	86.37%	87.33%	87.49%	87.82%
3	86.71%	87.47%	87.81%	88.08%
4	86.97%	87.69%	88.04%	88.26%
5	86.90%	87.81%	88.19%	88.32%

false positives obtained in our experiment might be a useful insight to decide the characteristics of customers that are likely to change their 2G subscription to 3G. If a false positive is found, it is possible that this record is closer to the characteristics of 3G customers rather than 2G customers, therefore, by analyzing the characteristics of all the false positives that are found, we can find some common characteristics that differentiates the 3G customers from the 2G customers.

To perform this experiment, we randomly divide the training data into 90% training set, and 10% testing set. After training the algorithm with the training set, we classify the testing set and obtain the false positives produced by the algorithm. This experimentation is repeated several times, and the statistics of the false positives obtained for each experiment is compared to the statistics of the entire training data whether there are a constant deviation between the statistics of the false positives and the entire data. For numerical data field, we compared the average and standard deviation, while for categorical data field, we compared the frequency count.

We find some almost constant, strong deviation between the statistics of false positives and the statistics of training data in the following fields. The field name uses the original name that is found in the dataset.

- **MARITAL_STATUS**: *More singles* can be found in the false positives compared to the entire data; this suggests that singles are more likely to purchase a 3G subscription.
- **OCCUP_CD**: *Less* customers with *other (OTH)* occupation is found in the false positives; therefore, customers with occupation {EXEC, POL, STUD, MGR, HWF, ENG, CLRC, SELF, GOVT, TCHR, SHOP, FAC, AGT, MED} (this occupation code are other codes that can be found in this data field) might be more likely to change to 3G.
- **HIGHEND_PROGRAM_FLAG**: *More* customers with *high end* programs are found in the false positives. This is expected since a 3G plan can also be considered a high-end program.
- **TOP1_INT_CD, TOP2_INT_CD, TOP3_INT_CD**: *Considerably more* customers in the false positives with values for this parameters set to *other than NONE*. It is probable that customers who make international calls are more attracted and able to afford a 3G subscription.

- **VAS_GPRS_FLAG**: *More* customers who own a *GPRS Data Plan* (code 1) can be found in the false positives. This is expected, since customers without GPRS are less likely to appreciate the improvement provided by 3G, and therefore, might not find a 3G subscription attractive.
- **LOYALTY_POINTS_USAGE**: Customers in the false positives set have *considerably higher average of loyalty points.* Loyal customers might be more easily persuaded to switch to a 3G subscription.
- **TOT_TOS_DAYS**: Customers in the false positives set have *a lot less average total temporarily on suspended* days compared to the entire data. Customers who are routinely using their mobile phone are more likely to purchase a 3G subscription.
- **AVG_CALL_FRW_RATIO**: *Less call forwarding* is utilized by customers in the false positive set. Customers who are carrying their mobile phone everywhere, therefore they do not need call forwarding services, are more likely to purchase a 3G subscription which would enable them to do more with their mobile set.
- **AVG_MIN_OBPK, AVG_MIN_OBOP**: *More minutes are spent in outbound calls in peak and off-peak period* by customers in the false positives set. Customers who make a lot of calls might be interested in the video phone feature provided by a 3G subscription.
- **AVG_MIN_FIX**: More minutes are spent by customers to call fixed line numbers in false positives set. Customers who are using their mobile phone actively are more likely to purchase a 3G subscription.
- **AVG_MIN_T1:** More top 1 minutes spent by customers in false positives set. Customers who are using their mobile phone actively are more likely to purchase a 3G subscription.
- **AVG_CALL_1900**: *Considerably more than 1,900 calls* by customers in the false positives set. Customers who are using their mobile phone for social use as well as for communication are more likely to purchase a 3G subscription.
- **AVG_REVPAY_AMT, REVPAY_FREQ**: *Slightly more reverse payment* in average for both the amount and the frequency can be detected in the false positives set.
- **CONTRACT_FLAG**: *Slightly more* customers *with contract* are found in the false positives. This may be caused by the price of 3G mobile phones that are still expensive; therefore, an attractive contract plan might attract more customers to switch to 3G.
- **AVG_VAS_QTUNE**: Customers in the false positives set *downloaded more quick tunes* than the average of the entire data. However, other services such as quick games, text, or pix do not exhibit any statistical deviation from the data.
- **AVG_VAS_GBSMS**: *More e-mail SMSs* are sent by customers in the false positives set. These customers might be interested in the functionality provided by 3G.

CONCLUSION

In this article, we described our approach in mining interesting patterns from the dataset of mobile phone customers to identify whether the customer is currently subscribed to a 2G or 3G subscription plan. To solve this problem we use the AIRS algorithm which operates using the principles of the human immune system. We experimented with different sets of parameter values to find the optimal values that are suitable for our purpose. Our experimentation shows that this algorithm is very effective; with proper parameter values it can achieve an accuracy rate near 90%. After a classification model was produced, we analyze

the training data for patterns found in the classification model. These patterns that we found can hopefully be used to identify the common characteristics of 3G and 2G customers. We also discuss how these patterns can assist a mobile phone service provider in marketing their 3G subscription plan.

Chapter 7.24
Mobile Ontologies:
Concept, Development, Usage, and Business Potential

Jari Veijalainen
University of Jyvaskyla, Finland

ABSTRACT

The number of mobile subscribers in the world is soon reaching the three billion mark. According to the newest estimates, majority of the subscribers are already in the developing countries, whereas the number of subscribers in the industrialized countries is about to stagnate around one billion. Because especially in the developing countries the only access to Internet are mobile devices, developing high quality services based on them grows in importance. Ontologies are an important ingredient towards more complicated mobile services and wider usage of mobile terminals. In this article, we first discuss ontology and epistemology concepts in general. After that, we review ontologies in the computer science field and introduce mobile ontologies as a special category of them. It seems reasonable to distinguish between two orthogonal categories, mobile domain ontologies and flowing ontologies. The domain of the former one is in some sense related with mobility, whereas the latter ones are able to flow from computer to computer in the network. We then discuss the creation issues, business aspects, and intellectual property rights (IPR), including patentability of mobile ontologies. We also discuss some basic requirements for computer systems architectures that would be needed to support the usage of mobile ontologies.

INTRODUCTION

The mobile subscriber base in the world is growing fast. The industry itself estimates that at the end of 2006, the number of subscribers reached 2.7 billion and it is expected that the number of subscribers will grow with 480 million during 2007 (Umsoy, 2007). The biggest growth will be in the developing countries, like India and China. There are over 130 3G WCDMA networks in 60 countries with 100 million subscribers. The latter number will grow to 170 million during 2007.

Low-cost WCDMA terminals (65 € a piece) are coming to the market. High Speed Packet Access (HSPA) with 3.6 Mbps downlink capacity is deployed in 51 countries in 93 networks and there were 128 devices on the market supporting HSDPA in March 2007 (Umsoy, 2007).

Digital convergence is tearing apart the old barriers between entertainment, media, telecom and computer industries, and all these industries are melting together into one huge industry. At the same time, the wireless operators are pondering their position on this market. They want to be more than bit pipes providing access to Internet for wireless terminals. Many operators think that they must provide better and more appealing services to the subscribers. How can appealing services be offered to mobile users both in developed and developing countries? These can be location-based or context-aware in a wider sense, or other services adapted to mobile Internet.

At the same time, the top models of mobile wireless terminals have reached capabilities of a laptop computer a few years ago with gigabytes of memory, programmability, fast processors, GPS receivers, text editors, calendars, e-mail clients, browsers, and so forth. Many have cameras and can record images and video with sound. Thus, users have begun to generate multimedia contents using these devices. Assuming that a user takes, for example, 2,000 digital photographs and some video clips in a year, there will be a substantial number, tens of thousands, even hundred thousand of these kinds of objects after 30-50 years. These are mostly relevant for the person himself or herself and for his friends and family members. Managing reasonably these emerging digital archives requires semantic metadata that cannot be generated fully automatically. Rather, user's help is needed (Sarvas, 2006). Also, storage space (approaching terabyte range for a life-time archive) is a problem and the stability of the formats used. Who guarantees that for example, the currently so popular JPEG-format would be supported in 2060? If the format originally used to store the images or video clips is not any more supported, what kind of automatic means are there to transform the contents into newer formats?

YouTube (Youtube, 2007) is currently one of the most known sites in the world where people can upload their video clips and other users can download them. Many of those videos have been produced by mobile handsets. Flickr (Flickr, 2007) offers sharing of photographs and a simple annotation in the form of tags. Not all material is suitable for distribution all over the world, though, for moral, legal, cultural, or privacy reasons. For instance, Flickr site does not allow sexually-oriented contents beyond a certain limit, although the tags "sex" and "sexy" are in use.

The above needs of individuals while managing and sharing digital contents are rather different from those of the companies offering various kinds of *mobile services.* Both can be satisfied in several ways. Perhaps the most sophisticated approach is to use *ontologies* in all these contexts. Because terminals are becoming more and more powerful over time, they can also be used to run complex computations, for example, inferences, required while using *formal ontologies* for various purposes. This is the main motivation behind this article.

In section 2, we discuss the concept of ontology and epistemology in general and in section 3, we discuss the concept of ontology in computer science field. In section 4, we discuss what should be understood by mobile ontologies. In section 5, we will turn our attention to the ontology creation issues in general and the peculiarities when creating mobile ontologies. In section 6, we discuss so-far largely ignored business and IPR issues related to mobile ontologies. Section 7 concludes the article.

ONTOLOGY AND EPISTEMOLOGY

"What is there? What exists?" This could be understood as the basic question of ontology,

that is, *study of being* or existence in philosophy. Different answers to this question were given over the course of history. One fundamental issue is, whether the deepest reality is ever changing and moving or whether it is stable and movement is just a human illusion After the Renaissance in Europe, one began to explore the nature in order to find the explanations from it itself by the methods of natural science. The starting point of the scientific inquiry is that there are no reasons or causes external to the nature and that the causes and true explanations can be found by interacting with the nature. Another starting point is that human perception of the nature is different from the nature itself, because otherwise we would know the essence of nature without further interactions and its exploration would be unnecessary. We adhere to the view that there are two different realities, one within the individual human *consciousness* and the other outside of it. Further, change and movement are real and change is actually the ultimate attribute of the realities. Stability is just transient.

The modern thinking and the concrete exploration of the nature have radically changed the answer to the ontological question and also the structure of modern societies. It has brought up such *concepts* as electrons, neutrons and other particles, atoms consisting of them and possibility to split atoms to gain energy, molecules and chemical industry, DNA, living cells, bio-industry and modern medicine, electro-magnetism, electronics and electrical industry including computer industry, relativity theory, galaxies, black holes, and so forth. In mathematics, one has developed axiomatic mathematics, formal logic and formal languages, paving the way to computing and formal ontologies.

The modern thinking has further divided the external reality into *physical* and *social* reality. Physical reality exists also without people, that is, it existed before any human being existed and will exist after human beings have vanished from the universe with their concepts and ideas, such as stability, gods, good life, good and bad, right and wrong. That is, physical reality is more fundamental than social reality, although admittedly also other views on the structure of physical reality and its relationship with the social reality have existed in the consciousness of the individuals and collectives over history.

Already the great Greek philosophers Plato and Aristotle posed the *epistemological* questions "What can we humans know of the reality?", "What is truth?", "What is knowledge?" These questions are always related with the basic ontological *world view that* covers all the elements considered basic by a certain group of people, such as nature or matter, human beings and perhaps various kinds of spirits or souls. *Concepts* and their relationships, *theories*, form the knowledge part of the contents of the consciousness and thus the above epistemological questions can be rephrased in terms of concepts and utterances about their relationship with the physical and social external reality. Which concepts refer to something existing and which relationships can be confirmed in the reality?

Coming back to the fundamental questions of ontology and epistemology and their relationships, our view is the following. A plausible solution to a consistent ontology and epistemology is that human beings develop their concepts using their mental, creative capabilities, while *interacting* with the physical reality and communicating with other people in a society, that is, while being part of the social reality. The *individual and collective needs* to develop and adopt new *concepts* emerge always in a certain social context. This means that the answer to the basic ontological question, "what is there", changes over time, represented in new concepts and their relationships. The concepts are developed by various groups of people in interaction with themselves and with the physical reality. During the modern times, these kind of activities produce ontology that is based on

the methods of natural and other sciences and explain the nature from and within itself, whereas in the past various kinds of spirits or gods were often included into the ontologies supported by various groups. Another object of the studies is the social reality, that is, human societies. In our view, macro- and microeconomic theories, as well as concepts of politics and social sciences belong to this sphere. The modern concepts and theories describing these are evidently widely different from those describing physical reality. Individuals adopt the views developed by previous generations and mediated by oral and/or written means and only some develop them further. In current societies different groups of people and even a single individual can have different ontological views that can be also contradictory.

In the modern separation of physical and social reality, the *artifacts* developed by human beings, such as houses, cars, fashion, mobile networks and terminals belong clearly to the physical reality created by human beings. But their existence or development cannot be explained in a similar manner from nature as development of, for example, mountains or oceans. Rather they are at the same time also results of human social activity. This duality should be reflected in the specific ontology describing them. There is an extensive discussion on a suitable ontology for these kind artifacts, that is, in Pohjola (2007). These kinds of discussions about the "true essence" of artifacts are relevant for ontologies in computer science, because they also are socially created artifacts that exist in the physical (digital) reality. What is a suitable "artifact ontology" for computerized ontologies is an interesting question, but beyond the scope of this article.

The general questions and issues above are relevant also for ontology development in the computer field. We point to them below at appropriate places.

ONTOLOGIES IN COMPUTER SCIENCE

In the computer science field, McCarthy introduced in 1980 the concept *environment's ontology* that contained a list of concepts involved in a problem (environment) and their meanings (Sanchez, 2007). Since then, the term has been associated with the representation of concepts and the usage has spread out to many fields of computer science. The often cited definition by Gruber reads "ontology is an explicit conceptualization of a domain", although in the abstract of the same paper it reads "A specification of a representational vocabulary for a shared domain of discourse — definitions of classes, relations, functions, and other objects — is called an ontology" (Gruber, 1993). The definition does not explicitly relate ontology to a specific group of people or its validity period. It has also been pointed out, for example, by Smith (2004) that "conceptualization" remains undefined in the definition.

In the sequel, we mean by ontology *a conceptualization of a domain created and shared by a group of human beings. The domain can also be called a possible world.* This definition stresses that an ontology must be understood by a group of people in the same way as far as it is possible; must be representable in an interpersonal form (using natural or formal language, pictures, etc.), and must refer to a common domain that the group agrees upon. The domain or possible world does not need to exist in the current physical or social reality, only in the consciousness of the group members, and as the corresponding externalized representation. Most often, though, an ontology is established with the goal of claiming that the domain indeed has had, has, or will have the structure, relationships and properties the ontology referring to the domain claims it to have. In this narrower sense, an ontology can be understood as a *body of knowledge describing*

some domain and as a representation vocabulary for it. In this capacity, it also makes sharing of knowledge among individuals and groups possible (Chandrasekaran, 1999). This view on ontology is narrower than the general definition above because knowledge should be truthful, that is, refer to reality it is to the best of our knowledge. One cannot say the same of an arbitrary possible world, or even about a possible future world. The fitness of an ontology as a carrier of knowledge is discussed, for example, in Smith (2006b) and more general discussion on the various aspects on ontologies can be found in Brewster (2007) and in the special issue of the International Journal of Human-Computer Studies.

Conceptualizations we have in mind are *terms* with natural and/or formal language definitions that *refer* to universals or instances in the physical or social reality or human consciousness, and the relationships between the terms. A fairly general way to construct ontology is expressed in LOA (2007): "ontology is assumed here as a semiotic object, including at least three objects: a graph (information object), a conceptualization (description), a semantic space (abstract). The semantic space refers to the 'formal' semantics of an ontology graph, while the conceptualization refers to its 'cognitive' semantics". For instance, "VW is-a car" means that there is a collection of physical artifacts called cars on Earth and some of them are manufactured by Volkswagen. The semantic space contains the set of cars and VW-cars are a subset of it. These can be represented by set-theoretic, inter-subjective notations, but the notations can only again refer to the real collection of physical cars by human mental act—or by computerized version thereof. The cognitive "car" refers to the culturally given connotations of a car as an artifact, vehicle, status symbol, and so forth, as individuals perceive them. Depending on the goal of the ontology, certain relationships with other concepts are included into the ontology graph, but not necessarily all. For example, the concept of car can only be related with vehicle (as a subclass), but other culturally relevant concepts are not included into the ontology. Thus, an ontology can be understood in the same way by different people, as concerns the concepts (signs), but these can have different connotations and thus the ontology is not understood in the same way by the people (Mancini, 2006).

Ontologies in computer science have been classified in several ways. The authors of vHeijst (1997) classify ontologies, according to their use, in *terminological, information, and knowledge modeling* ontologies, whereas Guarino (1998) divides them into *top-level, domain/task,* and *application* ontologies, based on their generality. The authors in Gomez-Perez (2003) classify ontologies into *lightweight* and *heavyweight* ontologies. The former include concepts, concept taxonomies, relationships between concepts, and properties describing the concepts. The latter enhance the former with axioms and constraints. D. Fensel introduces five categories differentiating between *metadata, domain, generic, representational,* and *method/task* ontologies (Fensel, 2004). Thus, we see that currently there is no commonly accepted single classification for ontologies.

Ontology development is an activity performed by a group of people. At the beginning of the development process, humans usually rely on written and spoken natural language and informal schemata and the end result can even remain in this informal form. The process of developing ontology can be from bottom-up or top-down, although both directions are usually mixed. The mixed version, where both directions are used simultaneously, is often called middle-out. In the bottom-up approach, the existing terms and concepts of a domain are taken as a starting point, definitions given and relationships between concepts established that reflect the relations in the domain. In the top-down approach, one can

start from an existing upper ontology and refine and enhance it with the concepts of the domain. Of course, the process of developing ontologies is rather complex. For instance, the borders of the domain can be unclear and the domain understood in a different way by participants at the beginning. Thus, as part of the ontology development, the exact domain can emerge and become shared by the people.

In general, the external representation of ontology is composed of symbols of one or several languages. It is a representation of the shared understanding of the group members of what the domain is and what is essential or interesting for the domain. As such, it is just a finite (information) object, carrying meanings to people, and it can be encoded into a bit string and stored on a computer. It means something only for those people who understand the languages used. A computer "understands" an ontology or part of it, if there is a portion represented with a formal enough language that can be interpreted by the computer. In other words, programs must run that use this portion as input and that compute results using it. Such ontologies that are composed using a formal language or contain a formal language portion are called *formal ontologies,* others are called informal *ontologies.*

The formal languages used are usually subsets of first-order predicate logic, such as description logic or frame logic (Staab, 2004), but also (extended) UML and ER-notation have been proposed to be used as a formal ontology language (Sanchez, 2007). *Automatic reasoning* in computers based on the axioms and inference rule(s) of the logic become thus possible. Generally, any formal language that can be given an operational, computable semantics would be a possible candidate for an ontology description language, as long as it is easy for a human being to represent concepts and their relationships, as well as restrictions that are typical of the domain. In Smith (2006), it is stated that such a resulting ontology should be *intelligible*, that is, understandable by other persons that did not develop it, with a reasonable effort. Often, formal ontologies are not especially intelligible; check the proposed ontologies, for example, at WSMO (2007) or LOA (2007). Therefore, formal ontologies usually contain also portions that contain descriptions of the concepts and relationships in natural language. Based on the informal and formal parts one can also ask, whether on ontology is internally *coheren*t, that is, do the informal and formal part specifies the same domain, the same relationships and axioms.

Another set of requirements presented by Smith (2006a) requires *openness:* "ontology should be open and available to be used by all potential users without any constraint, other than (1) its origin must be acknowledged and (2) it should not to be altered and subsequently redistributed except under a new name… In addition the ontology should be (3) explained in ways which make its content intelligible to human beings, and (4) implemented in ways which make this content accessible to computers." It is rather clear that open ontologies in the above sense would be usable by anybody and those who develop them could not sell them and thus directly take the benefit. Indirectly, it might be possible, though. The last point (4) would namely mean that all ontologies should be flowing (or native) and thus mobile in one sense (see below). In this form, they could possibly be integrated or downloaded into larger computer systems and used by software. A business opportunity might exist here both for the developers of the ontology or for the third parties (see the next section).

MOBILE ONTOLOGIES

What would then be mobile ontologies? While answering this question, we are actually constructing a further classification of ontologies. The term mobile could be added to almost any class above, obtaining such terms as mobile top-level, mobile domain, mobile application, mobile metadata, or

mobile terminological ontology. But what would they mean? We gave a tentative characterization for the term mobile ontology in Veijalainen (2006), and refined it in the preliminary version of this article (Veijalainen, 2007). According to it, a mobile ontology can conceptualize a mobile domain, that is, the possible world the ontology is conceptualizing must be related with mobility. On the other hand, an ontology can itself be mobile, that is, its digital representation can move from one node to another among networked computers, or it can move physically with the terminal. These two aspects are largely orthogonal.

What should be understood by a mobile domain in this context? Let us start from bottom up. In the current business practice and also in the scientific literature, the term mobile is used in many different ways. One speaks, for example, about mobile networks, mobile applications, mobile users, mobile terminals, and so forth. Often, the term mobile refers only indirectly to physical movement, and the reference is primarily to wireless and other technologies that make physical movement possible or that can be used while on the move. In some contexts, the term mobile could be replaced with the term wireless to emphasize that the central issue dealt with is wireless communication technology that facilitates physical movement of the terminal during service delivery. Seen from the service accessibility point of view, mobility in service delivery refers to the possibility to *deliver the services anytime anywhere*. Where the user happens to be and whether the user moves or not or is not of importance for the service delivery.

How should "mobile" or by "mobility" be defined in the context of the mobile ontology? If we think that these terms are somehow directly or indirectly related with the physical movement of the human user or movement of the ontology representation either from one computer to another or within the computer around, we can conceptualize the movement as *context change*. We can ask, what a user or ontology would need in a *new context* and in which cases she/it would need (portions of) her existing context? In general, a context can always be related with a particular physical place, but there can be different relevant contexts attached to a place. The context can change even if the user sits in her chair in the office, once speaking to (VoIP) phone, once having a face-to-face meeting with some people in her office, once wanting to concentrate alone on her work. The context usually changes, though, if the user is roaming to another country, and it could change as a result of the micro-mobility, at least from the network infrastructure perspective.

The user context and its management can be taken care of mainly by the terminal with the help of the user, but it often requires support also from the network infrastructure. From the network infrastructure point of view, "mobility" of a terminal or person can refer to at least five different aspects (cf. (Puttonen, 2006)):

1. A person changes the terminal in use (often as a result of physical movement, or context change)
2. A terminal changes its point of attachment to the network (often as a result of the physical movement with its owner; cf. hand-over)
3. Application is migrated from one network node to another (cf. mobile agents)
4. An on-going session is moved from one terminal to another (cf. 1)
5. Services available for a subscriber at one network location are offered at a new location the subscriber physically moves to (cf. 2; context transfer)

The above view on mobile domain and mobility is mainly a context change issue from the network infrastructure point of view. Although this is an important domain, it does not cover all mobile domains. Keeping this in mind, we can refine the concept of mobile ontologies further. We introduce the shorthand notion *md-ontology* for mobile *domain ontology*, where the domain

is related with mobility (see below). On the other hand, if ontology (representation) can move from one computer network node to another, such ontology is called *flowing or fl-ontology*. Those ontologies that are stored (by manufacturers or operators, etc.) into terminals or other devices and move physically with them, but cannot flow into them from the network, are called *native* or *nt-ontologies*. Notice that we allow the native ontologies to be read, that is, flow out, from the terminal or other wireless device. In addition, all mobile ontologies can be divided into formal and informal ontologies as discussed above. These two aspects are orthogonal and thus, informal-formal and flowing-native divide the set of mobile ontologies into pair-wise disjoint subsets. Are there any ontologies that are not mobile in any sense? Yes, those whose domain is not mobile (say bioinformatics (OBO, 2007)) and which are neither installed into terminals by manufacturers nor can be downloaded into them later for whatever reason.

All the aspects, 1-5 above, seen from the network infrastructure's point of view, can be a domain of a md-ontology. In addition, there can be further md-ontologies that model, for example, physical movements of objects on earth. In that case, the ontology would support, for example, tracking applications where the physically moving objects are not primarily users, but physical objects that are tracked, such as trucks or parcels—or terminals or RFID chips mounted on them. Ontologies describing essential concepts for this application domain (such as tracking, positioning, trace, trajectory, velocity, etc.) can also be regarded as mobile domain ontologies.

Ontologies that help in anywhere/anytime service delivery to mobile terminals are also typical md-ontologies. They do not need to be installed at the terminals, but can reside also at other network components, like servers providing the anywhere/anytime services. This subcategory might contain md-ontologies that support content format transformations and mobile Web service descriptions. Another case is described in Massimo (2007) where the mobile device accesses a tag in its vicinity to which information and/or a Web service is provided from a server. The (ontology-based) service description is dynamically loaded into the device and, for example, information on movies or a movie ticket can be provided to the device as a result of the service invocation.

Fl-ontologies are a special case of 3 if we consider ontologies to be a special kind of software or belonging to a software package moving in the network from one node to another. They have many commonalities with mobile agents, and one might argue that such ontologies are as such actually pieces of software moving around in the network. This view is valid, if the ontology can be directly interpreted or compiled at the receiving node and appropriate actions taken by the computer. An example of this is presented in Khusraj (2005), where a user interface for a Web service is generated from a semantic description at a mobile device. The ontologies might also be carried by mobile agents as part of their state. Another possible scenario is software package that is downloaded from the network and is installed at the terminal. Its functionality might be guided by an ontology component that travels with it or that is downloaded separately.

Any ontology that is stored at a home location or by manufacturer into a device can be considered an nt-ontology. The significance of this concept is that such an ontology could have been designed to a certain environment or context (e.g., by an operator or a manufacturer) and it might not work properly in other environments or contexts the terminal roams to. But it might also be upper-level ontology that works everywhere and does not need to be changed, based on the location. Some nt-ontologies might be invisible to the outside world, but some of them might flow out, that is, they might be readable from outside. This might a possibility for future digital tags that can tell what to store and how to access it.

Point 5 above is challenging from the usage and development point of view of such services that are based on ontologies. Challenge concerning point 3 is heterogeneity and autonomy, but also the applicable business model that makes transfer of (formal) ontologies profitable, or at least possible.

What is the relationship between informal-formal and flowing-native ontologies? Informal ontologies can flow "more easily" than formal ones, because they are only based on natural language and perhaps on some commonly available drawing tool or text editor formats, including XML-based ones, whereas the formal ontologies need rigorous execution (reasoning) environment and in a heterogeneous environment in addition powerful mediators that translate from one formal language to another (Roman, 2005; Euzenat, 2007). The formal ontologies usually also have an XML encoding for transmission purposes, so that at this basic level they can be transported in computer networks or over a wireless short-range link from node to node. In these cases, the enhancement of an ontology with another might happen and the consistency issues are of importance.

DEVELOPING MOBILE ONTOLOGIES

Developing ontologies can be performed by various actors. Known alternatives are research groups, research projects, and larger organizations who have hired specialists to do the work for themselves, or coordinate the work paid by large companies and government organizations. Further, developer communities can engage in the development of ontologies, in a similar fashion as some groups develop free software. ISO is an example of a large international organization that has developed a standard ISO 15926 (ISO, 2003) that could be used as an upper ontology. Barry Smith has checked the quality of the ontology, though, and comes to the conclusion that it is not an ontology at all due to many flaws (Smith, 2006b). Because it can be downloaded from the ISO site as a pdf-file, it would be an fl-ontology, but not a formal one.

Another example of an existing ontology is, for example, "high-level mobile ontology" developed by the SPICE project (Zhanova, 2006). It is developed for the mutual understanding of the project. It is also exploiting many other existing ontologies and related specifications, such OMA's UAp (OMA, 2006) and FOAF vocabulary (FOAF, 2007). The ontology specifies the concept of service and subtypes thereof, device and subtypes thereof, mobile access network and subtypes thereof, person (a physical thing), user groups, configuration, location, context, contents and contents types, and so forth. It is an md-ontology in our classification that can be used to describe mobile infrastructures. It is a formal upper-level ontology that could be used by various terminals and by the service delivery sites. It is developed by a research consortium.

Is developing mobile ontologies any different from other ontologies? If it is question of md-ontologies, the same challenges are encountered as while developing ontologies for other domains. The only difference might be that some md-ontologies are inherently related with changes in the domain, and change is a general challenge for ontologies. As concerns methodologies, Sanchez (2007) reviews shortly several proposed ontology development methodologies. It seems that any of them could be used, but it is too early to say whether various md-ontologies would have specialties that would require modifications to the methodologies, or perhaps new developing methodologies to be developed. In any case, Fl-ontologies, especially formal ones, present additional challenges, both organizational and technical. When an ontology crosses an organizational border, the receiving organization should understand and accept the world view its developers had and also *trust* the sending side. Neither is by no means generally given between autonomous organizations. Detect-

ing the discrepancies between different world views is easy in the case of intelligible ontologies (cf. above), because they explicate the views of the developers for other humans. Perceiving the world view is more difficult in the case of usual software, because any piece of software crossing an organizational border carries with it a world view of the developers, but it is often represented only in the code and detected only when using the software. The same might be true for large formal ontologies that cannot be understood by humans without a big effort and high technical skills. And of course, if the ontology comes as data part of mobile agent or software package, the problem is essentially the same as for any moving software. If we think that pure ontologies or mobile agents would be downloaded by ordinary mobile users, without special technical skills, the problem is aggravated. They could not check the quality of the ontology, mobile agent or piece of software, but rather they could only trust the provider.

The technical challenges are mostly software engineering challenges in the mobile environment for the flowing ontologies. They are similar to downloading software from the network. There must be a platform support for correctly installing and interpreting the ontology. What the support exactly looks like depends at least partially on the formalism used to represent the ontology and the nature of the ontology (top-level vs. application, lightweight vs. heavyweight, etc.). A requirement peculiar to ontologies is that if the ontology is to be integrated with an existing one, or existing ones, then the resulting ontology should be at least *consistent*. This means that no contradictions can be inferred from valid input definitions (Gomez-Perez, 2004). There should be tools to check this at least at the provider site, but perhaps also at the terminal. Like in the case of other software entities, there should be versioning mechanisms and valid configuration schemes for mobile ontologies. Using them, compatibility relationships could be expressed between different ontologies and their versions.

According to Gomez-Perez (2004), ontologies should also be evaluated for *completeness* (everything meant to be there is explicit or can be inferred, and each definition is complete), *conciseness* (no redundancy), *expandability* (how easy is it to add new definitions and knowledge without altering the set of already guaranteed properties), and *sensitiveness* (how small changes alter the well-defined properties already guaranteed). All these are relevant attributes for md- and fl-ontologies and should be taken into consideration when developing and updating them.

There are many emerging formal ontologies in various domains, such as biomedicine, law, software engineering, and so forth, (LOA, 2007; OBO, 2007; Ontomed, 2006). Some of these could be perhaps used as part of mobile ontologies.

The problem of generating metadata for private photographs taken by camera phones has been investigated in Sarvas (2006). The author concluded that this area is a special domain and requires metadata—or ontology—that is different from the commercial multimedia material. He also discovered in user tests that people are not willing to insert the metadata at spot (who are on the picture, what was the social situation the picture was taken in, etc.), because it tends to disturb the photographing act.

In jpg-metadata there is already some information, such as camera type, shutter, date, and so forth, but coordinates where the picture was taken should be added. This would require GPS or other satellite receiver to be integrated to or accessible for the terminal. Currently, the trend is that high-end terminals begin to include a GPS receiver. To the coordinates, one could attach the name of the place automatically when precise enough geographic information was made available. Automatic face recognition might be possible for acquainted people in the picture, if once done and the resulting meta-information stored at the terminal. The hard parts are the semantically high level concepts, like "situation" or "social context" where the picture was taken. This should

be described by the user textually or orally and transformed into text by speech recognition. Speech recognition could be also used to identify people in the picture if they happened to speak when the picture was taken. In Khusraj (2005), the concept of semantic cache was proposed that keeps track of the places that the user has visited lately. These can be directly included into the metadata and used by the inference engine.

A general solution to ontology development is to reuse existing pieces of ontology. In Salminen (2005) the authors present an architecture that allows a mobile terminal user to develop, organize, and share the digital contents and the associated metadata. The device manufacturer would provide a software that is able to store and interpret the metadata, and evidently, a native (meta)ontology. The user can then enhance this with flowing components or develop himself or herself new ontologies.

Although the ontologies conceptualizing low-level mobile protocol layers or device characteristics are important for the end-to-end service delivery, still modeling the service, context, and contents domains is the key for the proliferation of nice services. Could the vast end-user population help here? What are the minimal skills and minimal knowledge required? If we are speaking of informal taxonomies, such as folksonomies (Koivunen, 2006; Wikipedia, 2007), the requirements are not so high. They can be generated by ordinary users and are used to tag all kinds of digital objects. A collection of such tags is usually not a genuine conceptualization of a domain, that is, an ontology in a strict sense. This is because tagging can be contradictory and usually lacks hierarchical relationships, such as "is a", "part-of", and so forth. Collectively, generated tags can still be used to organize private photographs either at Web sites like Flickr (Flick, 2007) or on private devices. What kind of tools would be needed at the mobile terminals to support generation of remote tags? It seems that inserting photos to the above Flickr site directly from camera phones and tagging them is possible already now.

Folksnomies are developed by a user community. The approach bears resemblance to the development of open source software. Whereas open software cannot be developed by unskilled people, folksnomies can be developed by people who cannot write code. How big is the distance from folksonomies to ontologies and further to proper formal ontologies that could be used by programs as input? Folksonomies can be used at least as some kind of starting point to develop ontologies for certain domains bottom up, but it is evident that developing even an informal ontology and especially a formal ontology requires expert work. For instance, the Flickr tags are just a collection of individual words and the frequency they occur in metadata of the photographs reflects the frequency of the situations the pictures were taken in. A rather common tag is for instance "Canon" referring to the camera manufacturer, and "Wedding" referring to a situation the picture was taken in. One might argue that not even every person who is able to write, for example, Java programs would be able to compile a formal ontology. The latter requires different skills than programming.

ONTOLOGY SHOPPING

The organization or a group of individuals that develops an ontology, or fraction of it, primarily owns it. Some capable experts might be interested in developing ontologies in the same spirit as they are ready to write articles to Wikipedia or open source software. Still, if formal ontologies would become directly usable by mobile terminals, then it would make sense to develop them as commercial activity and pay for the work. This is currently hardly envisaged in the research literature. Probably, because developing ontologies, especially formal ones, requires high skills and is currently still research activity.

What legal status would ontologies have? They are scientific or technical works and fall under the Berne Convention that also regulates software ownership and rights (WIPO, 2007). According to Berne convention, a copyright holder is inherently the creator of the work. The rights cover economic and moral rights and the creator has thus the right to demand economic compensation when the work is performed or distributed to audience. The creator can also sell his or her rights to another person or company totally or in part. Those countries that have joined the Berne Convention treat the rights uniformly, although the convention allows exceptions. The local legislation may, for instance, automatically move the copyrights of an employee to the employer in some cases. For instance, the rights to (production) software, if produced by employees as part of their normal duties at a Finnish university, are moved by the law to the university without further action and without additional compensation. The copyright protection holds of course to original enough works, not works that would infringe the rights of other copyright owners. Another question is whether ontologies would be software or other scientific of technical works. The informal ontologies could hardly be considered as software, but the formal ones could be interpreted as software if they can be executed in a computer like any other program. Some formal ontologies have been copyrighted as software, such as Ontomed ontology (Ontomed, 2006). This can be inferred from the fact that the ontology includes a GPL-like license at the beginning and categorizes the contents as "software". In any case, all kind of ontologies are material that is protected by copyright if developed in a country that has joined Berne Convention (cf. WIPO, 2007).

Whereas copyright grants legal and moral rights to the owner, it does not protect the ideas presented in the work. That is, if somebody buys a book, where a construction of a machine a process, a business model, and so forth, is presented, the copyright owner neither can prohibit the buyer to construct the machine or implement the process or business model, nor can demand any economic compensation for the possible yield. *Patents* protect the innovations and give the exclusive rights to the patent owner to reap the economic benefits from the innovation for a limited period of time (e.g., 20 years) in the jurisdiction the patent has been granted in (e.g., USA, EU, Japan). A patent is a public document. After the patent has expired, the innovation can be copied and developed further by others and economic benefits reaped freely.

Could ontologies be *patented?* In this case, there is evidently a difference between informal and formal ontologies. The former cannot be patented, only copyrighted and usage perhaps licensed in some cases. If formal ontologies are considered to be software, then in some countries (such as USA) they might be patentable even as such, or at least as part of some larger software system or other technical context. The patentability seems to be largely open, though, because the exact nature of them as creative work is not established yet..

Digital music, videos and software can be bought and used in the mobile terminals. Full-fledged formal ontologies are also machine-process able and could become at least in theory, separate objects of trade. Their behavior and usage is quite close to a of piece software. They need some kind of interpreter in order to be usable, in a similar fashion as Java byte code. But can formal ontologies be considered as software in the legal sense? Or are they treated rather like other digital contents? This is largely open, but in both cases ontologies could become intangible goods—or information society services as the EU jargon proposes.

There are not many examples of ontology shopping. ISO has developed an international standard ISO 15926 (IS, 2003) that is also considered by some groups to be an upper-level ontology (cf. above). As a standard, it has a price tag of CHF

258 (EUR 156). It is protected by copyright that denies its further distribution. Thus, it evidently could not be used in computerized ontology applications without licensing—if somebody managed to make it executable in computers, that is, to formalize it properly.

In order for ontology market to be economically viable, several conditions must be met. They are rather similar as those for the other mobile contents or mobile application software. Some device manufacturers could, for example, implement some functionality of the devices using ontology-based technology and thus increase the attractiveness of the devices. The devices could have an ontology (reasoner) engine installed by the manufacturer, in a similar manner as some now have a Java virtual machine or a media player. This engine could then be used to process ontologies in various contexts. The engine could also be licensed and installed later, and necessary ontologies could then be downloaded and processed using it.

The manufacturer could install some nt-ontologies into the device that would not need to be md-ontologies. A typical example would be an ontology for digital pictures that would make their indexing and retrieval possible for the user or other digital contents (Salminen, 2005).

Mobile md-ontologies might also come with the device, but the user could order various md-ontologies as he or she needs, over the network or on a memory stick/memory card. So, those md-ontologies that are bought during the usage should be designed as fl-ontologies. Technical problems are similar to those of downloading software from the network. Perhaps it makes sense to develop "source code form" and some kind of "byte code" for the mobile ontologies as well, in analogy to Java, or one could also develop the interpreter in Java. Source code format should have XML encoding, like OWL-S and WSML (WSMO, 2007) have.

While selling or otherwise distributing private contents, privacy becomes an issue. The actual contents, but also metadata can contain information that a person might not want to share with a larger audience, although this would be shareable within, for example, family. This has been addressed, for example,. in Sarvas (2006) and Salminen (2005).

CONCLUSION

We have discussed in this article mobile ontologies; what should be understood by them, how they could be used, who would develop them, and why. The concept is still under development and the term "mobile" can refer to two rather different aspects. On one hand, the domain of the ontology can be related to mobility (md-ontology), on the other hand the interpersonal representation of the ontology can move (flow) from node another in the network (fl-ontology) or move with the terminal (native or n-ontology). In the latter cases, the domain of the ontology can be anything. The definition of mobile ontology should address these aspects. We suggest the following definition: *If the domain of an ontology is related with mobility or it can be mounted or downloaded to and used at a mobile terminal, or both, th*en *it is a mobile ontology.* Informal ontologies can flow more easily, as far as technical constraints are considered, whereas formal ontologies that have usually a portion consisting of first-order logic expressions have more difficulties in crossing heterogeneous and autonomous system borders. The latter kind of ontologies facilitate formal reasoning, and further automatic processing, whereas informal ontologies can only be applied by humans. Organizational autonomy is also an important issue in the scenario, where ontologies are dynamically downloaded to mobile terminals or incorporated into the ICT infrastructure of an organization. Because ontologies are difficult to understand and inspect, an organization, not to speak about a usual user, must trust the ontology provider.

Mobile formal ontologies might become objects of trade, if they turn out to be useful enough to justify the investment in developing a software infrastructure and terminal and ontology base for them. Business models for these might look similar to those of the mobile software and both native and flowing ontologies could be used. Free ontologies are also possible, in a similar manner as free software, and in analogy, open mobile ontologies are also possible.

Quality of ontologies is an emerging theme and the identified attributes like consistency, completeness, conciseness, expandability, and sensitiveness are important to evaluate for mobile ontologies. It is evident that if ontologies are downloaded to a terminal, the providers should indicate with which earlier versions of which other ontologies a certain ontology is compatible. Compatibility statements must evidently consider all quality attributes above.

Intellectual property rights in the context of ontologies seem similar to scientific pieces of work or software and are thus primarily governed by copyright laws. Only formal ontologies could be viewed as software and as patentable is some countries, but the entire area of intellectual property rights in the context of ontologies is largely open. The solution might have some ramifications to the possible mobile ontology market, though, as we have seen in software business in the context of free/open software.

ACKNOWLEDGMENT

Chapter 7.25
Web Mining System for Mobile-Phone Marketing

Miao-Ling Wang

National Tsing Hua University, Taiwan, ROC[1]

ABSTRACT

With the ever-increasing and ever-changing flow of information available on the Web, information analysis has never been more important. Web text mining, which includes text categorization, text clustering, association analysis and prediction of trends, can assist us in discovering useful information in an effective and efficient manner. In this chapter, we have proposed a Web mining system that incorporates both online efficiency and off-line effectiveness to provide the "right" information based on users' preferences. A Bi-Objective Fuzzy c-Means algorithm and information retrieval technique, for text categorization, clustering and integration, was employed for analysis. The proposed system is illustrated via a case involving the Web site marketing of mobile phones. A variety of Web sites exist on the Internet and a common type involves the trading of goods. In this type of Web site, the question to ask is: If we want to establish a Web site that provides information about products, how can we respond quickly and accurately to queries? This is equivalent to asking: How can we design a flexible search engine according to users' preferences? In this study, we have applied data mining techniques to cope with such problems, by proposing, as an example, a Web site providing information on mobile phones in Taiwan. In order to efficiently provide useful information, two tasks were considered during the Web design phase. One related to off-line analysis: this was done by first carrying out a survey of frequent Web users, students between 15 and 40 years of age, regarding their preferences, so that Web customers' behavior could be characterized. Then the survey data, as well as the products offered, were classified into different demand and preference groups. The other task was related to online query: this was done through the application of an information retrieval technique that responded

to users' queries. Based on the ideas above the remainder of the chapter is organized as follows: first, we present a literature review, introduce some concepts and review existing methods relevant to our study, then, the proposed Web mining system is presented, a case study of a mobile-phone marketing Web site is illustrated and finally, a summary and conclusions are offered.

LITERATURE REVIEW

Over 150 million people, worldwide, have become Internet users since 1994. The rapid development of information technology and the Internet has changed the traditional business environment. The Internet has enabled the development of Electronic Commerce (e-commerce), which can be defined as selling, buying, conducting logistics, or other organization-management activities, via the Web (Schneider, 2004). Companies are finding that using the Web makes it easier for their business to communicate effectively with customers. For example, Amazom.com, an online bookstore that started up in 1998, reached an annual sales volume of over $1 billion in 2003 (Schneider, 2004). Much research has focused on the impact and mechanisms of e-commerce (Angelides, 1997; Hanson, 2000; Janal, 1995; Mohammed, Fisher, Jaworski, & Paddison, 2004; Rayport & Jaworski, 2002; Schneider, 2004). Although many people challenge the future of e-commerce, Web site managers must take advantage of Internet specialties which potentially enable their companies to make higher profits and their customers to make better decisions. Given that the amount of information available on the Web is large and rapidly increasing, determining an effective way to help users find useful information has become critical. Existing document retrieval systems are mostly based on the Boolean Logic model. Such systems' applications can be rather limited because they cannot handle ambiguous requests. Chen and Wang (1995) proposed a knowledge-based fuzzy information retrieval method, using the concept of fuzzy sets to represent the categories or features of documents. Fuzzy Set Theory was introduced by Zadeh (1965), and is different from traditional Set Theory, as it uses the concept of membership functions to deal with questions that cannot be solved by two-valued logic. Fuzzy Set Theory concepts have been applied to solve special dynamic processes, especially those observations concerned with linguistic values.

Because the Fuzzy concept has been shown to be applicable when coping with linguistic and vague queries, Chen and Wang's method is discussed below. Their method is based on a concept matrix for knowledge representation and is defined by a symmetric relation matrix as follows:

$$A = \begin{array}{c} \\ A_1 \\ A_2 \\ \vdots \\ A_n \end{array} \begin{array}{c} \begin{array}{cccc} A_1 & A_2 & \cdots & A_n \end{array} \\ \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & & \vdots \\ \vdots & & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{bmatrix} \end{array}$$

$$0 \le a_{ij} \le 1,\ 1 \le i \le n,\ 1 \le j \le n \qquad \textbf{(1)}$$

where n is the number of concepts, and a_{ij} represents the relevant values between concepts A_i and A_j with $a_{ii} = 1, \forall\ i$. It can be seen that this concept matrix can reveal the relationship between properties used to describe objects, which has benefits for product identification, query solving, and online sales development. For effective analysis, these properties, determined as the attributes of an object, should be independent of each other; however this may not always be so. Therefore a transitive closure matrix A^* must be obtained from the following definition.

Definition 1: Let A be a concept matrix as shown in Equation (1), define:

$$A^2 = A \otimes A$$
$$= \begin{bmatrix} \vee_{i=1,\cdots,n}(a_{1i} \wedge a_{i1}) & \vee_{i=1,\cdots,n}(a_{1i} \wedge a_{i2}) & \cdots & \vee_{i=1,\cdots,n}(a_{1i} \wedge a_{in}) \\ \vee_{i=1,\cdots,n}(a_{2i} \wedge a_{i1}) & \vee_{i=1,\cdots,n}(a_{2i} \wedge a_{i2}) & \cdots & \vee_{i=1,\cdots,n}(a_{2i} \wedge a_{in}) \\ \vdots & \vdots & \ddots & \vdots \\ \vee_{i=1,\cdots,n}(a_{ni} \wedge a_{i1}) & \vee_{i=1,\cdots,n}(a_{ni} \wedge a_{i2}) & \cdots & \vee_{i=1,\cdots,n}(a_{ni} \wedge a_{in}) \end{bmatrix} \quad \textbf{(2)}$$

where $\otimes$ is the max-min composite operation with "$\vee$" being the maximum operation and "$\wedge$" being the minimum operation. If there exists an integer $p \le n - 1$ such that $A^p = A^{p+1} = A^{p+2} = ...$, $A^* = A^p$ is called the Transitive Closure of the concept matrix A.

Matrix A^* is an equivalent matrix which satisfies reflexive, symmetric and transitive properties.

To identify each object by its properties, a document descriptor matrix D is constructed in the following form:

$$D = \begin{array}{c} \\ D_1 \\ D_2 \\ \vdots \\ D_m \end{array} \begin{array}{c} \begin{array}{cccc} A_1 & A_2 & \cdots & A_n \end{array} \\ \begin{bmatrix} d_{11} & d_{12} & \cdots & d_{1n} \\ d_{21} & d_{22} & \cdots & d_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ d_{m1} & d_{m2} & \cdots & d_{mn} \end{bmatrix} \end{array}$$
$$0 \le d_{ij} \le 1 \quad \textbf{(3)}$$

where d_{ij} represents the degree of relevance of document D_i with respect to concept A_j and m is the number of documents in general terms. By applying the max-min composite operation $\otimes$ to D and A^*, we have matrix $B = D \otimes A^* = [b_{ij}]_{m \times n}$ where b_{ij} represents the relevance of each document D_i with respect to a particular concept A_j.

The implication of this approach for Web mining is: when we classify objects by their properties, if we can also cluster people according to their properties and preferences, then when a query is made, matching a user's properties to retrieval of the corresponding concept matrices of each cluster will speed up online response.

Clustering is fundamental to data mining. Clustering algorithms are used extensively, not only to organize and categorize data, but also for data compression and model construction. There are two major types of clustering algorithms: hierarchical and partitioning. A hierarchical algorithm produces a nested series of patterns with similarity levels at which groupings change. A partitioning algorithm produces only one partition by optimizing an objective function, for example, squared-error criterion (Chen, 2001). Using clustering methods, a data set can be partitioned into several groups, such that the degree of similarity within a group is high, and similarity between the groups is low. There are various kinds of clustering methods (Chen, 2001; Jang, Sun, & Mizutani, 1997; Wang, Wang, & Wu, 1994). In this study, we applied the forward off-line method in order to group people according to their properties and preferences.

The *c*-Means algorithm (Tamura, Higuchi, & Tanaka, 1971) also called Hard *c*-Means (HCM), is a commonly used objective-clustering method, which finds the center of each cluster and minimizes the total spread around these cluster centers. By defining the distance from each datum to the center (a measure of Euclidean distance), the model ensures that each datum is assigned to exactly one cluster. However, in this case in contrast to the HCM, there is vague data and elements may belong to several clusters, with different degrees of belonging. For such situations, Bezdek (1973) developed an algorithm called the Fuzzy *c*-Means (FCM) algorithm for fuzzy partitioning, such that one datum can belong to several groups with degrees of belonging, specified by membership values between 0 and 1. Obviously, the FCM is more flexible than the HCM, when determining data related to degrees of belonging.

Because of the vague boundaries of fuzzy clusters, Wang et al. (1994) showed that it is not

sufficient to classify a fuzzy system simply by minimizing the within-group variance. Instead, the maximal between-group variance also had to be taken into account. This led to a Bi-objective Fuzzy c-Means Method (BOFCM) as shown below, in which the performance of clustering can be seen to be improved:

$$\text{(BOFCM):}\quad \begin{aligned} &Min \quad Z(U;V)=\sum_{i=1}^{c}\sum_{k=1}^{K}(\mu_{ik})^2\|x_k-v_i\|^2 \\ &Max \quad L(U;V)=\sum_{i=1}^{c}\sum_{j<i}\|v_i-v_j\|^2 \\ &\text{subject to} \quad \sum_{i=1}^{c}\mu_{ik}=1, \quad \forall k=1,...,K \\ &\qquad \mu_{ik}\geq 0, \quad \forall i=1,..,c, k=1,...,K \end{aligned} \qquad \textbf{(4)}$$

where c is number of the clusters, $\|\cdot\|$ is an inner product norm, x_k, $k = 1, ..., K$, denote K elements, v_i, $i = 1, ..., c$ is the center of Cluster i and μ_{ik}, $i = 1, ..., c$; $k = 1, ..., K$ are the membership values of x_k belonging to Cluster i.

THE WEB MINING SYSTEM

When looking at Web site development, it needs to be appreciated that Web users can be quite capricious, given the multitude of Web sites available on the Internet. The question arises: how should a Web site be set up so that it provides the right product information to the right customers? And specifically, how can the query response time be speeded up?

Clustering types of users with their preferences is one solution. From the above discussion, it can be seen that we may use the BOFCM algorithm for this purpose. After introducing the weights α, β, $\alpha+\beta = 1$ for the objectives, Model (4) was transformed into a single objective nonlinear problem. The following lemmas provide the basis for solving it:

Lemma 1 (Wang et al., 1994): The solution set of Model (4) can be found by:

$$v_i=\frac{\beta\sum_{k=1}^{K}\mu_{ik}^2x_k}{\beta\sum_{k=1}^{K}\mu_{ik}^2-\alpha c}-\frac{\alpha\sum_{s=1}^{c}\dfrac{\beta\sum_{k=1}^{K}\mu_{sk}^2x_k}{\beta\sum_{k=1}^{K}\mu_{sk}^2-\alpha c}}{\left(\beta\sum_{k=1}^{K}\mu_{ik}^2-\alpha c\right)\left(1+\alpha\sum_{s=1}^{c}\dfrac{1}{\beta\sum_{k=1}^{n}\mu_{sk}^2-\alpha c}\right)} \qquad \textbf{(5)}$$

$$\mu_{ik}=\frac{\left(\dfrac{1}{\|x_k-v_i\|^2}\right)^{1/f-1}}{\sum_{s=1}^{c}\left(\dfrac{1}{\|x_k-v_s\|^2}\right)^{1/f-1}}. \qquad \textbf{(6)}$$

Then, the solution procedures can be summarized as:

Step 1. Fix c. Give the initial membership value of each datum to each cluster, that is, the membership matrix $U^{(0)} = [\mu_{ik}^{(0)}]$ is constructed. Assign an allowed perturbed value τ and set $\delta = \tau$, f=2, and l=0.

Step 2. Calculate α and β by using $U^{(l)}$,

$$\alpha=\min_i\left\{\frac{\sum_{k=1}^{K}(\mu_{ik}^{(0)})^2}{\sum_{k=1}^{K}(\mu_{ik}^{(0)})^2+c-1}\right\}-\delta$$

and

$$\beta=\max_i\left\{\frac{c-1}{\sum_{k=1}^{K}(\mu_{ik}^{(0)})^2+c-1}\right\}+\delta.$$

Step 3. Calculate $\{v_i^{(l)}\}$with Equation (5) and $U^{(l)}$.

Step 4. Calculate the new membership matrix $U^{(l+1)}$ by using $\{v_i^{(l)}\}$ and Equation (6), if $x_k \neq v_i^{(l)}$; else set

$$\mu_{jk}^{(l+1)} = \begin{cases} 1, \text{for} & j = i \\ 0, \text{for} & j \neq i \end{cases}.$$

Step 5. Let $\delta = \tau + \delta$ and go to Step 2 if $\{m_k^{(l+1)}\}$ does not satisfy

$$\alpha < \min_i \left\{ \frac{\sum_{k=1}^{K} (\mu_{ik}^{(l+1)})^2}{\sum_{k=1}^{K} (\mu_{ik}^{(l+1)})^2 + c - 1} \right\}$$

and

$$\beta > \max_i \left\{ \frac{c-1}{\sum_{k=1}^{K} (\mu_{ik}^{(l+1)})^2 + c - 1} \right\}.$$

Step 6. Calculate $\Delta = \left\| \tilde{U}^{(l+1)} - \tilde{U}^{(l)} \right\|$. If $\Delta > \varepsilon$ set l=l+1 and go to Step 3. If $\Delta \leq \varepsilon$ stop.

From the above analysis, we can obtain the clustered data within each center.

To speed up the process, the documents can also be grouped according to their degrees of similarity, as defined by Jaccard's coefficient as follows:

$$r_{ij} = \frac{\sum_{s=1}^{m} \min\left[b_{is}, b_{js}\right]}{\sum_{s=1}^{m} \max\left[b_{is}, b_{js}\right]}, \quad 0 \leq b_{is}, b_{js} \leq 1, \tag{7}$$

where r_{ij} is the similarity between document D_i and document D_j. b_{iS}, b_{jS} from matrix B are the relevant values with respect to documents D_i, D_k and documents D_j, D_k. So we can obtain the document fuzzy relationship matrix R:

$$R = \begin{array}{c} \\ D_1 \\ D_2 \\ \vdots \\ D_m \end{array} \begin{array}{c} \begin{array}{cccc} D_1 & D_2 & \cdots & D_m \end{array} \\ \begin{bmatrix} r_{11} & r_{12} & \cdots & r_{1m} \\ r_{21} & r_{22} & \cdots & r_{1m} \\ \vdots & \vdots & \ddots & \vdots \\ r_{m1} & r_{m2} & \cdots & r_{mm} \end{bmatrix} \end{array} \tag{8}$$

Again a transitive closure R* of R must be obtained. Then by defining an acceptable level of λ by the mean of the upper triangular matrix R*, i.e.,

$$\lambda = \frac{\sum_{i=1}^{m-1} \sum_{j>i}^{m} r_{ij}}{\binom{m(m-1)}{2}},$$

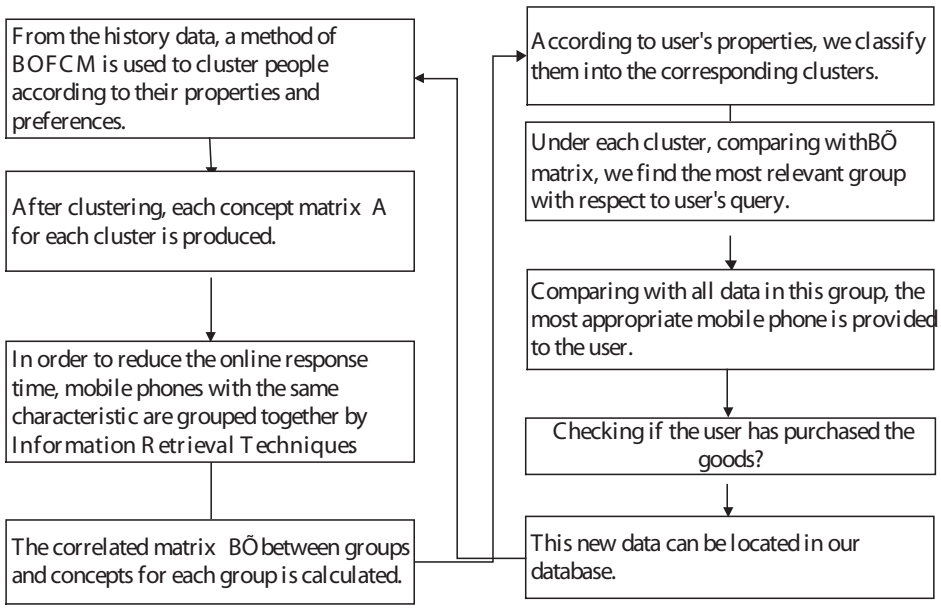
we have an λ-threshold partition of documents into clusters. Based on the document descriptor of each document, we can obtain a cluster-concept matrix B':

$$B' = \begin{array}{c} \\ Group\ 1 \\ Group\ 2 \\ \vdots \\ Group\ u \end{array} \begin{array}{c} \begin{array}{cccc} A_1 & A_2 & \cdots & A_n \end{array} \\ \begin{bmatrix} b'_{11} & b'_{12} & \cdots & b'_{1n} \\ b'_{21} & b'_{22} & \cdots & b'_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ b'_{u1} & b'_{u2} & \cdots & b'_{un} \end{bmatrix} \end{array},$$

where u is the number of clusters of documents. **(9)**

With the results of above off-line analysis, a user can take advantage of the clustered documents to improve response time when making an online query. By comparing the matrix B' with the user's query vector, the most relevant cluster(s) are selected. Then, by searching the documents within the selected cluster(s), the documents may

Figure 1. Framework of the Web mining system



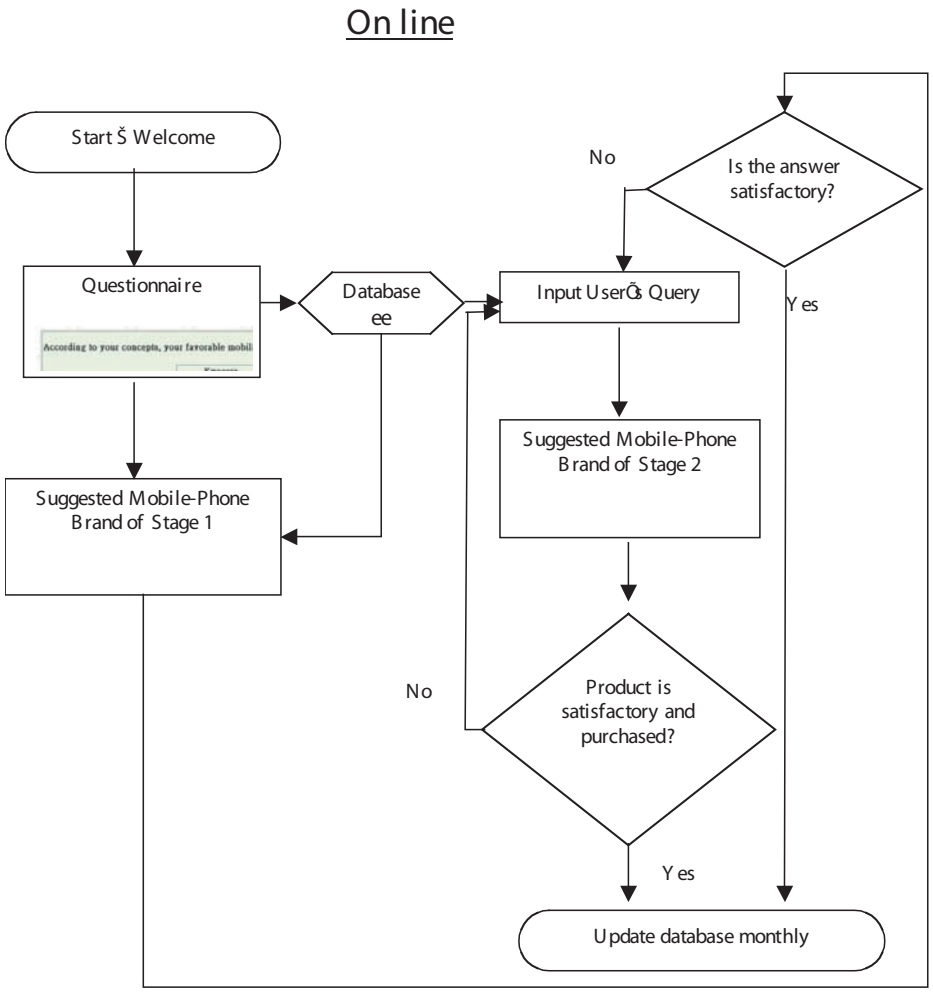
be retrieved more efficiently. The framework of the proposed Web mining system (Lin, 2002), with both online and off-line operations, is shown in Figure 1.

A CASE STUDY OF THE WEB MINING SYSTEM

In order to demonstrate the proposed system, a Web site, called veryMobile-Phone (http://203.68.224.196/verymobile/), was constructed in Chinese, in order to catch the behavior of local customers in Taiwan. The online operation procedure, based on the information provided from an off-line established database, is shown in Figure 2.

This initial database was established based on a survey of 800 individuals. The respondents were full- and part-time students, ranging from 15 to 35 years of age, at the Minghsin University of Science and Technology and full-time students, ranging from 20 to 30 years of age, at the Tsing Hua University. A total of 638 questionnaires were returned. After deleting invalid questionnaires, we had 562 valid responses. In this questionnaire, personal data, such as *Sex — male or female*; *Age — under 15, 16~18, 19~22, 23~30 or over 30*; *Education — senior high school, college, university, masters, Ph.D. or others*; *Average Income — none, under NTS 18,000, 18,000~30,000, 30,000~45,000 or over 45,000* were recorded, along with their preferences in purchasing a mobile phone, with features made up of A_1:*brand*, A_2:*external*, A_3:*price*, A_4:*service*, A_5:*function*, A_6:*ease of use*, A_7:*special offer*, etc. Via the BOFCM, users were classified into c=4 groups. The mobile phones, in stock, were also grouped by their

Figure 2. Flow diagram of verymobile-phone system



features, according to the concepts defined for information retrieval. Below, we demonstrate how the proposed mechanism can be used to suggest the appropriate mobile phone brand for each user, by responding to his or her query, based on his or her features and preferences.

Off-Line Phase

The off-line analysis is used mainly to establish the initial database features, including user categories and preferences, as well as mobile phone clusters. The users' data were grouped by applying the

BOFCM. Four clusters were obtained and stored. For each group of users, the concept matrix was calculated, as shown below, to describe the preference relationships obtained among the mobile phones features:

$A1 =$

	brand	external	price	service	function	ease of use	special offer

In consequence, 5(*u*=5) groups of mobile-phone types can be obtained from the 14 available brands, as follows:

Group 1 = {BenQ, SAGEM},

Group 2 = {ALCATEL, Sony ERICSSON, Mitsubishi, MOTOROLA, NEC, NOKIA, PHILIPS, SIEMENS},

Group 3 = {Kyocera, Panasonic},

Group 4 = {BOSCH},

Group 5 = {Others}

Based on the document descriptor of each document, we obtained the group-concept matrix *B*2', which extensively reduces the data dimension and thus speeds up the information retrieval process.

$B2' =$

	brand	external	price	service	function	ease of use	special offer

Group 3	0.12	0.67	0.12	0.10	0.13	0.12	0.08
Group 4	0.15	0.12	0.67	0.10	0.09	0.15	0.33
Group 5	0.15	0.12	1.00	0.10	0.09	0.15	0.00

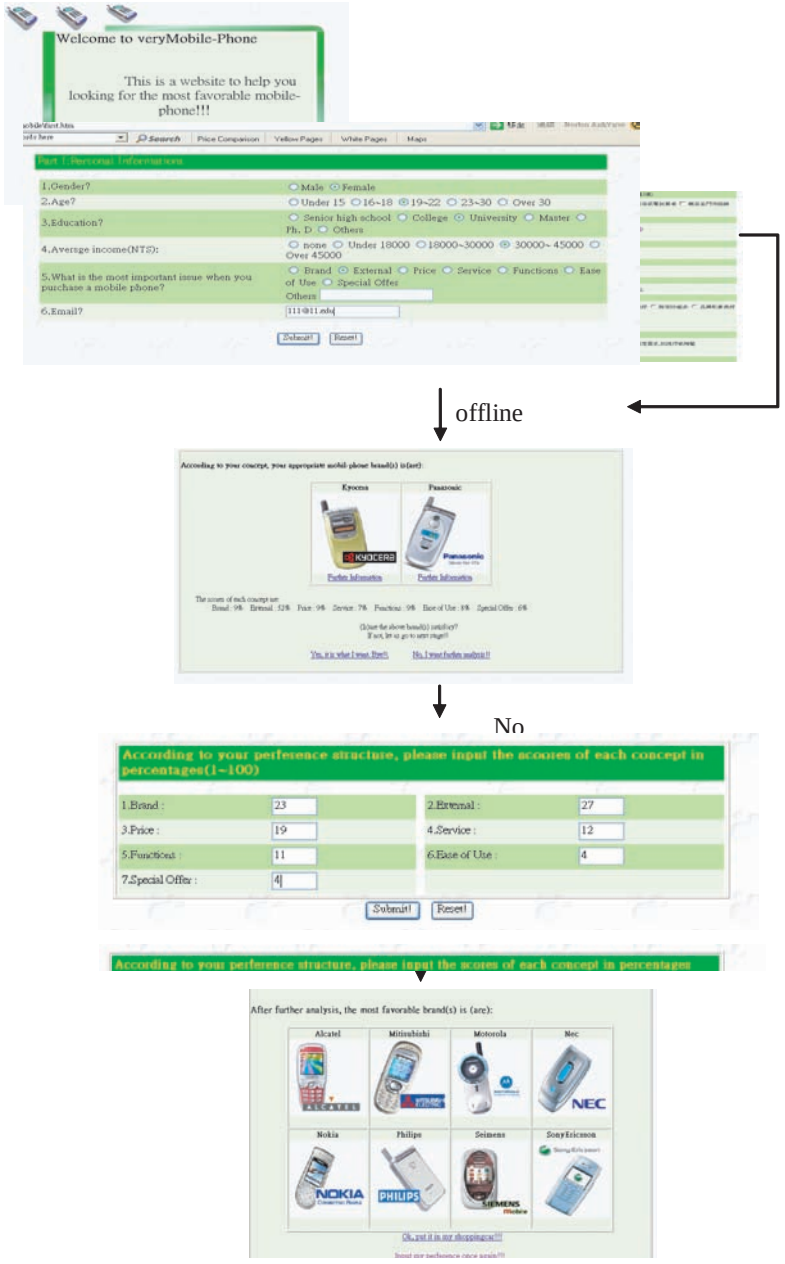
With the same procedure, we can calculate the document-concept matrices *B1, B3, B4* for each set of clustered users, respectively; this clustering information is also stored in the database. This completes the off-line phase.

Online Phase

If a Web user wants to buy a mobile phone, and signs into the Web site, he or she is asked to provide basic data. If, say, the user is *female*, *22 years old*, *university* educated and earns *NTS 30,000~45,000 Income*, and emphasized *external* as her top preference in purchasing a mobile phone, then this information will allow the sys-

tem to classify the user into user-cluster 2, and with lexicographic ordering of the components, corresponding to the concept "*external*" of *B*2', the system will provide { Kyocera, Panasonic } of *Group* 3 with the scores of each concept in percentages of (9,50,9,7,10,9,6). The correspond-

Figure 3. Result of the case study



ing scores come up with *brand*: 12, *external*: 67, *price*: 12, *service*: 10, *function*: 13, *ease of use*: 12, and *special offer*: 8 for reference.

If she is not satisfied, the system will ask for her preference structure with reference to the above scores. If she replies with the scores of (23, 27, 19, 12, 11, 4, 4), comparing vector Q with the matrix *B'*, we can find that the most compatible group of mobile phone is the second one, *Group* 2 = {ALCATEL, Sony ERICSSON, Mitsubishi, MOTOROLA, NEC, NOKIA, PHILIPS, SIEMENS} and then suggest that this user purchase the most relevant mobile phone. The result, shown below, has been translated into English for ease of understanding (see Figure 3). Different types of users map into different users' clusters and the system provides the most appropriate information corresponding to different clusters of documents. For example, if a *male* user, *18 years old*, *college* educated, with *no Income*, and an emphasis on *function*, he would be classified into Cluster 4. The documents would be grouped as *Group* 1: {BenQ, SAGEM}; *Group* 2: {ALCATEL, Sony ERICSSON, Kyocera, Mitsubishi, MOTOROLA, NEC, NOKIA, PHILIPS, SIEMENS}, *Group* 3: {Panasonic}, *Group* 4: {BOSCH} and *Group* 5: {Others}. The system will provide {Panasonic} with the scores of each concept in percentages of (11, 13, 18, 8, 25, 9, 15). Furthermore, if he is not satisfied, after entering a new set of scores, the system will provide a new suggestion.

If the users referred to above purchased the mobile phones recommended, their data would be used to update the database, otherwise the database will not be changed. Due to the billing system, such updating processes would be carried out once a month.

SUMMARY AND DISCUSSION

Internet technology has developed rapidly in recent years and one of the primary current issues is how to effectively provide information to users. In this study, we utilized a data mining information retrieval technique to create a Web mining system. Since existing retrieval methods do not consider user preferences and hence do not effectively provide appropriate information, we used an off-line process to cluster users, according to their features and preferences, using a bi-criteria BOFCM algorithm. By doing so, the online response time was reduced in a practical test case when a user sent a query to the Web site. The case study in this chapter (a service Web site selling mobile phones) demonstrated that by using the proposed information retrieval technique, a query-response containing a reasonable number, rather than a huge number, of mobile phones could be provided which best matched a users' preferences. Furthermore, it was shown that a single criterion for choosing the most favorable mobile-phone brand was not sufficient. Thus, the scores provided for the suggested group could be used as a reference for overall consideration. This not only speeds up the query process, but can also effectively support purchase decisions. In system maintenance, counterfeit information causes aggravation for Web site owners. Our proposed system updates the database only if the purchase action is actually carried out, which reduces the risk of false data. Further study into how a linguistic query may be transformed into a numerical query is necessary to allow a greater practical application of this proposal.

ABSTRACT

The requirement for ubiquitous service access in wireless environments presents a great challenge in light of well-known problems like high error rate and frequent disconnections. In order to satisfy this requirement, we propose the integration of two modern service technologies: Web Services and Mobile Agents. This integration allows wireless users to access and invoke semantically enriched Web Services without the need for simultaneous, online presence of the service requestor. Moreover, in order to improve the capabilities of Service registries, we exploit the advantages offered by the Semantic Web framework. Specifically, we use enhanced registries enriched with semantic information that provide semantic matching to service queries and published service descriptions.

Finally, we discuss the implementation of the proposed framework and present our performance assessment findings.

INTRODUCTION

Efficient execution of wireless applications is of paramount importance due to the highly dynamic wireless network conditions. Link outages occur in a near-stochastic pattern, thus, rendering the execution of applications quite tedious and uncertain. Research on mobile computing has for a long time focused on this specific aspect of wireless application engineering (Pour, 2006). In this article, we adopt the mobile agent paradigm in order to overcome the difficulties discussed above. Surely, this is not the first time that mobile agents are proposed as the vehicle for the implementation of wireless/mobile applications. Their autonomic nature and wide spectrum of characteristics render the specific technological platform a great enabler for the emerging ubiquitous computing paradigm.

Mobile computing is not the only development that significantly impacts the computer industry nowadays. Service-oriented architectures (SOA) are gradually changing the contemporary structure of the Internet and become a key facilitator for electronic commerce applications and related application domains. We try to incorporate both the discussed technologies into our wireless/mobile computing framework. Mobile agents are dispatched by mobile terminals in order to efficiently and safely satisfy the specific computing needs of their nomadic owner. After securing the autonomicity characteristic in order to progress the required task without the need for the mobile terminal to be constantly online, we try to minimize the service-related tasks. Our prime concern lies on the exact identification of the services to be executed at the demand of the user and minimize potential waste of time on unwanted invocations. The accuracy of the service inquiry mechanism has to be improved to really boost the mobile agent and service-oriented architecture. To expedite the service querying procedure and simplify the querying semantics, we employ a semantically enriched service registry. A precise definition of the user's requirement is mapped to existing services through a semantically enriched registrar.

In this article, we introduce a novel framework for dynamic discovery and integration of semantically enriched Web Services (WS) with Mobile Agents (MA). The proposed framework is mostly intended for wireless environments where users access Semantic Web Services (SWS) in the fixed network (the terms Web Service (WS) and Semantic Web Service (SWS) are used interchangeably within this article). This framework enhances the fixed network with the intelligence needed to dispatch the service requests of the wireless user in an efficient, reliable and transparent manner. The proposed approach enables users to execute multiple services with minimum interaction, without the requirement of being online during their entire session. Additionally, the proposed framework provides better fixed network utilization since unnecessary communication overhead is avoided and reliable delivery of the service results is provided.

The rest of this article is structured as follows. In section 2, we provide some background knowledge about the implemented technologies, whereas section 3, we discuss relevant prior work. In section 4, we present an overview of the proposed architecture. Section 5 studies the performance of the proposed framework and presents the results. Finally, section 6 concludes the article.

BACKGROUND KNOWLEDGE

In this section, we briefly describe the two technologies that are integrated in our proposed framework, namely Web Services and Mobile Agents.

Web services (WS) provide a loosely coupled infrastructure for service description, discovery and execution. In the traditional WS model, service requestors find the appropriate service by placing a request to the service registry, often implemented with universal description, discovery and integration (UDDI), obtain the result(s)—public interfaces of the chosen service(s) (expressed in Web services description language - WSDL) and, finally, send simple object access protocol (SOAP) messages to WS provider(s).

The main problems experienced in these interactions are:

- UDDI guarantees syntactic interoperability, and does not provide a semantic description of its content. UDDI is characterised for its lack of semantic description mechanisms, such as semantic interoperability, explicit semantic models to understand the queries and inference capabilities. UDDI service discovery is performed primarily by service name (keyword matching), but not by service attributes/capabilities. UDDI tModels may be regarded as a vocabulary where service descriptions are unstructured and intended for human comprehension. Different services with the same capabilities can thus be categorized in different business categories.
- WSDL is XML-based and used to specify the interface of a WS. It describes the information being exchanged (structure of the SOAP messages), how this information is being exchanged via interactions with the WS (transport protocols) and where the WS is located. However, WSDL does not contain any information about the capabilities of the described service and as such service discovery based on service capabilities or semantics cannot be performed.

Several efforts have been made to address the lack of expressiveness in WSDL in terms of semantic description that fall into the area of the Semantic Web (SW). SW is a vision in which Web pages are augmented with semantic information and data expressed in an unambiguous manner and can be understood and interpreted by machine applications and humans alike (Berners-Lee, 2001). This requires means to represent the semantics of the exchanged data so that it could be automatically processed. This requirement is met with the use of ontologies. Ontologies facilitate knowledge sharing among heterogeneous systems, through explicit formal specifications of the terms used in a knowledge domain and relations among them (Gruber, 1993). Ontologies are machine-understandable and, as such, a computer can process data, annotated with references to ontologies. Through the knowledge encapsulated in the ontology, a computer can deduce facts from the originally provided data. The use of ontologies enables systems to share common understanding of the structure of information and reuse of domain knowledge, make domain assumptions explicit and separate domain knowledge from the operational knowledge.

Currently, several upper ontologies (terminology in the form of an ontology) have been proposed for Web Service description. The first was DAML-S (McIlraith, 2003), which was based on DAML+OIL ontology language. When DAML+OIL evolved to the widely accepted OWL (Web Ontology Language) family of languages, DAML-S was replaced by OWL-S (OWL-S, 2007). Still, OWL-S does not constitute a commonly accepted description language; there are also other languages proposed such as WSDL-S (Verma, 2006), WSMO (Roman, 2005) and SWSO (SWSL Committee, 2007). All these languages differ in terms of expressiveness, complexity and tool support.

OWL-S, which is adopted in our work, has well-defined specifications by the W3C (World Wide Web) consortium (OWL-S, 2007) and is widely accepted by the scientific community. OWL-S ontology implicitly defines message types

(as input/output types of processes) in terms of OWL classes, which allows for a rich, class-hierarchical semantic foundation. Specifically, OWL-S models the Web services via a three-part ontology: (i) a service profile describes what the service requires from users and what it gives them; (ii) a service model specifies how the service works; and (iii) a service grounding provides information on how to use the service.

With OWL-S, SWS are described in an unambiguous manner allowing for a potential service requestor to place a capability search in a service registry rather than a keyword search in UDDI registries. Registries that offer such capability search functionalities are called Semantic Web Registries (SWR).

The most representative matching techniques used are detailed in Tsetsos (2007) and are summarised below:

- **Semantic capability matching:** The basic idea is that an advertised service matches a requested one, when all the inputs (respectively outputs) of a requested service are matched by the inputs (respectively outputs) of the advertised service. For this purpose, description logics (DL) reasoning services are exploited for inferring relations between ontology concepts.
- **Multi-level mapping:** Matching is performed in many levels, not only between input and output descriptions. Service categories or other custom service parameters (e.g., OoS) may be exploited. The result is a more efficient ranking of the matched services.
- **DL matching with service profile ontologies:** Each service and query is represented as ontologies following the DL formalization. Hence, a DL reasoner is utilized for placing the query concept in its proper position in each service ontology description (e.g., as a sub-concept). Then specific rules are applied for computing the degree of relevance between the query and each service description.
- **Information-retrieval-based:** In this category, vector space techniques (Raghavan, 1986) are utilized for locating the most related service to a provided query.
- **Graph-based approaches:** Ontologies representing services are transformed into directed graphs and various algorithms accomplish the matching between such graphs.

There is a plethora of tools that provide Semantic Web Services functionalities (e.g., OWLS-MX (OWLS-MX, 2007) and TUB OWLSM (OWLSM, 2007), each one implementing a portion of the above matching techniques. In our work, we adopted the OWL-S/UDDI Matchmaker tool (Paolucci, 2002; Srinivasan, 2004; OWL-S/UDDI Matchmaker Web Interface, 2007), which mainly implements techniques from the first aforementioned matching technique.

Mobile agent technology is one of the most promising technologies for communicating and managing functional components comprising a mobile service (Lange, 1998; Wooldridge, 2002). A MA has the unique ability to autonomously transport itself from one system to another. The ability to travel allows a MA to move to a system that contains an entity (-ies) with which the agent wishes to interact and take advantage of being in the same host or network with the collaborating entity. MAs can operate synchronously and asynchronously, and are equipped with the appropriate intelligence and knowledge to dynamically accomplish their task without user interaction. MAs are not trying to replace traditional ways of communication but to enhance the functionality and operation of the involved service entities. Researchers agree that MAs are not always the best solution and a combination of the MA, client-server and remote execution paradigms delivers

the best performance with respect to network operation metrics like bandwidth, response time, and scalability.

RELATED WORK

In this section, we provide an overview of the related work performed in the areas of semantic WS and multi-agent systems and, especially, on research activities that integrate these two technologies.

In Ishikawa (2004; 2004b), BPEL (business process execution language) is used to form simple rules to describe MA physical behaviours (e.g., migration and cloning). Such simple rules are separated from the integration logic, allowing for addition or change of physical behaviours without modification of the BPEL description. This separation is considered helpful in dealing with the dynamic environment of WS, however, the discussed framework supports actions only in case of predefined events. The implemented rules do not consider dynamic events that might be generated during WS invocation and MA roaming. Moreover, and importantly, directory services and multicast protocols are assumed pre-existing and not discussed. The discussed framework refers only to interactions occurring among MA and WS without considering the interactions of the MA and service registries that have equal importance in such a system. Finally, the system description does not include any implementation, hence benchmarking is not considered.

There are several proposed models that adopt BPEL4WS (Business Process Execution Language for Web Services) as a specification language for expressing the social behaviour of multi-agent systems and adapt to changing environment conditions (Bulher, 2003;2004). Moreover, in Montanari (2003; 2003b), the authors propose a policy-based framework for flexible management and dynamic configurability of agent mobility behaviour in order to reduce code mobility concerns and support rapid mobile code-based service provisioning. Policies specify when, where, how and the parts of the agent that will perform a given task (e.g., migrating to a host and invoke a service). However, these models do not provide for the semantic description of the WS involved in their systems. Other proposed frameworks adopt DAML-S for describing the WS, thus, allowing for service capability search and matching (Kagal, 2002; Gibbins, 2004). However, the proposed systems are intended for fixed networks, and problems related to the wireless environments are not considered.

An agent-based approach for composite mobile WS is proposed in Zahreddine (2005), where three methods for compositions are discussed: parallel, sequential and a hybrid of these two. The service composition scenario is that a user with a wireless device places a request to execute a WS and a MA executes the service on behalf of the user by moving to the service registry, query the registry, get service description (in WSDL), and finally invoke the service. Service execution, depending on the WS itself, is performed with one of the aforementioned composition methods. This approach does not consider semantic information describing the involved WS, thus services are selected by simple keyword queries to the UDDI registry. Additionally, it does not include mechanisms to decide which composition approach to follow. Integration depends upon the nature of the WS (if the service is a composition of other services it must be accessed sequentially, if not, then in parallel). A similar approach is proposed in Cheng (2002), with the difference that a personal and a service agent are used to perform the task of the MA described in the previously mentioned approach.

Moreover, in the research literature, it has proposed the use of Asynchronous Web Services (AWS) in order to access WS with asynchronous interaction. AWS can be used where the standard

Web Service Business Model has some limitations, as described in Brambilla (2004): a. when service time is expected to be too long, b. when response time is not predictable, and c. when users may not be continuously online. The most common way to achieve asynchronous calls to Web Services is by using a correlation or conversation ID (Huang, 2003; Brambilla, 2004). This unique ID is assigned initially by the Web Service providers to each Web service transaction and it is passed in each exchanged message between the conversational parties. This way, the client is able to perform correlation and to retrieve application data related to current conversation. The drawback though of such an approach is the production of possible mismatches. Specifically, if multiple asynchronous Web Service calls happen in the context of a single conversation, responses might not be able to be unambiguously related to their requests (Brambilla, 2004).

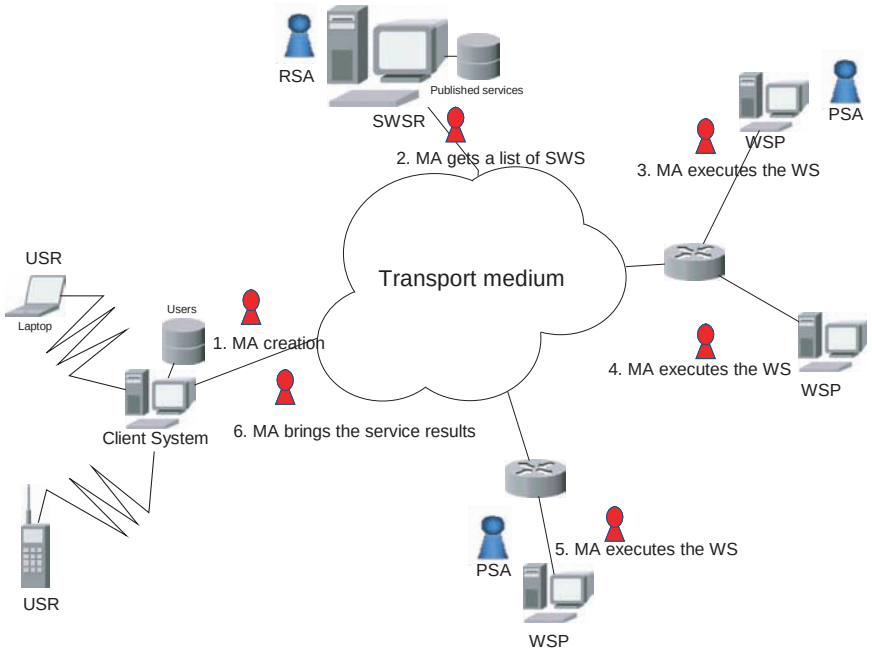
FRAMEWORK ARCHITECTURE

The proposed framework consists of the mobile user that uses SWS, the MA representing the user in the fixed network, the service registry and the SWS provider. The last two entities are implemented as stationary agents. According to the service implementation scenario (Figure 1), a mobile user accesses the proposed system and places service requests specifying some criteria. Subsequently, the system creates a MA (step 1) that migrates to the registry to find the WS that best meets the user requirements (step 2). Service registry allows for a capability search to be performed, since it is enriched with semantic information. The MA, after acquiring the WS listing and technical details, migrates to service provider(s), invokes the WS, collects the results (steps 3-5) and returns to the service requestor to deliver the results to the mobile user (step 6). In the presented scenario, the SWS that matched the service request were three thus MA migrates and invokes these three services (steps 3-5). If the service request matched more than three services during the step 2, the MA would migrate to all these matched WS (Figure 1 would include more steps). The advantages of this scenario is that the MA has the necessary intelligence to invoke only the best matched service(s) and unnecessary service invocations are avoided leading to better network utilization, and the wireless user is not required to be online and may obtain the results on future time.

In the proposed framework, the route of the agent may vary, depending on the service requestor preferences and the network topology. As explained below, the user may dynamically force his MA to send its clones to the providers, invoking the services in parallel, rather than serially migrate to each one. Moreover, the user may force the MA to implement different service execution strategies (e.g., execute all services locally or remotely, change timeout limit), during its itinerary and execution of service(s).

Our framework consists of the following functional components: (1) User service requestor (USR) who is the user that invokes a SWS, and the client system, the system in the fixed network that provides user access to the SWS, (2) mobile agent which is the representative of the user in the fixed network (3) provider stationary agent (PSA) which is a stationary agent that resides in the host offering a certain WS (its implementation is optional), (4) registry stationary agent (RSA) which is a stationary agent that acts as a broker between the MA and the service registry (its implementation is optional), (5) Semantic Web services registry (SWSR), the registry where the service providers advertise their services, and (6) Web service provider (WSP) which provides the WS to interested users. Their structure and functionalities are described below. In the end of this section, we provide a service implementation scenario presenting all possible supported service invocation alternatives.

Figure 1. Service implementation scenario



User Service Requestor (USR)

USR is the client that invokes a WS. USR logs into the client system, which communicates with the agent platform using IIOP (Internet Inter-ORB Protocol). The agent platform is responsible for creating and handling MA, according to user specifications. The client system is implemented in JSP/Servlet technology, and many users can be accommodated without having java runtime environment (JRE) or the MA platform (MAP) installed on their device. The only requirement is a browser to access the client system.

The client system offers services to clients like: account creation, user login/logout, service invocation policies profile editing, and control of existing agents. Moreover, the administrator is allowed to add/remove/edit user properties/profiles. Finally, users' service invocation policy profiles are serialised and stored into the server's database that enables the seamless and transparent provision of services.

The proposed framework is in addition able to communicate with mobile devices that are capable of hosting JADE/LEAP (Lightweight Extensible Agent Platform) (JADE, 2007). LEAP is an extension of JADE that enables MAs to be executed on wireless devices with limited processing capabilities. In such a case the MA is spawned on the mobile device, gathers the user preferences/specifications either from this device or from the client system. The behaviour of the system and of the device created the MA is exactly the same.

Mobile Agent (MA)

The MA is the representative of the user in the fixed network and is capable of roaming, finding and executing services and delivering results to the user. The MA may also spawn clones that execute the selected WS in parallel to minimize the total processing time. Clones can migrate and invoke simultaneously the chosen WS and return to the service requestor with the results. The MA has the following components: (1) data state, (2) code, (3) migration and cloning policies, (4) matching engine, and, (5) policy management component (Figure 2).

The proposed MA architecture is based on that the logic of the MA has to be separated from its implementation, enabling the modelling of the MA to be platform independent. That is to say, the physical behaviours of the MA are portable to any MAP (Jade, Grasshopper, etc.). Below, we describe the components of a MA.

The data component contains the information collected by the MA from the SWS invocations. Several compression algorithms may be applied in order to reduce the size of the collected information. The migration and cloning policies component specifies the autonomous behaviour of the MA. It should be noted that the social behaviour of the MA (migration, cloning) is separated from integration logic and code implementation. This separation is accomplished with user's specified invocation policies that govern the behaviour of the MA, being external and independent of its code and integration with the WS. Moreover, the matching engine component is responsible for post-processing the service registry query results, that is, confirm the availability of the service providers prior to agent migration.

The policy management component is responsible for the MA external communication and the transparent installation of policies into the agent's repository.

As shown in Figure 3, the policy management component provides four services, namely communication, update handler, specification and policy repository. Policy repository contains

Figure 2. Mobile agent structure

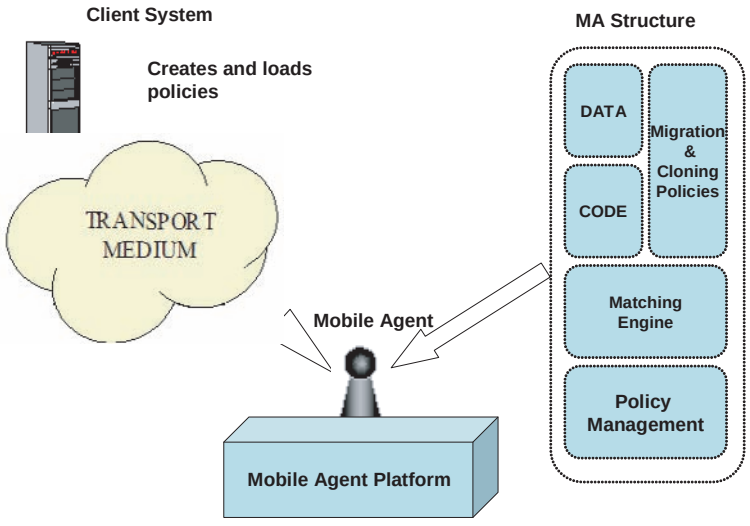


Figure 3. MA policy management component

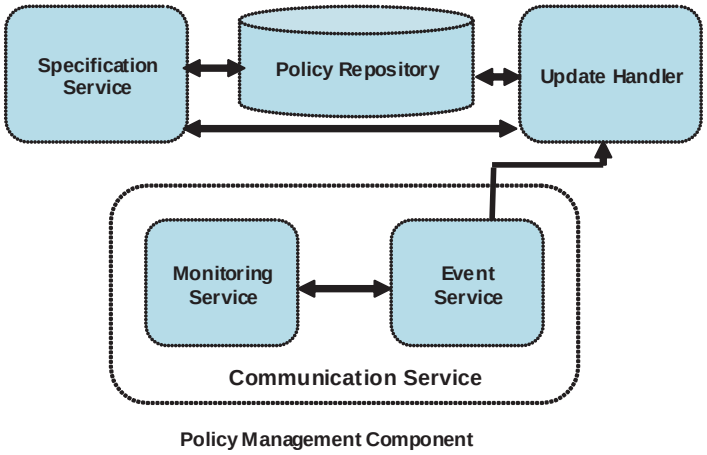


the user preferences and policies that govern the behaviour of the MA. Communication service enables the MA to interact with the client and other network entities. Such functionality is achieved through the monitoring service which filters the messages coming from the client system and through the event service which handles events concerning policy changes. When a policy change occurs, the update handler is notified to update the policy repository. Specification service is responsible for fulfilling this task.

The agent's policies determine its physical behaviour while roaming in the network and executing WS. Currently, the MA considers the policies (Table 1), which are Boolean and numerical variables. Agent policies are expressed in XML and stored in a serialised format into the client system database. For each registered user there is an associated policies file, to provide personalized WS access.

Provider Stationary Agent (PSA)

PSA is a stationary agent that resides in the host offering a certain WS. Its purpose is to wrap the functionality of the WS. The PSA is created and maintained by the service provider. PSA communicates with the service providers through protocols specified for WS invocation and interaction (e.g., SOAP). When the MA migrates to a host offering a WS with a PSA, it obtains the results through the PSA. This communication is performed with agent-to-agent protocols (either Remote Method Invocation or exchanging FIPA/ACL messages using a FIPA/Message Transport Protocol-MTP (FIPA, 2007)), instead of the resource consuming SOAP. In this approach, the MA need not be SOAP fluent, thus leading to a lightweight implementation. It should be noted that this implementation maintains the platform independence as far as it concerns the SWS provider. This is due to the fact that the PSA wraps

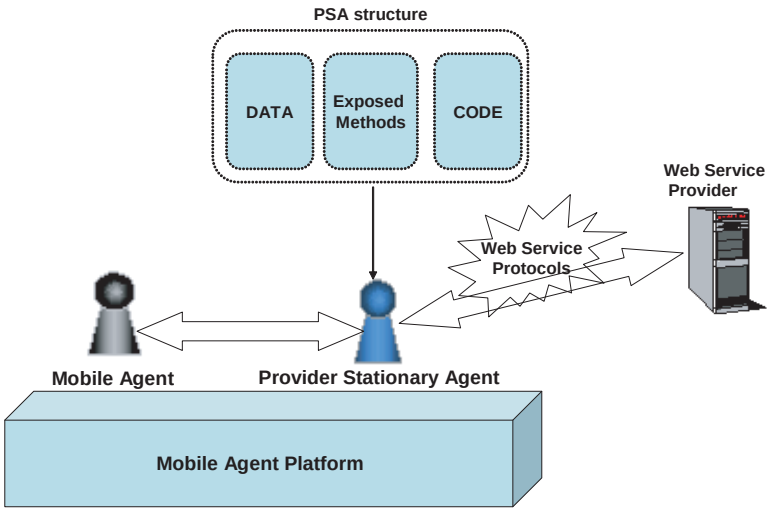
Table 1. Policy names and their respective meaning

Policy name	Type	Description
<Migrating> and <Cloning>	Boolean	MA's ability to migrate to another host and spawn clones respectively.
<retryTimes>	Numerical	The number of attempts that MA will perform when a WS is unavailable.
<timeBetweenReattempts>	Numerical	The time that MA will wait between consecutive reattempts.
<suspendWhenFinished>	Boolean	States if the user wishes (dis)-connected operation and what the MA should do when returns to the Client System (suspend its state and wait user to connect back or to deliver immediately the service results).
<rollBackBehaviour>	Boolean	Specifies in a case of failure if a roll back solution will be followed.
<maxNumberOfHits>	Numerical	The maximum number of services to be invoked.
<minNumberOfResults>	Numerical	The minimum number of results when searching the semantically enriched service registry (it is accomplished through the similarity level that is returned from the semantic engine that enables the system to always return a result, even though it does not always satisfy completely the request).
<pingServer>	Boolean	States that the MA should check if the targeted service provider is alive, before MA starts the migrating process to this host.
<migrateToServer>	Boolean	Specifies if the service will be invoked locally or remotely.
<remoteCall>	Boolean	MA invokes the chosen services using SOAP/RPC (remotely from other host) without migrating to each provider.
<callThroughStationary>	Boolean	Indicates if communication between WS and MA will take place with or without the Provider's Stationary Agent (PSA).
<HitAllServices>	Boolean	Forces the MA to invoke all retrieved services from service registry.
<cloneToServer>	Boolean	Enables the agent to decide whether to serially migrate to each located service provider or sent clones to accomplish the task in parallel and return service results to their parent agent and then are self destroyed.
	Boolean	States that user wishes to retrieve results in a future time, by reconnecting to the Client System.
<timeBetweenReattempts>	Numerical	The time that MA will wait between consecutive reattempts.

the SWS functionality, and is also SOAP fluent and exposes the same SWS's functionality in a native form to the MA.

Figure 4 presents the structure of a PSA. PSA interface exposes the available methods of the SWS as they are described in OWL-S. PSA consists of two parts: (1) its data state, and, (2) its code. PSA methods are multi-threaded to accommodate and simultaneously serve multiple MAs.

Figure 4. Provider stationary agent logic



Registry Stationary Agent (RSA)

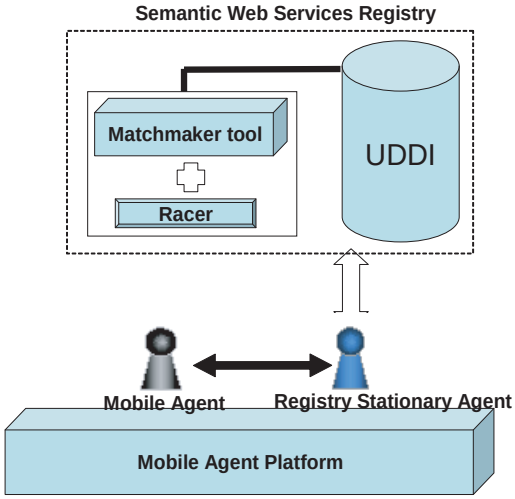
RSA is a stationary agent that acts as a broker between the MA and the service registry (Figure 5). RSA implements part of the registry's functionality and serves MA's requests. By using a RSA in the WS registry, MA does not have to be aware of the implementation-specific functionalities of the registry. Thus, different service registries can be used as long as RSA acts between WS registry and MA. The proposed framework can be used with different registries that are currently available (e.g., ebXML (ebXML, 2007), OWLS-MX (OWLS-MX, 2007), and TUB OWLSM (OWLSM, 2007)).

Semantic Web Services Registry (SWSR)

The SWSR (Figure 5) consists of the RSA, the matchmaking tool and the UDDI registry. The matchmaker (OWL-S/UDDI Matchmaker Web Interface, 2007) is a tool which enhances the UDDI server by adding capability-based discovery. In combination with Racer (RACER, 2007), it processes the ontologies expressed in OWL. Service advertisements are first processed by the UDDI server, and if any semantic information is contained by them, they are passed to the OWL-S matchmaking engine. Finally, the engine processes service queries and returns the results to the UDDI server, which in turn, communicated with the requesting service client.

The matching algorithm used by Matchmaker to match a service request to a service advertisement is based on matching all the outputs of the first to the outputs of the latter, and all the inputs of the latter to the inputs of the first. The matching degree (between I/O of a request and I/O of an advertisement) depends on the correlation of the domain ontology concepts associated with these I/O. Matchmaker specifies four matching degrees

Figure 5. Semantic WS registry



(in decreasing order of matching importance): Exact, plugin, subsumes, and fail. The query language used in the registry is the standard query language of Racer that has its basis on LISP. It is powerful and has more functionalities than standard OWL query languages.

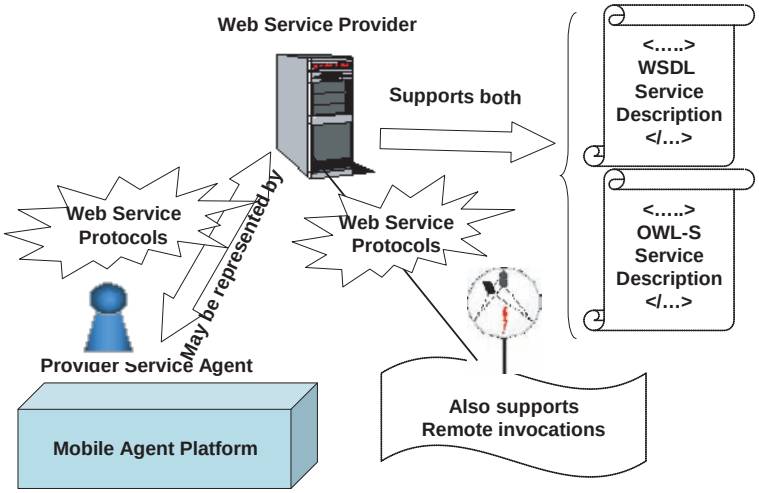
Matchmaker is a tool that integrates seamlessly with registries such as UDDI. In our system, we used a local implementation of UDDI, called jUDDI (jUDDI, 2007). JUDDI is a Web application for Apache Tomcat. The matchmaker tool is responsible for the mapping of the OWL-S service description to JUDDI. Matchmaker is plugged in JUDDI and is available in two versions, a Web-based and a standalone version. The standalone version provides a matching engine and a client API for invoking this engine. In our framework, we used the standalone version of Matchmaker. An extensive description of matchmaker can be found in Paolucci (2002) and Sycara (2004).

Web Service Provider (WSP)

The WSP provides the WS to interested clients. It maintains a description of the WS expressed in WSDL and OWL-S. Figure 6 depicts the WSP and their supported functionalities. Service invocation by the MA depends on the OWL-S description of the service. In our framework, service invocation by MA is performed either directly or through the PSA. In the direct access case, the agent has to be SOAP fluent, a fact that increases the size of the MA when moving over the network. Inside the OWL-S description of the WS, it is indicated if a PSA wraps the functionality of the service to allow the roaming MA to interact with the PSA instead of the SWS.

As mentioned above, OWL-S is used to enhance the expressiveness of WSDL in terms of semantic information. For this reason, in our framework, WS are described both in WSDL and

Figure 6. Web service provider



OWL-S. WSDL is used to describe the technical details (information included in the service grounding) and OWL-S is used to specify the input and output ontologies, thus, enabling an advanced service capability search (service profile and model). Upon retrieval of the desired services from the registry, the WSDL description is used to find the necessary definitions for its successful invocation.

As already mentioned, the SWS provider can expose a PSA to act as his delegate and interact with the user's MA. This is revealed to the MA through the OWL-S description. If this is not the case, the MA infers that no PSA is offered and the service should be accessed directly.

Service Usage Description

In this section, a functional description of the proposed framework is provided, through a service scenario. According to this scenario, a USR needs to find and invoke a certain WS by using a mobile device. Therefore, he/she connects to the client system, the platform front-end. After a successful registration, the USR sets the desired criteria for the WS. The user also defines the MA service invocation policies and forces the MA to follow a certain policy while roaming throughout the network. Subsequently, a MA is created, equipped with the user's unique ID, service invocation and agent behavioural policies, to represent the user in the fixed network and dispatch his service requests. The aforementioned policies are passed to the MA in XML format and stored into its policy repository, which remind the update handler that he has the authority to change these policies, according to the messages that the event service may receive from the USR or other network entities. The MA, after creation, migrates to the SWSR. The SWSR provides SWS descriptions and allows service capability search. When the MA arrives at the service registry, it communicates with the

RSA, which queries the registry on behalf of the MA. RSA finds the service(s) that meet the user needs and delivers them to the MA, which decides on the next step according to its specified service invocation and agent behavioural policies.

The MA may follow several WS invocation alternatives and these are listed below:

1. Poll the servers where the services are located to check their availability, in order to migrate only to those that are alive. In this way, the MA is released from the burden of migrating to a malfunctioning remote server. This strategy improves the overall performance of the framework by avoiding unnecessary migrations.
2. Try to invoke the services from remote and not migrate to the provider. Remote invocation or migration of MA is specified in the MA policies. Specifically, depending on the size of the MA or the distance between its current location and the location of the provider, it might be preferable not to migrate, but remotely invoke the WS.
3. Migrate to the WSP and collaborate with the PSA. The MA invokes the service and obtains the results through the PSA.
4. Migrate to the WSP and directly invoke the WS. This option requires the MA to carry additional code libraries. The implementation of the WSP is much simpler and straightforward since there is no change in the traditional WS implementation model.
5. Finally, to send clones to each WSP, instead of migrating serially to each one. This scenario results to a parallel invocation of WSs where each MA clone invokes one WS. In this way, the overall service invocation time is reduced in comparison to the previous service invocation alternatives.

All these service invocation alternatives are decided at runtime through the user's specified service invocation and agent behavioural policies. When the MA(s) have collected the results, there are two options depending on the selected policies:

1. When the MA invokes all the services, it migrates back to the client system. If the user is logged in the system, the MA passes the results to the user. Otherwise, the MA waits for the user to login and ask for the service results.
2. When the MA clones have been used for service invocation, they return to the client system and deliver service results to the father MA. After this interaction, the MA clones are destroyed. Consequently, the father MA delivers the services results to the user in a similar way to the previous case.

When the USR obtains the results, he may ask the MA to repeat one of the above scenarios by changing, if necessary, its policies, or he may cancel the execution of the agent. The USR may also, at any time, search for the agent, instruct him to return or cancel its execution at runtime.

A practical example of the proposed framework usage could be to book a trip from a place A to a place B and probably specifying some preferences on each action (e.g., the flight to have an intermediate stop to location C). The user requests this service by specifying his preferences and a MA fulfils this request. The MA has the intelligence to query the Semantic Web Service Registry and with the help of the semantic matchmaking capability of the registry to retrieve the most accurate service (that meets the requirements of the user), to invoke this service and provide synchronously or asynchronously the results to the user without his/her on-line presence. The semantic expression of the WS to the registry and the unambiguous matching of the user's criteria with the capabilities of the available SWS, leads to as many accurate results as possible, as well as maximization of the recall.

Maximization of the matching performance is of paramount importance, since it might be possible that the exact service does not exist in the registry catalogue, but still the most accurate result has to be retrieved. The matching algorithm that is used in the registry ensures this fact: it defines a flexible matching mechanism based on the OWL's subsumption mechanism. The degree of match between the request and the available services depends on the match between the concepts of the two ontologies. Specifically, the matching mechanism relies on a semantic matching between concepts, rather than a syntactic one. Let us consider the practical example mentioned above. The user wants to book a "flight" from location A to location B, and the registry contains a service that does not match exactly with the user's request in the sense that in the service advertisement the output is specified as "trip", as shown in Figure 7. Although there is no exact match between the output of the request and the advertisement, the matching algorithm recognizes a match, since "trip" subsumes "flight". This is a clear advantage over a simple string matching-based UDDI registry.

Figure 8 illustrates the semantic matching process that ensures efficient service retrieval since compares concepts that are unambiguous specified on three levels, service profile, model, and grounding.

If traditional methods of WS invocation are followed, this booking would be performed as follows: the user would browse to a UDDI registry, request all the WSs that provide a flight booking service and get the results. Due to the lack of semantics in the service registry (UDDI does not supports for WS semantic annotation) and to keyword search that is performed in such registries, the user would obtain WSs that provide booking services, probably either irrelevant WSs or services that are not classified according to the relevance of the query. As a result, the user would need to sequentially or randomly invoke each service till he finds a service that best meets his requirements. This interaction requires the online presence of the user during the whole interaction.

Figure 7. Semantic matching

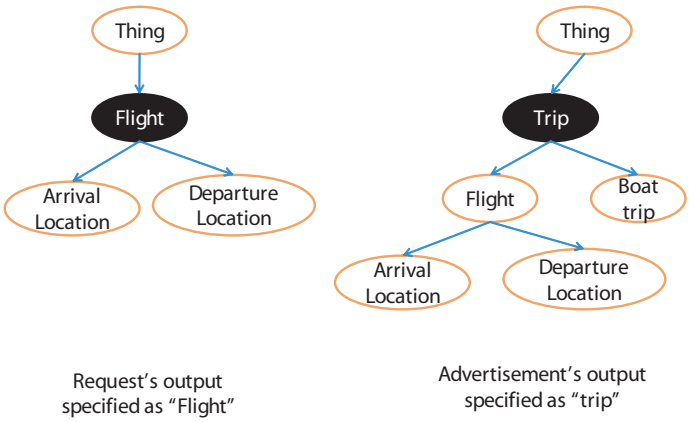


Figure 8. Web service retrieval

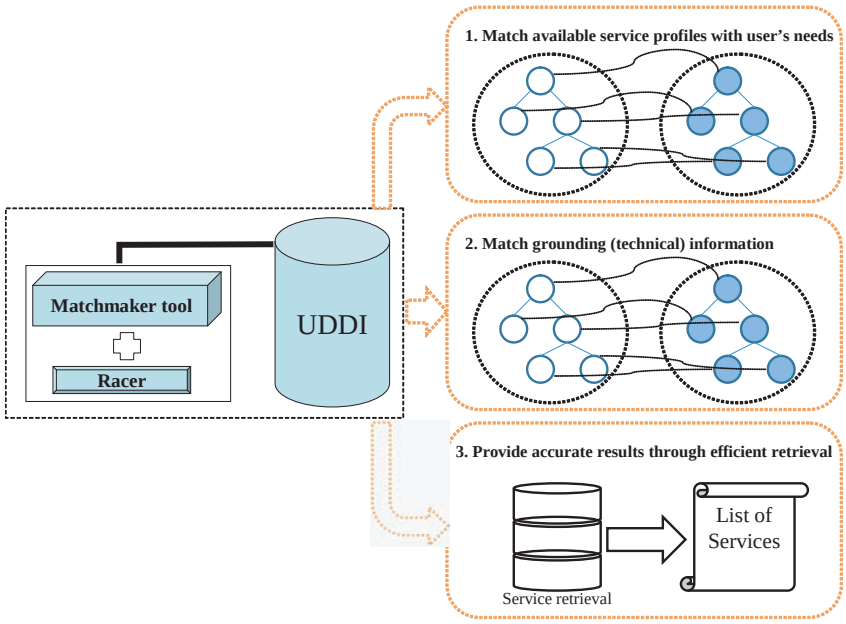


PERFORMANCE EVALUATION

In this section, we discuss the performance evaluation and present the results of the proposed system. Specifically, we compare the performance of our framework against the traditional business model of WS provision. In the following description, the term "conventional WS Business Model" (WSBM), refers to the model where a user requests a service to be executed and the system dispatches (either automatically or with user intervention) the request by discovering the appropriate service(s) from the service registry, and then, sequentially, invokes these WS, receives and forwards/presents to the user the service results. All communication among the involved network entities is performed with SOAP. Moreover, in our framework the mobile agents are implemented on JADE (JADE, 2007) MA platform. We have developed and tested the following system:

a. A WS system implemented with the "Conventional WS Business Model" (WSBM).
b. Our framework (Semantic Web services and mobile agents) (SWS& MA)

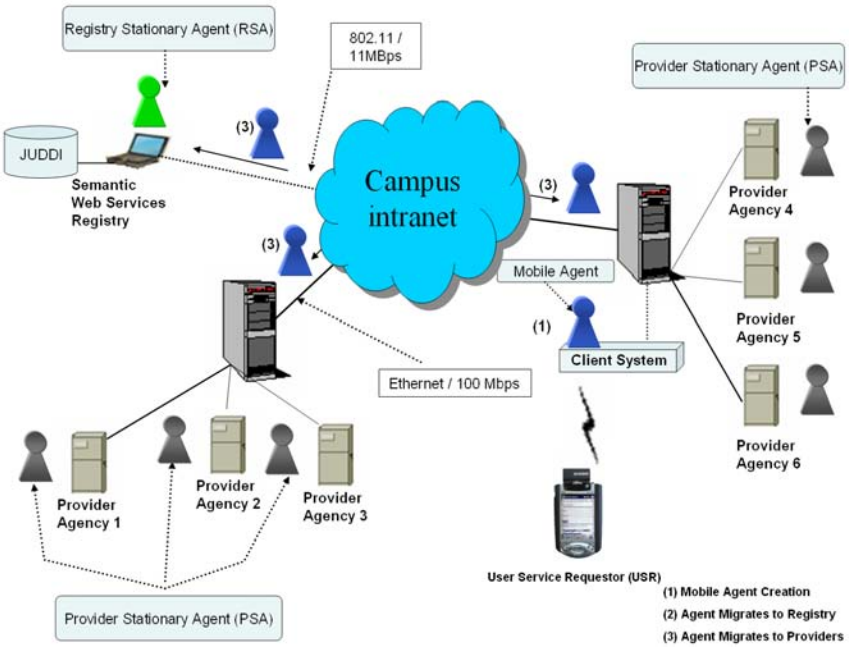
The SWS logic implemented in our experiments is as follows: the SWS have an extensive service description, stating unambiguously their capabilities in OWL-S. This description is published in the registry (SWSR). However, the SWS internal functionality is fairly simple, returning a pre-specified data volume subject to the service request. In our trials, these service results are 1

KB, 10 KB, 100KB and 1 MB. Moreover, six SWS have been implemented and distributed in the testing network.

In the performance evaluation scenario, a user requests a service, specifies his/her preferences and each of the above systems dispatches this request to the service registry. The service registry in the WSBM is a simple local UDDI providing a keyword service search on each service request, whereas in the SWS&MA system the registry is offering a service capability search to the placed service requests. In our evaluation, the description of SWS had small differences in the OWL-S descriptions. As a result, in the WSBM system, the service search to the UDDI registry had an average of three matches per service search/request. Contrary to WSBM system, in the SWS&MA system the MA had the necessary intelligence and knowledge to filter the results from the semantic registry and invoke only a SWS where its semantic description matched the service request and user's preferences. Consequently, in the WSBM system, we considered the average time this system requires to execute a service and we multiplied that by three (the average service results from the registry), whereas in SWS&MA system we consider the average time that is needed to invoke only a SWS. Moreover, in the SWS&MA system, the average time need was used from all the system variations to execute a SWS. These system variations are: (a) a system that uses MA cloning, (b) a system that uses PSA, and (c) a system that uses both MA cloning and PSA.

The testing platform we used is depicted in Figure 9. The system is a LAN that is composed of two workstations and a portable PC, all connected to the Internet through University's MAN.

Figure 9. Performance evaluation network topology



Below, we elaborate on the metrics that we adopted in order to assess the performance of the two systems. In Equation (1), total service time (TST_{MA}) (for the SWS&MA platform) is the sum of registry interaction time (*RIT*), migration of MA to a service provider time (MSPT) and the interaction time with this service provider (ITSP):

$$TST_{MA} = RIT + MSPT + ITSP \quad (1)$$

In the WSBM system, Equation (1) has the form:

$$TST_{\text{WSBM}} = RIT + \left\lfloor \frac{N}{2} \right\rfloor * \overline{ITSP} \quad (2)$$

where the $\overline{ITSP}$ is defined as:

$$\overline{ITSP} = N^{-1} * \sum_{i=1}^{N} ITSP_i \quad (3)$$

In (2) $ITSP_i$ is the time between service request submission and service results reception.

In Figure 10, the results of the proposed system performance evaluation and comparison against a system implemented using the Conventional WS Business Model are presented. More specifically, the average time needed to execute three services for the WSBM, is plotted against the time required to invoke only one SWS in the SWS&MA for each service result size (1 KB, 10 KB, 100KB and 1 MB). We observe that the TST in the SWS&MA system is approximately half the TST in the WSBM system, irrespective of the service results size. It should be noted that the RIT in our system is considerably greater than the WSBM system, and this explains that the TST of the SWS&MA is half and not the one third (or even smaller) of the TST of the WSBM system. The high RIT of the proposed SWS&MA framework is attributed to the specific semantic registry implementation and might be less if other semantic registry is used (e.g., OWLS-MX (OWLS-MX, 2007), and TUB OWLSM (OWLSM, 2007).

CONCLUSION

In this article, we presented a framework that provides wireless access to WS using MA to

Figure 10. Total service time (TST) vs. service result size

find and execute WS in the fixed segment. The WS are semantically enriched and are expressed in OWL-S. Furthermore, the proposed system adopts an enhanced WS registry enriched with semantic information that provides semantic matching between service requests submitted and the service description published to them. The advantages of the presented system are: (1) users may invoke a set of services with only one interaction with the fixed network (post the request and receive the results), (2) users do not have to be connected during service discovery and invocation; the results of such operations are downloaded to their mobile devices after their network session re-establishment, (3) service invocations are performed locally or according to the user's specified policies, and unnecessary information is not transmitted over the network leading to better resource utilization, (4) the framework ensures the delivery of the service results to the user, (5) the MA dynamic behaviour improves system robustness and fault tolerance, (6) new services, agents, users and service registries can be easily integrated to the framework, thus, providing an expandable, open system.

Future work includes the study of agent mobility for SWS dynamic invocation and composition that takes network events into account. Network events (e.g., node failures, overloading) occurring while the service invocation is underway, may force the MA to dynamically reschedule its itinerary. The MA will implement routing algorithms that generate itineraries by considering network information published in the WS description, network status and topology.

INTRODUCTION

New mobile architectures allow for stable networked links from almost everywhere, and more and more people make use of information resources for work and business purposes on mobile systems. Although technological improvements in the standardization processes proceed rapidly, many challenges, mostly aimed at the deployment of value-added services on mobile platforms, are still unsolved. In particular the evolution of wireless-enabled handheld devices and their capillary diffusion have increased the need for more sophisticated service discovery protocols (SDPs).

Here we present an approach, which improves Bluetooth SDP, to provide m-commerce resources to the users within a piconet, extending the basic service discovery with semantic capabilities. In particular we exploit and enhance the SDP in

order to identify generic resources rather than only services.

We have integrated a "semantic layer" within the application level of the standard Bluetooth stack in order to enable a simple interchange of semantically annotated information between a mobile client performing a query and a server exposing available resources.

We adopt a simple piconet configuration where a stable networked zone server, equipped with a Bluetooth interface, collects requests from mobile clients and hosts a semantic facilitator to match requests with available resources. Both requests and resources are expressed as semantically annotated descriptions, so that a *semantic distance* can be computed as part of the ranking function, to choose the most promising resources for a given request.

STATE OF THE ART

Usually, resource discovery protocols involve a requester, a lookup or directory server and finally a resource provider. Most common SDPs, as service location protocol (SLP), Jini, UPnP (Universal Plug aNd Play), Salutation or UDDI (universal description discovery and integration), include registration and lookup of resources as well as matching mechanisms (Barbeau, 2000).

All these systems generally work in a similar manner. Basically a client issues a query to a directory server or to a specific resource provider. The request may explicitly contain a resource name with one or more attributes. The lookup server—or directly the resource provider—attempts to match the query pattern with resource descriptions stored in its database, then it replies to the client with discovered resources identification and location (Liu, Zhang, Li, Zhu, & Zhang, 2002).

These discovery architectures are based on some common assumptions about network infrastructure under the application layer in the protocol stack. In particular, current SDPs usually require a continuous and robust network connectivity, which may not be the case in wireless contexts, and especially in the ad-hoc ones. In fact in such environments, network consistence varies continuously and temporary disconnections occur frequently, so bringing to a substantial decrease traditional SDP performances (Chakraborty, Perich, Avancha, & Joshi, 2001).

Actually, there are several issues that restrain the expansion of advanced wireless applications, among them, the variability of scenarios. An ad-hoc environment is based on short-range, low power technologies like Bluetooth (Bluetooth, 1999), which grant the peer-to-peer interaction among hosts. In such a mobile infrastructure there could be one or more devices providing and using resources but, as a MANET is a very unpredictable environment, a flexible resource search system is needed to overcome difficulties due to the host mobility. Furthermore, existing mobile resource discovery methods use simple string-matching, which is largely inefficient in advanced scenarios as the ones related to electronic commerce. In fact, in these cases there is the need to submit articulate requests to the system to obtain adequate responses (Chakraborty & Chen, 2000).

With specific reference to the SDP in the Bluetooth stack, it is based on a 128-bit universally unique identifier (UUID); each numeric ID is associated to a single service class. In other words, Bluetooth SDP is code-based and consequently it can handle only exact matches. Yet, if we want to search and retrieve resources whose description cannot be classified within a rigid schema (e.g., the description of goods in a shopping mall), a more powerful discovery architecture is needed (Avancha, Joshi, & Finin, 2002). SDP should be able to cope with non-exact matches (Chakraborty & Chen, 2000), and to provide a ranked list of discovered resources, computing a distance between each retrieved resource and the request after a matchmaking process.

To achieve these goals, we exploit both theoretical approach and technologies of semantic Web

vision and adapt them to small ad-hoc networks based on the Bluetooth technology (Ruta, Di Noia, Di Sciascio, Donini, & Piscitelli, 2005).

In a semantic-enabled Web—what is known as the semantic Web vision—each available resource should be annotated using RDF (RDF Primer, 2004), with respect to an OWL ontology (Antoniou & van Harmelen, 2003). There is a close relation between the OWL-DL subset of OWL and description logics (DLs) (Baader, Calvanese, McGuinness, Nardi, & Patel-Schneider, 2002) semantics, which allows the use of DLs-based reasoners in order to infer new information from the one available in the annotation itself.

In the rest of the article we will refer to DIG (Bechhofer, 2003) instead of OWL-DL because it is less verbose and more compact: a good characteristic in an ad-hoc scenario. DIG can be seen as a syntactic variant of OWL-DL.

THE PROPOSED APPROACH

In what follows we outline our framework and we sketch the rationale behind it. We adopt a mobile commerce context as reference scenario.

In our mobile environment, a user contacts via Bluetooth a zone resource provider (from now on *hotspot*) and submits her semantically annotated request in DIG formalism. We assume the zone server—which classifies resource contents by means of an OWL ontology—has previously identified shopping malls willing to promote their goods and it has already collected semantically annotated descriptions of goods. Each resource in the m-marketplace owns an URI and exposes its OWL description.

The *hotspot* is endowed with a *MatchMaker* [in our system we adapt the MAMAS-tng reasoner (Di Noia, Di Sciascio, Donini, & Mongiello, 2004)], which carries out the matchmaking process between each compatible offered resource and the requested one measuring a "semantic distance." The provided result is a list of discovered resources matching the user demand, ranked according to their degree of correspondence to the demand itself.

By integrating a semantic layer within the OSI Bluetooth stack at service discovery level, the management of both syntactic and semantic discovery of resources becomes possible. Hence, the Bluetooth standard is enriched by new functionalities, which allow to maintain a backward compatibility (handheld device connectivity), but also to add the support to matchmaking of semantically annotated resources. To implement matchmaking and ontology support features, we have introduced a *semantic service discovery* functionality into the stack, slightly modifying the existing Bluetooth discovery protocol.

Recall that SDP uses a simple request/response method for data exchange between SDP client and SDP server (Gryazin, 2002). We associated unused classes of 128-bit UUIDs in the original Bluetooth standard to mark each specific ontology and we call this identifier *OUUID* (*ontology universally unique identifier*). In this way, we can perform a preliminary exclusion of supply descriptions that do not refer to the same ontology of the request (Chakraborty, Perich, Avancha, & Joshi, 2001). With OUUID matching we do not identify a single service, but directly the context of resources we are looking for, which can be seen as a class of similar services. Each resource semantically annotated is stored within the *hotspot* as resource record. A 32-bit identifier is uniquely associated to a semantic resource record within the *hotspot*, which we call *SemanticResourceRecordHandle*. Each resource record contains general information about a single semantic enabled resource and it entirely consists of a list of resource attributes. In addition to the *OUUID* attribute, there are *ResourceName*, *ResourceDescription*, and a variable number of *ResourceUtilityAttr_i* attributes (in our current implementation 2 of them). *ResourceName* is a text string containing a human-readable name for the resource, the second one is a text string including the resource description expressed in

DIG formalism and the last ones are numeric values used according to specific applications. In general, they can be associated to context-aware attributes of a resource (Lee & Helal, 2003), as for example its price or the physical distance it has from the *hotspot* (expressed in metres or in terms of needed time to get to the resource). We use them as parameters of the overall *utility function* that computes matchmaking results.

In particular, to allow the representation and the identification of a semantic resource description we introduced in the data representation of the original Bluetooth standard two new *data element type descriptor*: OUUID and DIG text string. The first one is associated to the type descriptor value 9 whereas to the second one corresponds the type descriptor value 10 (both reserved in the original standard). We will associate 1, 2, 4 byte as valid size for the first one and 5, 6, 7 for the DIG text string.

Since the communication is referred to the peer layers of the protocol stack, each transaction is represented by one request Protocol Data Unit (PDU) and another PDU as response. If the SDP request needs more than a single PDU (this case is frequent enough if we use semantic service discovery) the SDP server generates a partial response and the SDP client waits for the next part of the complete answer.

By adding two SDP features *SDP_OntologySearch* (request and response) and *SDP_SemanticServiceSearch* (request and response) to the original standard (exploiting not used PDU ID) we inserted together with the original SDP capabilities further semantic-enabled resource search functions (see Table 1).

The transaction between service requester and *hotspot* starts after ad-hoc network creation. When a user becomes a member of a MANET, she is able to ask for a specific service/resource (by submitting a semantic-based description). The generic steps, up to response providing, for a service request are detailed in the following:

1. The user searches for a specific ontology identifier by submitting one or more

Table 1. List of PDU IDs with corresponding descriptions

PDU ID	**Description**
0x00	Reserved
0x01	SDP_ErrorResponse
0x02	SDP_ServiceSearchRequest
0x03	SDP_ServiceSearchResponse
0x04	SDP_ServiceAttributeRequest
0x05	SDP_ServiceAttributeResponse
0x06	SDP_ServiceSearchAttributeRequest
0x07	SDP_ServiceSearchAttributeResponse
0x08	SDP_OntologySearchRequest
0x09	SDP_OntologySearchResponse
0x0A	SDP_SemanticServiceSearchRequest
0x0B	SDP_SemanticServiceSearchResponse
0x0C-0xFF	Reserved

$OUUID_R$ she manages by means of her client application
2. The *hotspot* selects OUUIDs matching each $OUUID_R$ and replies to the client
3. The user sends a service request (*R*) to the *hotspot*
4. The *hotspot* extracts descriptions of each resource cached within the *hotspot* itself, which is classified with the previously selected $OUUID_R$
5. The *hotspot* performs the matchmaking process between *R* and selected resources it shares. Taking into account the matchmaking results, all the resources are ranked with respect to *R*
6. The *hotspot* replies to the user.

It is important to remark that basically all the previous steps are based on the original SDP in Bluetooth. No modifications are made to the original structure of transactions, but simply we differently use the SDP framework. In what follows we outline the structure of the SDP PDUs we added within the original framework to allow semantic resource discovery.

The first one is the *SDP_OntologySearchRequest* PDU. Their parameters are shown in Table 2.

The *OntologySearchPattern* is a data element sequence where each element in the sequence is a OUUID. The sequence must contain at least 1 and at most 12 OUUIDs, as in the original standard. The list of OUUIDs is an ontology search pattern. The *ContinuationState* parameter maintains the same purpose of the original Bluetooth (Bluetooth, 1999).

The *SDP_OntologySearchResponse* PDU is generated by the previous PDU. Their parameters are reported in Table 3.

The *TotalOntologyCount* is an integer containing the number of ontology identifiers matching the requested ontology pattern. Whereas the *OntologyRetrievedPattern* is a data element sequence where each element in the sequence is a OUUID matching at least one sent with the *OntologySearchPattern*. If no OUUID matches

Table 2. SDP_OntologySearchRequest PDU parameters

0x08	- ***OntologySearchPattern*** - *ContinuationState*

Table 3. SDP_OntologySearchResponse PDU parameters

PDU ID	**parameters**
0x09	- ***TotalOntologyCount*** - ***OntologyRetrievedPattern*** - *ContinuationState*

the pattern, the *TotalOntologyCount* is set to 0 and the *OntologyRetrievedPattern* contains only a specific OUUID able to allow the browsing by the client of all the OUUIDs managed by the *hotspot* (see the following *ontology browsing* mechanism for further details). Hence the pattern sequence contains at least 1 and at most 12 OUUIDs.

The *SDP_SemanticServiceSearchRequest* PDU follows previous PDU. Their parameters are shown in Table 4.

The *SemanticResourceDescription* is a data element text string in DIG formalism representing the resource we are searching for; *ContextAwareParam1* and *ContextAwareParam2* are data element unsigned integers. In our case study, which models an m-marketplace in an airport terminal, we use them respectively to indicate a reference price for the resource and the hour of the scheduled departure of the flight. Since a generic client interacting with a *hotspot* is in its range, using the above PDU parameter she can impose—among others—a proximity criterion in the resource discovery policy.

The *SDP_SemanticServiceSearchResponse* PDU is generated by the previous PDU. Their parameters are reported in Table 5.

The *SemanticResourceRecordHandleList* includes a list of resource record handles. Each of the handles in the list refers to a resource record potentially matching the request. Note that this list of service record handles does not contain header fields, but only the 32-bit record handles. Hence, it does not have the data element format. The list of handles is arranged according to the relevance order of resources, excluding resources not compatible with the request. The other param-

eters maintain the same purpose of the original Bluetooth (Bluetooth, 1999).

In all the previous cases, the error handling is managed with the same mechanisms and techniques of Bluetooth standard (Bluetooth, 1999).

Notice that each resource retrieval session starts after settling between client and server the same ontology identifier (OUUID).

Nevertheless if a client does not support any ontology or if the supported ontology is not managed by the *hotspot*, it is desirable to discover what kind of merchandise class (and then what OUUIDs) are handled by the zone server without any a priori information about resources. For this purpose we use the *service browsing* feature (Bluetooth, 1999) in a slightly different fashion with respect to the original Bluetooth standard, so calling this mechanism *ontology browsing.* It is based on an attribute shared by all semantic enabled resource classes, the *BrowseSemanticGroupList* attribute which contains a list of OUUIDs. Each of them represents the browse group a resource may be associated with for browsing.

Browse groups are organized in a hierarchical fashion, hence when a client desires to browse a *hotspot* merchandise class, she can create an *ontology search pattern* containing the OUUID that represents the *root browse semantic group.* All resources that may be browsed at the top level are made members of the *root browse semantic group* by having the root browse group OUUID as a value within the *BrowseSemanticGroupList* attribute.

Generally a *hotspot* supports relatively few merchandise classes, hence all of their resources will be placed in the root browse group. However, the resources exposed by a provider may be organised in a browse group hierarchy, by defining additional browse groups below the root browse group.

Having determined the goods category and the corresponding reference ontology, the client can also download a DIG version of it from the *hotspot* as *.jar* file [such a file extension—among other things—also allows a total compatibility with the Connected Limited Device Configuration (CLDC) technology].

Also notice that since the proposed approach is fully compliant with semantic Web technologies, the user exploits the same semantic enabled descriptions she may use in other Semantic Web compliant systems (e.g., in the Web site of a shopping mall). That is, there is no need for different customized resource descriptions and modelling, if the user employs different applications either on the Web or in mobile systems. The syntax and formal semantics of the descriptions is unique with respect to the reference ontology and can be shared among different environments.

In e-commerce scenarios, the match between demand and supply involves not only the description of the good but also data-oriented properties. It would be quite strange to have a commercial transaction without taking into account price, quantity, and availability, among others. The demander usually specifies how much she is willing to pay, how many items she wants to buy, and the delivery date. Hence, the overall match value depends not only on the distance between the (semantic-enabled) description of the demand and of the supply. It has to take into account the description distance with the difference of (the one asked by the demander and the other proposed by the seller), quantity, and delivery date. The overall utility function combines all these values to give a global value representing the match degree.

Also notice that, in m-commerce applications, in addition to "commercial" parameters also context-aware variables should influence matching results. For example, in our airport case study, we consider the price difference but also the physical distance between requester and seller to weigh the match degree. The distance becomes an interesting value since a user has a temporal deadline for shopping: the scheduled hour of her flight. Hence, a resource might be chosen also according to its proximity to the user.

We will express this distance in terms of time to elapse for reaching the shop where a resource is, leaving from the *hotspot* area. In such a manner the *hotspot* will exclude resources not reachable by the user while she is waiting for boarding and it will assign to resources unlikely reachable (farther) a weight smaller than one assigned to easily reachable ones.

The above approach can be further extended to other data-type properties.

The utility function we used depends on:

- p_D : price specified by the demander
- p_O : price specified by the supplier
- t_D : time interval available to the client
- t_O : time to reach the supplier and come back, leaving from the *hotspot* area
- *s_match*: score computed during the semantic matchmaking process, computed through *rankPotential* (Di Noia, Di Sciascio, Donini, & Mongiello, 2004) algorithm.

$$u(s\_match, p_D, p_O, t_D, t_O) =$$

$$\frac{s\_match}{2} + \frac{\tanh\frac{t_D - t_O}{\beta}}{3} + \frac{(1+\alpha)p_D - p_O}{6(1+\alpha)p_D} \quad (1)$$

Notice that p_D is weighted by a (1+α) factor. The idea behind this weight is that, usually, the demander is willing to pay up to some more than what she originally specified on condition that she finds the requested item, or something very similar. In the tests we carried out, we find α=0.1 and β=10 are values in accordance with user preferences. These values seem to be in some accordance with experience, but they could be changed according to different specific considerations.

RUNNING EXAMPLE

A simple example can clarify the rationale of our setting. Here we will present a case study analogous to the one presented in Avancha, Joshi, and Finin (2002), and we face it by means of our approach.

Let us suppose a user is in a duty free area of an airport, she is waiting for her flight to come back home and she is equipped with a wireless-enabled PDA. She forgot to buy a present for her beloved little nephew and now she wants to purchase it from one of the airport gift stores.

In particular she is searching for a learning toy strictly suitable for a kid (she dislikes a child toy or a baby toy) and possibly the toy should not have any electric power supply.

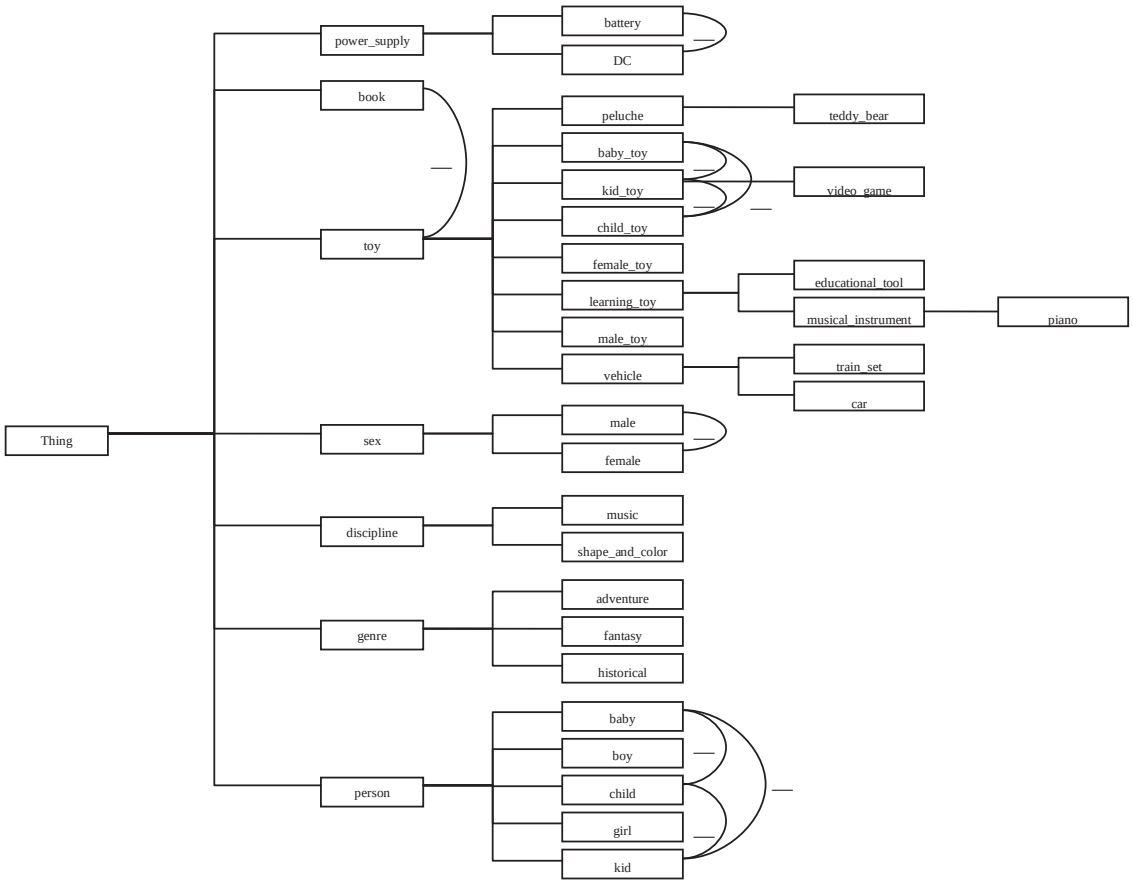
Clearly this request is too complex to be expressed by means of standard UUID Bluetooth SDP mechanism. In addition, non-exact matches between resource request and offered ones is highly probable and the on/off matching system provided by the original standard in this case could be largely inefficient.

Hence both the semantic resource request and offered ones can be expressed in a DIG statement exploiting DL semantics and encapsulated in an SDP PDU.

The *hotspot* equipped with MAMAS reasoner collects the request and initially selects supplies expressed by means of the same ontology shared with the requester. Hence a primary selection of suitable resources is performed. In addition, the matchmaker carries out the matchmaking process between each offered resource in the m-marketplace and the requested one measuring a "semantic distance" (Colucci, Di Noia, Di Sciascio, Donini, & Mongiello, 2005). Finally the matchmaking results are ranked and returned to the user.

A subset of the ontology used as a reference in the examples is reported in Figure 1. For the sake of simplicity, only the class hierarchy and disjoint relations are represented.

Figure 1. The simple toy store ontology used as reference in the example



Let us suppose that after the *hotspot* selects supplies, its knowledge base is populated with the following individuals whose description is represented using DL formalism:

- *Alice_in_wonderland*. Price 20$. 5 min from the *hotspot*:
  book ⊓ ∀has_genre.fantasy
- *Barbie_car*. Price 80$. 10 min from the *hotspot*:
  car ⊓ ∀suggested_for.girl ⊓ ∀has_power_supply. battery
- *classic_guitar*. Price 90$. 17 min from the *hotspot*:
  musical_instrument ⊓ ∀suitable_for.kid ⊓ (≤ 0 has_power_supply)
- *shape_order*. Price 40$. 15 min from the *hotspot*:
  educational_tool ⊓ ∀suitable_for.child ⊓ ∀stimulates_to_learn. shape_and_color

- *Playstation*. Price 160$. 28 min from the *hotspot*:
  video_game ⊓ ∀has_power_supply.DC
- *Winnie_the_pooh*. Price 30$. 15 min from the *hotspot*:
  teddy_bear ⊓ ∀suitable_for.baby

On the other hand, the request ***D*** submitted to the system by the user can be formalized in DL syntax as follows:

learning_toy ⊓ ∀suggested_for.boy ⊓ ∀suitable_for.kid ⊓ (≤ 0 has_power_supply)

In addition she imposes a reference price of 200$ (p_D=200) as well as the scheduled departure time as within 30 minutes (t_D=30).

In Table 6 matchmaking results are presented. The second column shows whether each retrieved resource is compatible or not with request *D* and, in case, the *rankPotential* computed result. In the fourth column, matchmaking results are also expressed in a relative form between 0 and 1 to allow a more immediate semantic comparison among requests and different resources and to put in a direct correspondence various rank values.

Finally in the last column results of the overall utility function application are shown.

Notice that the semantic distance of the individual *classic_guitar* from *D* is the smaller one; then the system will recommend to the user this resource first. Hence the ranked list returned by the *hotspot* is a strict indication for the user about best available resources in the airport duty free piconet in order of relevance with respect to the request. Nevertheless a user can choose or not a resource according to her personal preferences and her initial purposes.

After having selected the best resource, the server of the chosen virtual shop will receive a connection request from the user PDA with its connection parameters and in this manner the transaction may start. The user can provide her credit card credentials, so that when she reaches the store, her gift will be already packed. This final part of the application is not yet implemented, but it is trivially achievable exploiting the above SDP infrastructure.

CONCLUSION AND FUTURE WORK

In this article we have presented an advanced semantic-enabled resource discovery protocol for m-commerce applications. The proposed approach aims to completely recycle the basic functionalities of the original Bluetooth service discovery

Table 6. Matchmaking results

demand – supply	**compatibility (y/n)**	**score**	**s_match**	**u(·)**
D - Alice_in_wonderland	n	-	-	-
D - Barbie_car	y	7	0.364	0.609
D - classic_guitar	y	3	0.727	0.748
D - shape_order	n	-	-	-
D - Playstation	y	5	0.546	0.378
D - Winnie_the_pooh	n	-	-	-

protocol by simply adding semantic capabilities to the classic SDP ones and without introducing any change in the regular communication work of the standard. A matchmaking algorithm is used to measure the semantic similarity among demand and resource descriptions.

Future trends of the proposed framework aim to create a more advanced DSS to help a user in a generic m-marketplace. Under investigation is the support to creation of P2P small communities of mobile hosts where goods and resources are advertised and opinions about shopping are exchanged (Avancha, D'Souza, Perich, Joshi, & Yesha, 2003). If a user decides to "open" her shopping trolley sharing information she owns (purchased goods, discounts, opinion about specific vendors or products) the system will insert her in a buyer mobile community where she can exchange information with other users.

Another future activity focuses on strict control of the good advertising. In an m-marketplace, the system will send to various potential buyers best proposals about their interests.

We intend to implement a mechanism to advertise goods or services in a more direct and personalized fashion. From this point of view, an additional feature of the system is oriented to the user profiling extraction and management (Prestes, Carvalho, Paes, Lucena, & Endler, 2004; Ruta, Di Noia, Di Sciascio, Donini, & Piscitelli, 2005; von Hessling, Kleemann, & Sinner, 2004). Without imposing any explicit profile submission to the user, the system could collect her preferences by means of previously submitted requests (Ruta, Di Noia, Di Sciascio, Donini, & Piscitelli, 2005); that is, by means of the "history" of the user in the m-marketplace.

KEY TERMS

Description Logics (DLs): A family of logic formalisms for knowledge representation. Basic syntax elements are concept names, role names, and individuals. Intuitively, concepts stand for sets of objects, and roles link objects in different concepts. Individuals are used for special named elements belonging to concepts. Basic elements can be combined using constructors to form concept and role expressions, and each DL has its own distinct set of constructors. DL-based systems are equipped with reasoning services: logical problems whose solution can make explicit knowledge that was implicit in the assertions.

M-Marketplace: Virtual environment where demands and supplies (submitted or offered by users equipped with mobile devices) encounter each other.

Ontology: An explicit and formal description referred to concepts of a specific domain (classes) and to relationships among them (roles or properties).

Piconet: Bluetooth-based short-range wireless personal area network. A Bluetooth piconet can host up to eight mobile devices. More piconets form a *scatternet.*

Service Discovery Protocol (SDP): It identifies the application layer of an OSI protocol stack and manages the automatic detection of devices with joined services.

Semantically Annotated Resource: any kind of good, tangible or intangible (e.g., a document, an image, a product or a service) endowed of a description that refers to a shared ontology.

Semantic Matchmaking: The process of searching the space of possible matches between a request and several resources to find those best matching the request, according to given semantic criteria. It assumes that both the request and the resources are annotated according to a shared ontology.

Chapter 7.28
Improving Mobile Web Navigation Using N-Grams Prediction Models

ABSTRACT

In this article, we propose to use N-gram models for improving Web navigation for mobile users. N-gram models are built from Web server logs to learn navigation patterns of mobile users. They are used as prediction models in an existing algorithm which improves mobile Web navigation by recommending shortcuts. Our experiments on two real data sets show that N-gram models are as effective as other more complex models in improving mobile Web navigation.

INTRODUCTION

Wireless users of the Web grow rapidly as more and more mobile devices such as PDAs, mobile phones and pagers are now equipped with browsing capabilities. Many current Web sites are optimized for desktop, broadband clients, and deliver content poorly for mobile devices due to display size and bandwidth. Moreover, the associated cost will prohibit maintaining two versions of a site, one for wired users and the other for mobile users. A viable solution is adaptive Web sites (Perkowitz & Etzioni, 1997). An adaptive Web site dynamically changes its contents or structure based on browsing activities.

Following the idea of adaptive Web sites, Anderson, Domingos, and Weld (2001) proposed shortcuts to improve mobile Web navigation. A shortcut is a dynamic link that provides a shorter path with fewer clicks for users to reach their desired pages. A shortcut to a destination page is dynamically created and inserted into the next page a user is going to browse. If that destination page is the one in which the user is interested, the user can access the page by following the shortcut. For example, assume a browsing session consists of A-B-C-D-E-F-G, where each letter represents a page. After browsing pages A and B, if a shortcut to G is created and inserted into page C, the user can follow the shortcut to reach G, without going through intermediate pages D, E, and F. The critical question is how to find shortcuts that are useful with only part of the session known. A shortcut C → H, for example, is useless in the previous example.

In order to provide useful shortcuts, Web usage mining techniques are employed. User browsing patterns are extracted from Web server logs. These patterns are built into prediction models that can be used to predict user browsing behaviors. Given a partial session, such prediction models will compute what other pages in which the user may be interested. These predictions are used to create and recommend shortcuts for mobile users.

A critical component in this approach is the prediction model. The model should be as accurate as possible with as little information about the session as possible. An accurate shortcut found earlier in a session is more worthwhile than one found close to the end of a session. Moreover, the prediction model should be easy to build and use. In their MINPATH algorithm, Anderson et al. (2001) used Markov models, which proved to be accurate (Anderson et al., 2001). However, those models require Web graphs. In this article, we propose to use a simpler prediction model, N-gram, for learning user browsing patterns.

N-grams are well known and are widely used in speech and text processing applications. Researchers have found that accuracy increases with N, the order of N-grams. For example, 4-grams are more accurate than 3-grams, which is turn is more accurate than 2-grams. Though accuracy increases with higher values of N, it requires a larger number of training sessions to have a well trained N-gram model.

An N-gram based prediction model for Web browsing patterns is proposed by Su et al. (2000). The N-gram model has several advantages over other prediction models. It is simple, robust, and easy to use. Besides, N-gram does not use a Web graph. In our study, the same N-gram model with a slightly different lookup operation is used. Moreover, its effectiveness in improving mobile Web navigation is examined.

In our approach, first, Web server logs are preprocessed to identify sessions. A session is conceptually a single visit. The sessions are then used to train an N-gram model. A revised version of MINPATH algorithm, MINCOST, is proposed to find shortcuts. MINCOST uses a different function in calculating the saving and ranking of shortcuts. Our approach has been implemented and evaluated against two real data sets from NASA and EPA Web servers. Our experiments show that the N-gram prediction model is as effective as more sophisticated models in recommending useful shortcuts.

The article is organized as follows. The second section discusses related work in Web usage mining, adaptive Web sites, and MINPATH algorithm. Our approach is presented in Section 3. Experimental results with two data sets are reported in the fourth section The fifth section concludes the article and gives some future research direction.

RELATED WORK

We briefly discuss Web usage mining techniques and its applications in adaptive Web sites and mobile Web navigation.

Web Usage Mining

Web usage mining refers to the mining of Web server logs to find interesting patterns in Web usage. Web server logs are preprocessed to find sessions. Conceptually, a session is a single visit to a Web site by a user. A session is represented by the pages browsed in that visit. From sessions, many Web usage patterns can be extracted, including associations, frequent paths, and clusters.

Association rules represent correlations among objects, which were first proposed to capture correlations among items in transactional data. If a session is viewed as a transaction, association rule mining algorithms can be employed to find associative relations among pages browsed (Mobasher, Cooley, & Srivastava, 1999a; Yang, Zhang, & Li, 2001). Using the same algorithms, we may find frequent paths traversed by many users (Frias-Martines & Karamcheti, 2002).

If each Web page represents a dimension, a session can be represented as a vector in the page space. Sessions can be clustered based on their similarity in the page space. In other words, sessions containing similar pages will be grouped into clusters (Fu, Sandhu, & Shih, 1999; Shahabi, Zarkesh, Adibi, & Shah, 1997).

Adaptive Web Sites

Perkowitz and Etzioni (1997) proposed adaptive Web site as a solution to the problem of Web navigation. An adaptive Web site is a Web site that automatically or semi-automatically adapts it structure based on user browsing. They proposed creating dynamic links using Web usage mining techniques. Koutri, Daskalaki, & Avouris, (2002) gives an overview of techniques for adaptive Web sites.

Anderson et al. (2001) argued that an adaptive Web site is especially interesting for mobile Web navigation. Due to limited display size, computing and storage capability, and network bandwidth, Web sites developed mainly for desktops deliver content poorly to mobile devices. To better serve the needs of mobile Web users, they proposed building Web site "personalizers" that observe the behavior of Web visitors and automatically customize and adapt Web sites for each mobile visitor. The MINPATH algorithm as described in Section 2.3 epitomizes their approach.

The MINPATH algorithm tries to improve the mobile Web user browsing experience by suggesting useful shortcuts. MINPATH finds shortcuts by using a learned model of user behavior to estimate the savings provided by shortcuts. The shortcuts are dynamically inserted into the page that the user will browse next. For example, after a user browsed pages A-B-C, MINPATH may provide a shortcut D->K in the next page D. It uses a prediction model that learns the user browsing behaviors to find the best shortcuts. If the user follows this shortcut, the user session becomes A-B-C-D-K. Assuming that without shortcut, the user session would contain pages A-B-C-D-E-F-G-H-I-J-K, the shortcut results in a saving of six pages or links.

MINPATH Algorithm

The MINCOST algorithm works as follows Anderson et al. (2001). Given a sequence of pages, called prefix, it uses prediction models to find the possible next pages and their probabilities. These pages and their savings are added to a shortcut list. For each page found by the prediction model, it is appended to the sequence, forming a suffix, which is used to find more shortcuts following the same procedure. This process continues recursively until the length of the suffix exceeds the depth bound or the probability of the predicted page becomes less than the probability threshold. Once the recursive part is over, the shortcuts found are sorted in descending order based on savings and the best shortcuts are returned. The number of shortcuts to be returned are user specified.

To estimate savings of a shortcut, MINPATH counts the number of links saved by following the

shortcut. For example, if a prefix is A-B-C, and a suffix is A-B-C-D-E-F-G, the expected saving for a shortcut D-> G is two.

There are two threshold parameters, depth bound and probability threshold; used in the MINPATH algorithm to limit searches for shortcuts. Depth bound represents the maximum length of the suffix. Probability threshold represents the minimum value of page probability.

MINPATH algorithm uses Markov models (Deshpande & Karypis, 2000; Sarukkai, 2000). Though accurate these models are complex and require Web graphs as a part of their implementation. There is a need to find less complex prediction models with comparable accuracy. Besides, MINPATH does not consider page size in estimating saving.

THE PROPOSED APPROACH

There are three steps in our approach to improve navigation for mobile Web users. First, Web server logs are preprocessed to extract sessions. Second, an N-gram prediction model is built from these sessions. Third, an algorithm that extends MINPATH, called MINCOST, recommends shortcuts based on the N-gram model and the current browsing sequence.

Server Log Preprocessing

A record in a server log file contains raw browsing data, such as the IP address of the user, date and time of the request, URL of the page, the return code of the server, and the size of the page, if the request is successful. Since such records are in chronological order, they do not provide much meaningful information about user browsing. The Web server log files are transformed into a set of sessions. A session represents a single visit of a user. The following procedure is used to transform a server log file into sessions (Mobasher, Cooley, & Srivastava, 1999b).

1. Records about image files (.gif, .jpg, etc.) and unsuccessful requests (return code belonging to the 4XX series) are filtered out.
2. Requests from the same IP address are grouped into a session. A timeout of *max-idle* is used to decide the end of a session, i.e., if the same IP address does not occur within a period of *max-idle* seconds, the current session is closed. Subsequent requests from the same IP address will be treated as a new session.

In our experiments, we used a value of 1800 seconds for *max-idle*, which is very common in Web usage mining studies.

Prediction Model Learning

Once we are done with preprocessing of Web logs, the next step is to build prediction models to predict the navigation patterns of Web users. If $P_1, P_2, P_3, \ldots, P_i$ are the pages browsed by the user so far, the prediction models will try to predict the next page, P_{i+1}.

We use an N-gram based prediction model. An N-gram is a substring of N characters, each character from an alphabet. The order of an N-gram is defined as N, the number of characters in the N-gram. In the context of this work, the alphabet is the set of URLs of Web pages on the Web server. An N-gram is a sequence of URLs.

After Web server logs are preprocessed into a number of sessions, an N-gram prediction model can be built as follows:

1. Each session is decomposed into a set of overlapping, subsequent paths of length N.
2. These paths are entered into an N-gram table T as N-grams.
3. For each path in T, the next pages right after it and their occurrences, in all the sessions, are recorded.

4. The probabilities of the next pages for all paths are calculated from the occurrences of all possible next pages.

For example, given a log file consisting of the following sessions, a 3-gram model for prediction can be built as follows:

A, B, C, D, H
B, C, D, G

The first session is decomposed into two 3-grams: "A, B, C" and "B, C, D." The second session is decomposed into one 3-gram: "B, C, D." For 3-gram "A, B, C," the next page would

Table 1. A 3-gram prediction table

3-gram	Predicted next page	Probability of next page
A, B, C	D	1.0000
B, C, D	G	0.5000
B, C, D	H	0.5000

Figure 1. Algorithm for constructing N-gram models

```
Input:
        L: sessions from Web server logs.
        N: order of N-gram
Output:
        T: N-gram prediction table
        // for an N-gram P and a predicted next page C, cell T[P, C] stores the probability.
Procedure:
        Begin
        For i = 1 to |L| do    // for every session
                S = L[i];       // the i-th session
                For j =1 to |S| do        // |S| represents the number of pages in session S
                        If (|S| - j)> N  // Find a sub-string of length N starting at j
                                P = sub-string (S, j, N);    // the j-th N-gram
                                                //sub-string returns N consecutive pages in S,
                                                // starting from j-th page,
                                C = sub-string(S, j+N, 1); // Find the next page
                                T [P, C] = T [P, C] + 1;    // increment count of (N-gram, next page) pair
                        End If
                End For
        End For
        For each [P, C] in T

                T [P, C] = T [P, C]  /  Σ_C(T[P, C]);  // convert count into probability

        End For
        Return T;
        End
```

be D, while for 3-gram "B, C, D," the next page may be G or H. The complete N-gram table, T, is given in Table 1.

The N-gram table T is used as our prediction model. Given an observed path, it is matched against N-grams in T. The predicted next pages and their corresponding probabilities of the matching entries in T are returned for shortcut recommendations.

The algorithm for constructing an N-gram model is given in Figure 1. It is modified from the algorithm from Su et al., (2000) such that it stores all possible next pages for an N-gram, rather than the most probable one only.

This algorithm has a time complexity of O(|L| * |S|) where |L| is the number of sessions and |S| is the length of sessions. The time of the algorithm is dominated by the first for loop. Its outer loop runs |L| times and its inner loop runs |S| times, which gives the time complexity of O(|L| * |S|).

An N-gram based prediction model is proposed in Su et al. (2000), which evaluates the model's accuracy without a specific application. In our study, the N-gram model is evaluated on its effectiveness in improving mobile Web navigation. To suit our application, the model is modified so that a lookup operation for an N-gram will return all predictions, instead of just the most probable one.

Shortcut Recommendation

The MINPATH algorithm ranks shortcuts based on their expected savings. In computing expected savings, MINPATH considers only the number of links saved. We modified MINPATH to reflect expected saving in total cost.

Given a prefix $< P_0, P_1, P_2,....,P_i >$, of a session $< P_0, P_1, P_2,....,P_n >$, a shortcut to P_n , i.e. , P_{i+1}-> P_n, can be added to page P_{i+1}. In MINPATH, the expected saving of the shortcut is calculated as the product of the number of links saved by following that particular shortcut and the probability that P_n is the destination page. Instead, we compute the expected saving as a cost function of page size and page probability.

The cost of browsing a page P_k, cost(P_k), is composed of the times to download the page, to view the page, and to click the link for next page. In other words, if a page is skipped by following a shortcut, the times to download, view, and click the page, are saved. The time to view and click is constant, but the time to download depends on page size. A parameter, Δ, is introduced to represent the download cost, which can be thought as time for transmission a unit of data. By introducing Δ, download time is separated from view and click time. The value of Δ is determined by network bandwidth and congestion. Since the cost function is relative, i.e., only the ratio of download time to view and click time matters, the view and click time is normalized to 1 in the cost function and Δ is adjusted accordingly.

$$\text{Cost}(P_k) = \text{download time} + \text{view and click time} = \text{Size}(P_k)*\Delta+1 \quad (1)$$

where $\text{Size}(P_k)$ is the size of page P_k in kilobytes.

The saving of a shortcut is the sum of the costs of pages skipped.

$$\text{Expected savings } (P_{i+1} \text{-> } P_n) = P_s * \{\sum_{k=i+2}^{N-1} \text{Cost}(P_k)\} =$$

$$P_s * \{\sum_{k=i+2}^{N-1} [\text{Size}(Pk)*\Delta+1\ ]\} \quad (2)$$

where P_s is the probability that page P_n is the destination page.

In our experiments, we found Δ has little effect on results, because pages have similar sizes. Its value is fixed at 0.5 assuming an effective bandwidth of 1 kbps and view and click time of 2 seconds. When pages have quite different sizes, Δ may have an impact on results.

To differentiate, we call the modified algorithm MINCOST since it takes into consideration cost for downloading. MINPATH considers only savings in view and click time, while MINCOST considers both view and click time and download time. It is easy to see that MINCOST is a generalization of MINPATH. When Δ is set to 0, the cost function in (2) degrades into the number of links saved which is used in MINPATH.

PERFORMANCE EVALUATION

The MINCOST algorithm is implemented in the C programming language and experiments are performed to evaluate the efficiency of our approach to improve mobile Web navigation with real datasets. The experiments are run on a PC with a 2.66 GHz Intel Pentium 4 processor, a memory of 512 MB, and running Windows XP professional.

Datasets

Two datasets are used in our experiments, the NASA dataset and the EPA dataset. The NASA dataset was collected from July 1, 1995 through July 31, 1995 for a total of one month's requests from the NASA server at Kennedy Space Center. The EPA dataset was collected from 23:53:25 August 29, 1995 through 23:53:07 August 30, 1995 for a total of 24 hours of requests from the EPA server at Research Triangle Park, NC.

The NASA and EPA datasets are converted into sessions as described in the third section. Table 2 gives a summary of the datasets.

Performance Measurements

The efficiency of the MINCOST algorithm is evaluated using average cost saved and percentage of average cost saved. The total cost of pages in the initial sessions and the total cost of pages in the final sessions after MINCOST are calculated using the definition in Equation 1. The difference between these two gives the total cost saved. The total cost saved is averaged over all sessions giving the average cost saved. The percentage of average cost saved is the average cost saved as a percentage of the average cost.

Total Cost Saved = Total Cost without MINCOST - Total Cost with MINCOST

Average Cost = Total Cost without MINCOST / Total Sessions

Table 2. NASA and EPA datasets summary

	NASA DATASET	EPA DATASET
Total Log Records	3,461,612	47,748
Total Sessions	132539	2074
Unique URLs	768	1821
Average Session Length (Number of Pages in a Session)	3.134	4.222
URL For Download	http://ita.ee.lbl.gov/html/contrib/NASA-HTTP.html	http://ita.ee.lbl.gov/html/contrib/EPA-HTTP.html

Average Cost Saved = Total Cost Saved/Total Sessions

Average Cost Saved (%) = (Average Cost Saved / Average Cost) * 100

Experimental Parameters

The average cost saved and the percentage of average cost saved are measured with respect to probability threshold, depth bound, number of shortcuts, and the order of the N-gram. In each experiment, we vary one parameter while keeping others to their default values. The results are reported from a 10 fold cross-validation. The entire dataset is divided into ten equal portions. Each portion is used as the testing set for MINCOST, while the remaining portions are used as training set for building the N-gram model as described in the third section. The results are averaged over these ten runs.

The parameters and their default values are given in Table 3.

The user behavior when provided with shortcuts is simulated by making two assumptions. First, it is assumed that when presented with one or more shortcuts that lead to destinations along the user's session, the user will select the shortcut that leads farthest along the session. Second, when no shortcuts lead to pages in the user's session, the user will follow the next link in the session.

Experimental Results from NASA Dataset

The results from experiments on NASA data set are presented in this section. Similar results are obtained from experiments on EPA data set, and are thus omitted.

Figures 2 and 3 show the average cost saved and percentage of average cost saved with respect to probability threshold, respectively. It is observed that both measures increase with decrease in probability threshold and stabilize around 0.0080. This is because there are not many shortcuts with significant savings after this value.

From Figures 2 and 3, it is obvious that the two performance measures, average cost saved and percentage of average cost saved, react similarly to changes in probability threshold. It is not a coincidence. Other experiments also reveal the

Table 3. Parameters and their default values

PARAMETER	DEFAULT VALUE	DESCRIPTION
Probability Threshold	0.006	Minimum probability of a shortcut
Depth Bound	5	Maximum length of suffix
Number of Shortcuts	3	Number of top shortcuts recommended
N	2	Order of N-gram model

Figure 2. Average cost saved vs. probability threshold

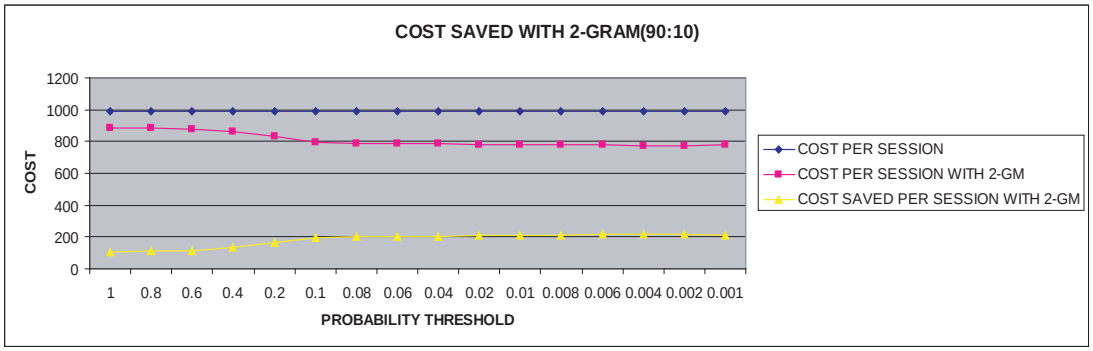

Figure 3. Percentage of average cost saved vs. probability threshold

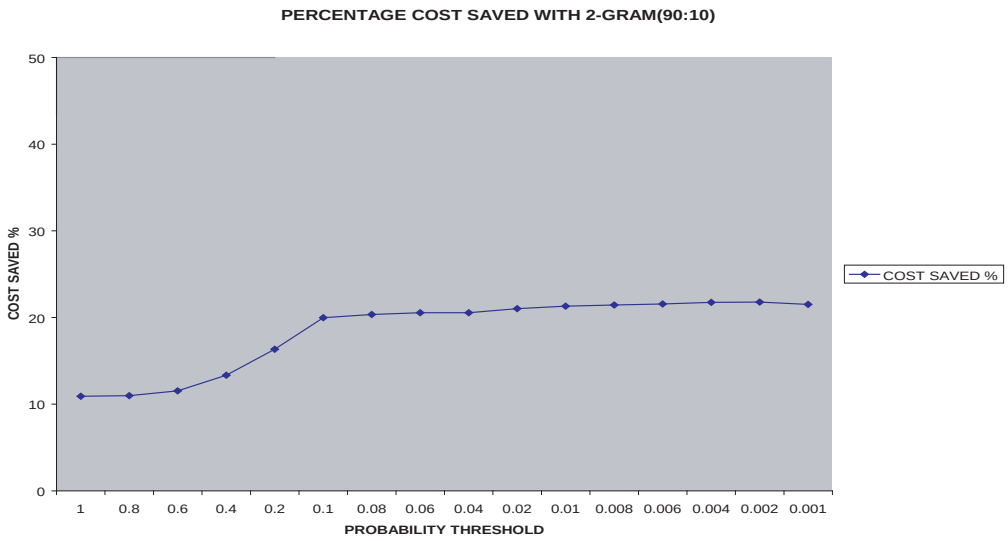

high correlation of these two measures. In the rest of this section, only the results for percentage of average cost saved are presented.

As shown in Figure 4, the percentage of average cost saved is not affected by depth bound except when it increases from 1 to 2. Just like MINPATH, MINCOST is more sensitive to probability threshold than depth bound. Depth bound has a larger impact when the probability threshold is large. However, for most reasonable probability

Figure 4. Percentage of average cost saved vs. depth bound

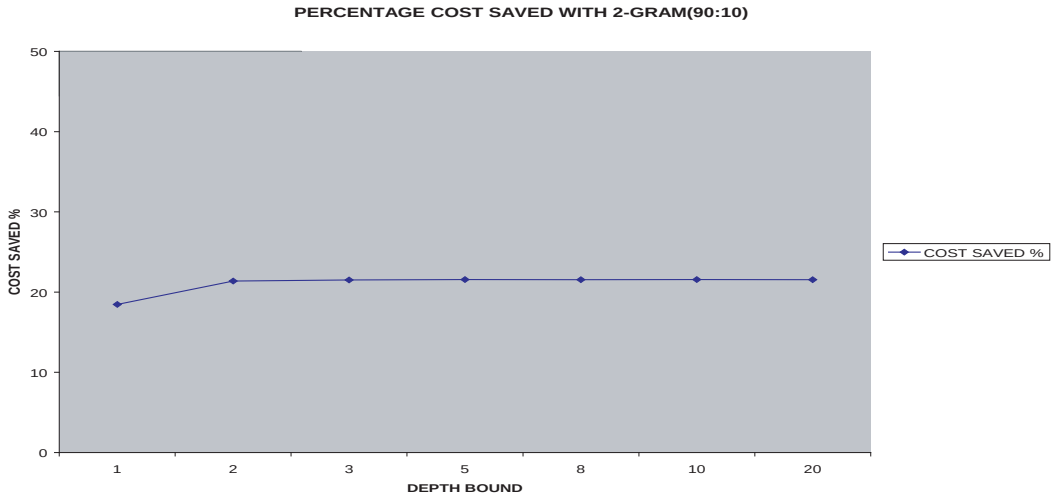

Figure 5. Percentage of average cost saved vs. number of shortcuts recommended

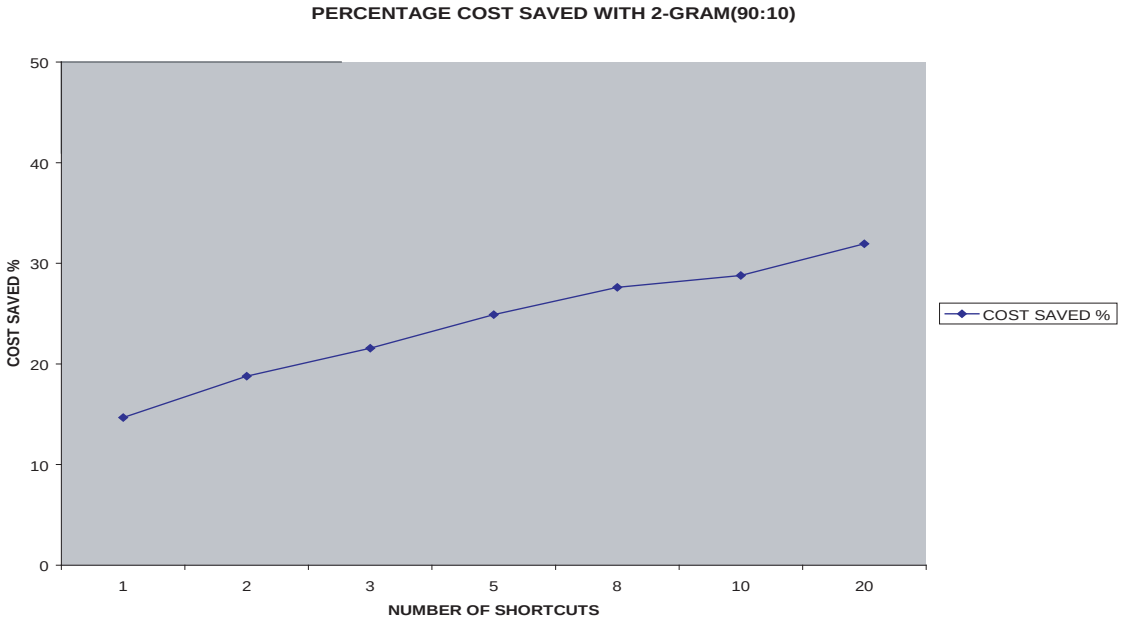

Figure 6. Percentage of average cost saved vs. N

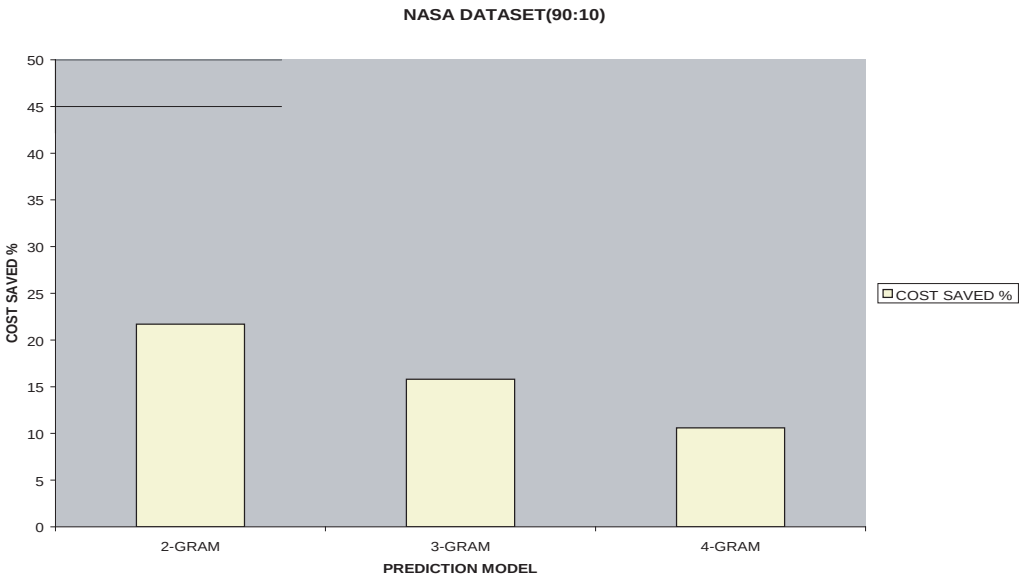

thresholds, depth bound's effect is overshadowed by that of probability threshold.

As expected, the percentage of average cost saved increases with the number of shortcuts recommended by MINCOST, as shown in Figure 5. The increase in percentage of average cost saved is especially significant when the number of shortcuts increases from 1 to 2 and 2 to 3. However, the increase is much smaller for larger numbers of shortcuts, for example, when the number of shortcuts increases from 10 to 20. More importantly, it is not possible to display many shortcuts due to screen size limitations of mobile devices. We select a default value of 3 even though it does not provide the maximum savings. Besides, too many shortcuts may confuse users.

From Figure 6 we see that the percentage of average cost saved decreases with N. We conclude that best results are obtained with the 2-gram model. This is somewhat surprising. As discussed in Section 3.2, N-gram model's accuracy increases with N. The explanation for Figure 6 is that as N increases, N-grams become less applicable, i.e., fewer predictions are available for a given prefix, which results in fewer shortcuts.

Observations and Discussions

The percentage of average cost saved ranges from 19.4% to 23.0% for the NASA dataset and from 9.6% to 37.1% for the EPA dataset. The number of shortcuts recommended has the biggest impact among the parameters followed by the probability threshold, while depth bound has little impact. The best prediction model is the 2-gram model followed by 3-gram model and 4-gram model.

These results are comparable to results from the MINPATH algorithm with N-gram model.

Moreover, the percentage of savings are comparable to these reported by Anderson et al., (2001), though a different data set was used. This demonstrates that N-gram models work as well as other models.

CONCLUSIONS AND FUTURE WORK

In this article, we proposed to use a simple prediction model, N-gram, for improving mobile Web navigation. Our approach is implemented and experimented with two real datasets. Experimental results show that N-gram is as effective as more complex models used in other research in predicting useful shortcuts. An interesting finding is that 2-gram works better than 3-gram and 4-gram in predicting useful shortcut. Higher order N-grams require more training and are less applicable.

In the future, we plan to use mixed N-gram models as a prediction model. Multiple N-gram models of various N used simultaneously for suggesting the best shortcuts.

It will also be interesting to mix Web content mining and Web usage mining techniques. For example, the destination page of a session is predicted by looking at current browsing sequence as well as its contents.

Another interesting research topic is to compare N-gram models with models that learn from their errors such as neural networks.

Chapter 7.29
A Study on the Performance of IPv6-Based Mobility Protocols:
Mobile IPv6 vs. Hierarchical Mobile IPv6

ABSTRACT

The performance of IP mobility protocols is highly dependent on the change of mobile nodes' (MNs') mobility and traffic-related characteristics. Therefore, it is essential to investigate the effects of these characteristics and to conduct an in-depth performance study of these protocols. In this paper, we introduce a novel analytical approach using a continuous-time Markov chain model and hierarchical network model for the performance analysis of IPv6 mobility protocols: Mobile IPv6 (MIPv6) and Hierarchical Mobile IPv6 (HMIPv6). According to these analytical models, we derive the location update costs (i.e., binding update costs plus binding renewal costs), packet tunneling costs, and total signaling costs, which are generated by an MN during its average domain residence time, when MIPv6 or HMIPv6 is deployed under the same network architecture, respectively. In addition, based on these derived costs, we investigate the effects of various parameters, such as the average speed of an MN, binding lifetime period, the ratio of the network scale, and packet arrival rate, on the signaling costs generated by an MN under MIPv6 and HMIPv6. Moreover, we conduct the performance comparison between these two protocols by showing the relative total signaling costs under the various conditions. The analytical results show that as the average speed of an MN gets higher and the binding lifetime period is set to the larger value or as its packet arrival rate gets lower, the total signaling cost generated by an MN during its average domain residence time under HMIPv6 will get relatively lower than that under

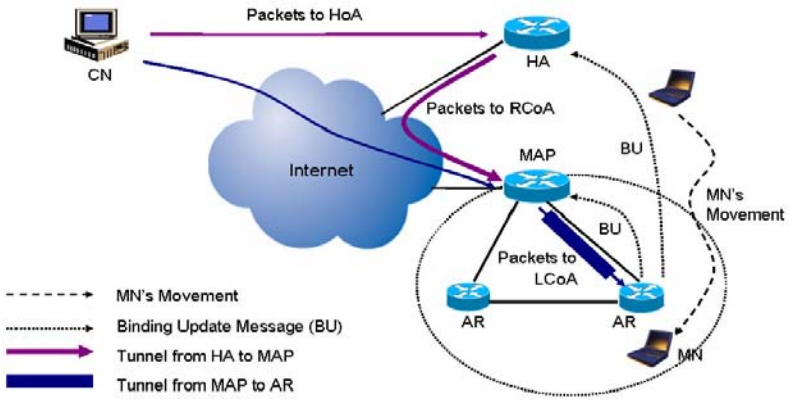
MIPv6, and that under the reverse conditions, the total signaling cost under MIPv6 will get relatively lower than that under HMIPv6.

INTRODUCTION

The demand for anywhere, anytime high-speed Internet access has been a driving force for the increasing growth and advances in wireless/mobile communication and portable devices. As a consequence, these trends have prompted research into mobility support in networking protocols. The IETF Mobile IP working group has proposed Mobile IPv4 (MIPv4) (Perkins, 1997, 2002) as a main protocol for supporting IP mobility. However, MIPv4 has some problems, such as triangle routing, security, and limited IP address space. Thus, based on the next generation Internet protocol, IPv6, Mobile IPv6 (MIPv6) (Johnson, 2004) has been developed by the IETF with new functionalities. In MIPv6, when a mobile node (MN) moves from one subnet to another, it acquires a care-of-address (CoA) by stateless address autoconfiguration (Johnson, 2004). After configuring the CoA, the MN registers the association between the CoA and its home address (HoA) by sending a binding update (BU) message to its home agent (HA) or correspondent node (CN). Although MIPv6 solves some drawbacks addressed in MIPv4, it still has a problem, nevertheless. That is, MIPv6 handles local mobility of an MN in the same way as it handles global mobility. As a result, an MN sends the BU message to its HA and its CN each time it changes its point of attachment, regardless of locality. Such an approach may cause excessive signaling traffic, especially for MNs with relatively high mobility or long distance to their HAs or CNs. In addition, this approach is not scalable, since the signaling traffic generated by the MNs can become quite overwhelming as the number of the MNs increases. In order to overcome these drawbacks, Hierarchical Mobile IPv6 (HMIPv6) (Castelluccia, 2000; Soliman, 2004) has been proposed to accommodate frequent mobility of the MNs and to reduce the signaling load in the backbone networks. In addition, handoff performance may be improved by reducing handoff latency. HMIPv6 introduces a new entity, the mobility anchor point (MAP), which works as a proxy for the HA in a foreign network. When an MN moves into a network controlled by a new MAP, it configures two CoAs: a regional care-of-address (RCoA) and an on-link care-of-address (LCoA). The RCoA is an address on the MAP's subnet, whereas the LCoA is an address configured to the MN's current point of attachment. Figure 1 shows the basic operation of HMIPv6. When the MN first enters a MAP domain, it sends the BU message to the MAP, the HA, and, potentially, to the CNs. When an MN changes the subnets within a same MAP domain, it only sends the BU message to the MAP. In other words, if the MN changes its current LCoA within a MAP domain, it only needs to register its LCoA with the MAP. The RCoA does not change, as long as the MN moves within the same MAP domain. This makes the MN's mobility transparent to the HA and the CNs. However, this does not imply any change to the periodic binding renewal (BR) message that an MN has to send to the HA and the CN, and now an MN additionally should send it to the MAP. In addition, since the MAP acts as a local HA, it receives all packets on behalf of the MNs that it is serving and tunnels the received packets to the MN's current LcoA.

Generally, the performance of IP mobility protocols may vary widely, depending on the change of MNs' mobility and traffic-related characteristics (Campbell, 2002). Our previous work on HMIPv6 (Kong, 2004) also revealed that such characteristics are the crucial factors that significantly may affect the signaling load on the Internet. Therefore, it is essential to analyze and evaluate the IP mobility protocols under various conditions, and more in-depth study on these protocols should be considered as the first step

Figure 1. Hierarchical Mobile IPv6



to design a more efficient IP mobility management scheme.

The remainder of this paper is organized as follows. In the second section, we briefly describe the existing works on the performance analysis of IP mobility protocols. In the third section, we introduce the user mobility model and network model for the performance analysis of IP mobility protocols. Then, the various cost functions under MIPv6 and HMIPv6 are analytically derived. In the fourth section, we investigate the results of the third section by applying the various numerical examples. Finally, conclusion and future work are given in the fifth section.

RELATED WORK

Although a lot of researches for the performance analysis of IP mobility protocols have been proposed, most of them, have been simulation-based approaches. Recently, several analytical approaches for IP mobility protocols have been proposed. This section focuses on describing the existing works on the analytical approaches for the performance analysis of IP mobility protocols.

In terms of performance analysis of HMIPv6, there is some difference between the work in Castelluccia et al. (2000) and our work. Castelluccia et al. (2000) presented a hierarchical mobility architecture that separates local mobility and global mobility for the mobility management that is hierarchical, flexible, and scalable. But they focused mainly on evaluating the signaling bandwidth according to the BU emission frequency. As already introduced and studied in location management for PCS networks (Akyildiz, 1999), in order to evaluate the efficiency of IP mobility management protocol, the tradeoff relationship between the location update cost and the packet tunneling cost has to be taken into consideration in terms of the total signaling cost (Xie, 2002). Nevertheless, in Castelluccia et al. (2000), they did not consider the signaling overhead generated by the packet tunneling. Moreover, when the network administrators or designers consider the deployment of either MIPv6 or HMIPv6, they should understand fully how various mobility and traffic-related parameters may have an effect on the overall system performance. While the work in Castelluccia et al. (2000) made a good contribution toward introducing a new IP mobil-

ity protocol, they just showed few of the effects and relations of the various mobility and traffic related parameters.

Woo (2003) investigated the performance of MIPv4 regional registration. The performance measures used were registration delay and the CPU processing overheads loaded on the agents to handle mobility of the MNs. Through the investigation, the effectiveness of adopting MIPv4 regional registration in the wide-area wireless network in terms of reducing the CPU processing overheads on the HA and lowering the signaling delay was observed.

Costa et al. (2002) compared the handover latency resulting from the handover procedures in MIPv6, FMIPv6, and HMIPv6. They conducted that the best option to get better performance was to implement both HMIPv6 and FMIPv6. In this work, they computed handover latency based on the length of the path among the MN, the HA, and the CN.

Pack et al. (2003) proposed an analytic model for the performance analysis of HMIPv6 in IP-based cellular networks, which is based on the random walk mobility model. Based on this model, they formulated location update cost and packet delivery cost. Then, they analyzed the impact of cell residence time on the location update cost and the impact of user population on the packet delivery cost. Although their analytical model is well-defined, they did not take the periodic BR and the effect of binding lifetime period into account, which may have a significant effect on the total signaling cost. In addition, their analysis was only investigated on the performance of HMIPv6, and their analysis about the packet delivery cost under HMIPv6 is not likely to be the pure extra signaling bandwidth consumption generated by the packet tunneling but the network bandwidth consumption, including the data traffic as well as the signaling traffic.

However, from the viewpoint of IP mobility management, the consideration of the extra signaling bandwidth consumption (not including the data traffic) generated during the processes of the location update and the packet tunneling should be taken into account (Xie, 2002).

In contrast to the related literature mentioned, we perform in-depth analysis and more integrated comparison between MIPv6 and HMIPv6 in terms of the total signaling cost. Moreover, while the previous analyses did not consider either the periodic BR or the extra packet tunneling, our work considers both of them for the analysis. Also, we present a novel analytical approach based on a continuous-time Markov chain and a simplistic hierarchical network model. Based on these models, we analytically derive the binding update cost, binding renewal cost, packet tunneling cost, and total signaling cost generated by an MN during its average domain residence time under MIPv6 and HMIPv6. Then, based on these derived costs, we investigate the effects of various mobility and traffic-related parameters on these costs. In addition, we conduct the performance comparison between MIPv6 and HMIPv6, and evaluate the conditions where the performance gain between the two protocols is larger or smaller in terms of the total signaling cost. The aim of this paper is not to determine which protocol performs better but to evaluate the performance that can be expected for each protocol, broaden our understanding of the various parameters that influence the performance, and help in the network design decision.

ANALYTICAL FRAMEWORK FOR THE ANALYSIS OF IPv6-BASED MOBILITY PROTOCOLS

First, we introduce our user mobility and network models to evaluate the performance of MIPv6 and HMIPv6. Then, for the analysis, we analytically derive the various cost functions under MIPv6 and HMIPv6.

User Mobility Model

Figure 2 indicates a state transition diagram of a continuous-time Markov chain model, which describes the BU process of an MN. The state of a continuous-time Markov chain, i ($i \geq 0$), is defined as the number of subnets where an MN has stayed within the given domain. Also, state *0* represents that the MN stays outside of the given domain. The state transition $a_{i,i+1}$ ($i \geq 1$) represents an MN's movement rate to an adjacent subnet within the given domain, and the state transition $a_{0,1}$ represents an MN's movement rate to a subnet within a given domain from another domain. On the other hand, $b_{i,0}$ ($i \geq 1$) represents an MN's movement rate to another domain from a given domain. In addition, for the analysis of the signaling costs generated by an MN during its average domain residence time, we assume that an MN moves out of a given domain within the maximum of finite K movements.

On the other hand, in order to obtain an MN's movement rates, we assume a fluid flow mobility model (Baumann, 1994). The model assumes that the MNs are moving at an average speed of v, and their movement direction is uniformly distributed over $[0, 2\pi]$, and that all the subnets are of the same rectangular shape and size and form together a contiguous area. The parameters used for the analysis of an MN's movement rates are summarized as follows.

- γ : The movement rate for an MN out of a subnet
- λ : The movement rate for an MN out of a subnet within the given domain
- μ : The movement rate for an MN out of domain

According to Baumann (1994), the movement rate γ for an MN out of a subnet is derived as

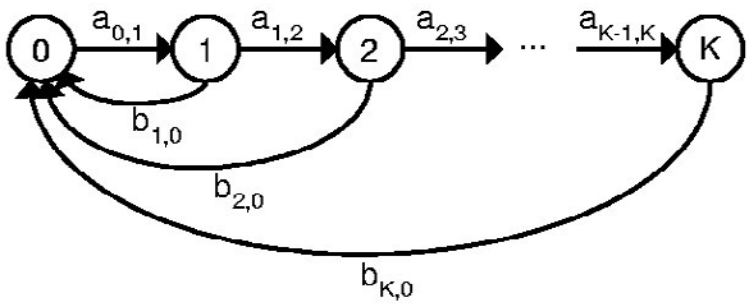
$$\gamma = \frac{4v}{\pi\sqrt{S}} \tag{1}$$

where S is the subnet area. We assume that a domain is composed of N equally subnets. Therefore, the movement rate μ for an MN out of a domain is

$$\mu = \frac{4v}{\pi\sqrt{NS}} \tag{2}$$

Note that an MN that moves out of a domain also will move out of a subnet. So, the movement

Figure 2. State transition diagram of a continuous-time Markov chain



rate λ for an MN out of a subnet within the given domain is obtained from Equations (1) and (2):

$$\lambda = \gamma - \mu = (1 - \frac{1}{\sqrt{N}})\gamma \tag{3}$$

Therefore, in Figure 2, we get $a_{i,i+1} (i \geq 1) = \lambda$ and $a_{0,1} = b_{i,0} = \mu$, respectively.

On the other hand, we assume π_i to be the equilibrium probability of state *i*. Thus, we can obtain the following equations from state transition diagram shown in Figure 2.

$$\mu\pi_0 = \mu(\pi_1 + \pi_2 + ... + \pi_K) \tag{4}$$

$$\mu\pi_{i-1} = (\lambda + \mu)\pi_i, \qquad i = 1 \tag{5}$$

$$\lambda\pi_i = (\lambda + \mu)\pi_{i+1}, \qquad 2 \leq i \leq K - 1 \tag{6}$$

$$\lambda\pi_{i-1} = \mu\pi_i, \qquad i = K \tag{7}$$

On the other hand, by the law of total probability, the sum of the probabilities of all states is 1. Thus,

$$\pi_0 + \pi_1 + \pi_2 + \cdots + \pi_K = \sum_{i=0}^{K} \pi_i = 1 \tag{8}$$

By substituting Equation (8) into Equation (4), we can obtain the equilibrium probability of state *0*, π_0. Thus,

$$\pi_0 = \frac{1}{2} \tag{9}$$

Finally, using Equations (5), (6), (7), and (9), π_i can be expressed as

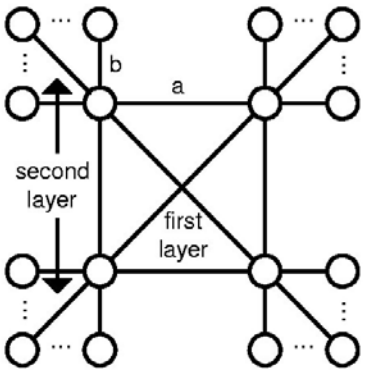
$$\pi_i = \begin{cases} \frac{1}{2} & if \quad i = 0 \\ \frac{1}{2}(\frac{\mu}{\lambda+\mu})(\frac{\lambda}{\lambda+\mu})^{i-1} & if \quad 1 \leq i \leq K-1 \\ \frac{1}{2}(\frac{\lambda}{\lambda+\mu})^{i-1} & if \quad i = K \end{cases} \tag{10}$$

Network Model

Similar to Ihara (2000), we assume a simplistic two-layer hierarchical network model given in Figure 3. The first layer has a mesh topology, which consists of *M* nodes. Each first layer node is a root of a *N*-ary tree with depth of 1. We assume that the HA and the access routers (ARs) are all second layer nodes, and that each domain is composed of all the second layer nodes under the same first layer node. For simplicity, the CN, MN, and HA are assumed to be located in the different domain. Also, we define the domain size *(N)* as the number of all the second layer nodes under the same first layer node. For the performance analysis of the two protocols under the same network architecture, we assume that when HMIPv6 is considered, the functionality of the MAP is placed on the first layer node. In this model, the link hops between the first layer nodes is *a*, and the link hops between the first and second layer nodes in the same domain is *b*, respectively. On the other hand, we assume that the link hop between the CN and the CN's default AR is zero. We also do not consider the transmission cost over the wireless link.

By adjusting the ratio of the network scale in the network model shown in Figure 3, we can investigate the effects of the distance among the CN, the HA, and the MN. Let the ratio of the network scale *(r)* be $0.1 < r = b/a < 1$, and $b = 3$ are assumed. Thus, the large value of *r* means that the MN is located close to the HA or the CN, and

Figure 3. Two-layer hierarchical network mode



the small value of *r* means that the MN is located far away from the HA or the CN.

Cost Analysis

According to our user mobility and network models given in the previous subsections, we analytically derive the location update costs (i.e., the binding update costs plus binding renewal costs), packet tunneling costs, and total signaling costs generated by an MN during its average domain residence time under MIPv6 and HMIPv6. There are two kinds of BU messages under MIPv6 and HMIPv6. That is, the one occurs from an MN's subnet crossing, and the other occurs when the binding is about to expire. In this paper, we use *binding update (BU) message* to refer to the former, and *binding renewal (BR) message* to refer to the latter in order to differentiate these two kinds of binding related messages. Also, we use *BAck message* to refer to the binding acknowledgment message from the HA or the MAP.

For the analysis, several parameters and assumptions given in the previous subsections are used.

Hierarchical Mobile IPv6

Based on our mobility model given in the previous subsection, the average binding update cost under HMIPv6 (U_{Hmip}) can be derived as

$$U_{Hmip} = \pi_0 \times (U_m + U_h + \delta U_c) + (\Phi(K) - 1) \times U_m \quad (11)$$

where U_m, U_h, and U_c are the binding update costs to register with the MAP, the HA, and the CN under MIPv6 and HMIPv6, respectively. Based on our network model and assumptions given in the previous subsection, U_m, U_h, and U_c are expressed as $2S_{bu}b$, $2S_{bu}(a + 2b)$, and $S_{bu}(a + 2b)$, respectively. Here, S_{bu} represents the signaling bandwidth consumption generated by a BU/BR/BAck message. Note that the HA and the MAP must return BAck message to the MN. In addition, for simplicity, we assume that the binding related messages only are sent alone in a separate packet without being piggybacked and do not consider the BAck message from the CN.

On the other hand, $\Phi(K)$ means the average number of the subnets that an MN stays within a given domain, which is derived from the continuous-time Markov chain in Figure 2 and can be expressed as follows.

$$\Phi(K) = \pi_1 + 2\pi_2 + 3\pi_3 + \cdots + K\pi_K = \sum_{i=1}^{K} i\pi_i \quad (12)$$

On the other hand, for the calculation of the signaling costs generated by performing location update with the CNs, we roughly define the ratio of an MN's average binding time for the CNs to its average domain residence time δ as the following:

$$\delta = \frac{\sum_{i=1}^{n} C_i}{n\Delta} \quad (13)$$

where C_i represents the binding time for the *i*-th CN, which has been recorded in an MN's binding update list during its average domain residence time, and *n* means the number of all the CNs recorded in the MN's binding update list during its average domain residence time. Also, Δ means an MN's average domain residence time.

On the other hand, let the binding lifetime periods for the MAP, the HA, and the CN under HMIPv6 be T_m, T_h, and T_c, respectively. From Equations (1) and (2), an MN's average subnet residence time is derived as

$$\frac{\pi\sqrt{S}}{4v}.$$

Thus, the average rate of sending the BR message to the MAP under HMIPv6 while an MN stays in a subnet is

$$\lfloor\frac{\pi\sqrt{S}}{4vT_m}\rfloor.$$

Similarly, the average rates of sending the BR message to the HA and the CN under HMIPv6 during an MN's average domain residence time become

$$\lfloor\frac{\Phi(K)\pi\sqrt{S}}{4vT_h}\rfloor$$

and

$$\delta\times\lfloor\frac{\Phi(K)\pi\sqrt{S}}{4vT_c}\rfloor,$$

respectively. Consequently, the average binding renewal cost under HMIPv6 (R_{Hmip}) can be derived as follows.

$$R_{Hmip}=U_m\Phi(K)\times\lfloor\frac{\pi\sqrt{S}}{4vT_m}\rfloor+U_h\times\lfloor\frac{\Phi(K)\pi\sqrt{S}}{4vT_h}\rfloor+\delta U_c\times\lfloor\frac{\Phi(K)\pi\sqrt{S}}{4vT_c}\rfloor \quad (14)$$

Thus, the average location update cost under HMIPv6 (L_{Hmip}) generated by the binding related messages is

$$L_{Hmip} = U_{Hmip} + R_{Hmip} \quad (15)$$

Let the probability that the CN has a binding cache entry for an MN be *q*. Then, the average packet tunneling cost under HMIPv6 (T_{Hmip}) can be derived as follows.

$$T_{Hmip}=\frac{\Phi(K)\pi\sqrt{S}}{4v}\times p\times\{qD_{dir}+(1-q)D_{indir}\} \quad (16)$$

where *p* is the average packet arrival rate per hour for an MN. Also, D_{dir} and D_{indir} are the tunneling cost generated by a direct packet delivery (not intercepted by the HA) and the tunneling cost generated by delivering a packet routed indirectly through the HA under HMIPv6, respectively. According to our network model and assumptions, D_{dir} and D_{indir} can be derived as $S_{pt}b$ and S_{pt} (a + $2b$), respectively. Here, S_{pt} represents the additional signaling bandwidth consumption generated by tunneling per packet. Finally, the total signaling cost (C_{Hmip}) under HMIPv6 can be expressed as follows.

$$C_{Hmip} = L_{Hmip} + T_{Hmip} \quad (17)$$

Mobile IPv6

Similar to Equation (11), the average binding update cost under MIPv6 (U_{Mip}) can be derived as follows.

$$U_{Mip} = \pi_0 \times (U_h + \delta U_c) + (\Phi(K) - 1)\ (U_h + \delta U_c) \quad (18)$$

Table 1. Default parameter value

Parameter	Type	Value
N	Domain Size	64
S	Subnet Size	10 Km^2
T	Binding Lifetime	0.3 hour
v	An average speed of an MN	10 Km/hour
S_{bu}	The signaling bandwidth generated by a BU/BR/Back message	68 byte
S_{pt}	The signaling bandwidth generated by tunneling per packet	40 byte

Let the binding lifetime period for the HA and CN under MIPv6 be $\overline{T}_h$ and $\overline{T}_c$, respectively. Then, the average binding renewal cost under MIPv6 (R_{Mip}) can be derived as follows.

$$R_{Mip} = U_h \Phi(K) \times \lfloor \frac{\pi\sqrt{S}}{4v\overline{T}_h} \rfloor + \delta U_c \Phi(K) \times \lfloor \frac{\pi\sqrt{S}}{4v\overline{T}_c} \rfloor \quad (19)$$

Therefore, the average location update cost under MIPv6 (L_{Mip}) generated by the binding related messages is

$$L_{Mip} = U_{Mip} + R_{Mip} \quad (20)$$

On the other hand, the average packet tunneling cost in MIPv6 (T_{Mip}) can be derived as follows.

$$T_{Mip} = \frac{\Phi(K)\pi\sqrt{S}}{4v} \times p \times \{q\overline{D}_{dir} + (1-q)\overline{D}_{indir}\} \quad (21)$$

where $\overline{D}_{dir}$ and $\overline{D}_{indir}$ are the tunneling cost generated by a direct packet delivery and the tunneling cost generated by delivering a packet routed indirectly through the HA under MIPv6, respectively. According to our network model and assumptions, $\overline{D}_{dir}$ and $\overline{D}_{indir}$ can be derived as *0* and $S_{pt}b(a + 2b)$, respectively. Finally, the total signaling cost (C_{Mip}) under MIPv6 can be expressed as follows.

$$C_{Mip} = L_{Mip} + T_{Mip} \quad (22)$$

NUMERICAL RESULTS

In this section, we compare the performance of MIPv6 and HMIPv6 based on the various cost functions derived in the previous subsection. For the analysis, we first investigate the effects of various parameters, such as the average speed of an MN, binding lifetime period, ratio of the network scale, packet arrival rate, and the probability that the CN has a binding cache for an MN. Then, we evaluate the conditions where the performance gain between the two protocols is the largest or the smallest in terms of the total signaling cost. The performance measure used is the signaling bandwidth consumption per packet multiplied by the number of link hops that the packet traverses during an MN's average domain residence time (i.e., *bytes* × *number of link hops* / *average domain residence time*).

For the analysis, we set the default values of p, q, r, and δ to be 100, 0.7, 0.2, and 0.1, respectively. Also, we assumed that K is equal to the domain size, 64. The other default parameter values for the performance analysis are given in Table 1. Most parameters used in this analysis are set to typical values found in Woo (2003) and Ramjee (2002). The size of a BU/BR/BAck message is equal to the size of an IPv6 header (40 bytes) plus the size of a BU extension header (28 bytes), so 68 bytes (Castelluccia, 2000). In addition, the additional signaling bandwidth consumption generated by tunneling per packet is equal to the size of IPv6 header, so 40 bytes. According to Ihara (2000), the binding lifetime periods (i.e., $\overline{T_h}$, T_h, $\overline{T_c}$, T_c, and T_m) under MIPv6 and HMIPv6 are assumed to be all the same and denominated as T.

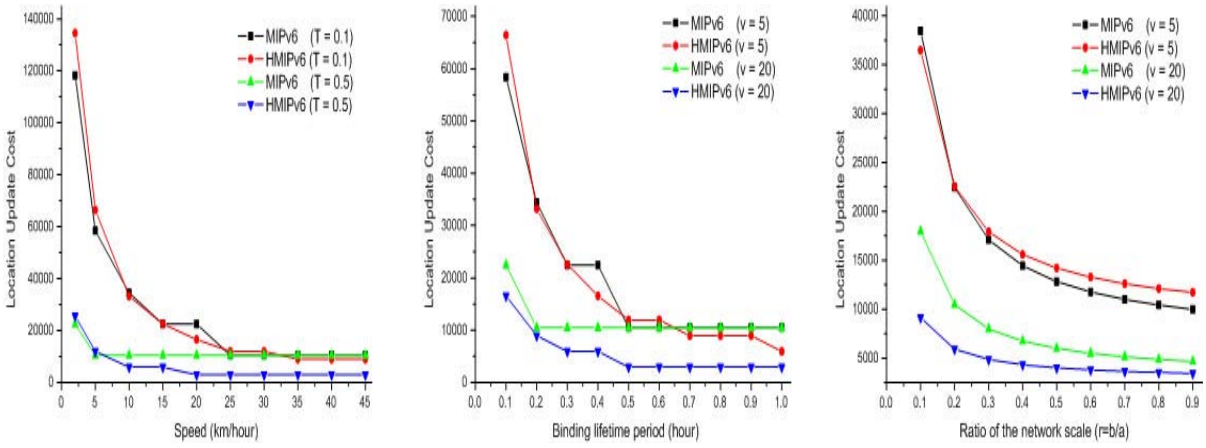
Analysis of Location Update Costs

Figure 4(a) indicates the effect of v on the average location update costs under MIPv6 and HMIPv6. As already mentioned, the location update cost consists of the binding update cost generated by an MN's mobility and the periodic binding renewal cost generated by the expiration of the binding lifetime period. The results presented in Figure 4(a) show that the location update costs under MIPv6 and HMIPv6 decrease as v increases. Also, this phenomenon gets larger as T is set to the larger value. When an MN is not moving fast, most of the signaling traffic is generated by the periodic BR messages. However, as the average speed of an MN increases, the number of the periodic BR messages decreases, and the BU messages generated by an MN's mobility dominate most of the signaling traffic. Note here that the location update cost under MIPv6 remains the same when v exceeds 5 km/hour for T = 0.5 hour in Figure 4(a). This is due to the fact that as the average speed of an MN increases, it moves to an adjacent subnet before the BR message occurs. In other words, that is the case that the average subnet residence time of an MN is shorter than the binding lifetime period. Therefore, when v exceeds 5 km/hour for T = 0.5 hour, the average location update cost is equal to the average binding update cost, and the average binding renewal cost is 0.

Figure 4(b) indicates the effects of T on the average location update costs under MIPv6 and HMIPv6. As shown in Figure 4(b), the average location update costs of the two protocols are decreased as T gets larger. The results shown in Figure 4(b) indicate that the binding lifetime period has a significant effect on the location update cost. Generally, the smaller the value of binding lifetime period is, the larger the binding renewal cost gets. Therefore, too much small value of binding lifetime period may result in significant signaling load throughout the networks. On the other hand, the larger the value of binding lifetime period is, the larger the binding cache entry size at the mobility agents gets. Thus, this may result in an increase of the binding cache lookup time and memory consumption at the mobility agents. In practice, the value of binding lifetime period must be specified in the implementation of MIPv6 and HMIPv6. Therefore, further study on the effects of binding lifetime period needs to be investigated to achieve the best performance.

Figure 4(c) indicates the effects of r on the average location update costs under MIPv6 and HMIPv6. Evaluating the ratio of the network scale enables the effect of the layer in which the HA or the CN is located or the effect of the network scales of each layer to be estimated. In Figure 4(c), the relationship $0.1 < r = b/a < 1$ and $b = 3$ are assumed to hold. Thus, the large value of r means that the MN is located close to the HA or the CN, and the small value of r means that the MN is located far away from the HA or the CN. As shown in Figure 4(c), the cost gain of HMIPv6 over MIPv6 gets larger as r decreases. However, for v = 5 km/hour, as r increases, the gain of MIPv6 over HMIPv6 gets larger. When v is fixed, an increase of r results in the relative reduction of

Figure 4. Analysis of location update costs: (a) Effects of v (top left), (b) Effects of T (top right), and (c) Effects of r (bottom)



(a) *(b)* *(c)*

the gain of HMIPv6, and thus, the gain of MIPv6 relatively increases. This phenomenon becomes more prominent as *v* decreases.

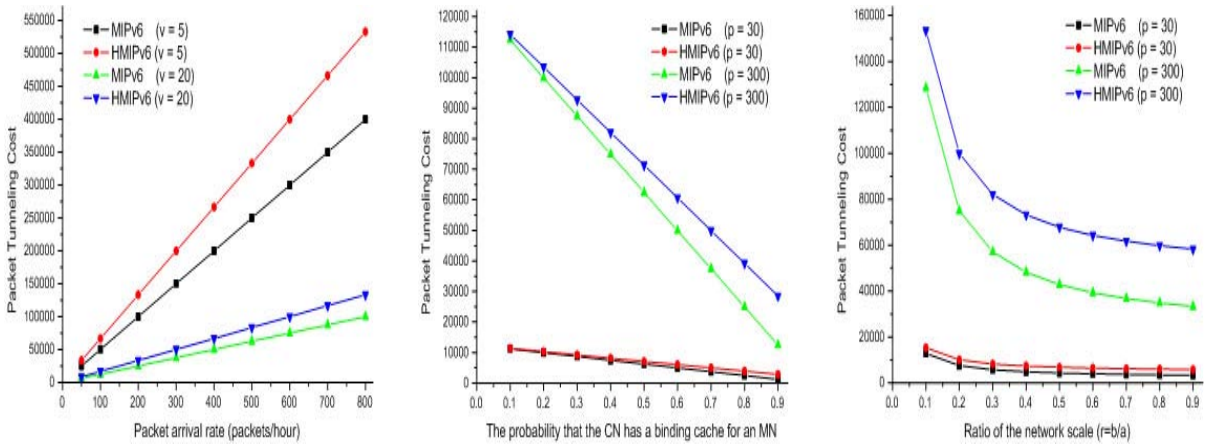
Analysis of Packet Tunneling Costs

Figure 5(a) indicates the effects of *p* on the average packet tunneling costs under MIPv6 and HMIPv6. The results shown in Figure 5(a) indicate that the packet tunneling costs are linearly increased as *p* increases. Figure 5(a) also indicates that a slowly moving MN is more affected by the packet arrival rate when the packet arrival rate is fixed. This is due to the fact that the average domain residence time of a slowly moving MN is longer than that of a fast moving MN, and thus, the packet tunneling cost of a slowly moving MN is larger than that of a fast moving MN. Also, the cost gap between the MIPv6 and HMIPv6 is due to the additional packet tunneling from the MAP to the AR under HMIPv6.

Figure 5(b) indicates the effects of *q* on the average packet tunneling costs. The results shown in Figure 5(b) indicate that the packet tunneling costs are linearly decreased as *q* increases. This is due to the fact that as *q* increases, the number of packets routed indirectly through the HA to the MAP decreases. In addition, the cost gap between the two protocols is due to the additional packet tunneling from the MAP to the AR under HMIPv6, and this gap increases as *q* does. Note that the cost gap occurs only from the difference between D_{dir} and $\overline{D}_{dir}$, and that D_{indir} and $\overline{D}_{indir}$ do not affect the cost gap between the two protocols (refer to the third section).

Figure 5(c) indicates the effects of *r* on the average packet tunneling costs. The results shown in Figures 5(b) and (c) indicate that when the packet arrival rate is low, the costs of the two protocols are almost the same, since the additional packet tunneling at the MAP is relatively negligible. In

Figure 5. Analysis of packet tunneling costs: (a) Effects of p (top left), (b) Effects of q (top right), and (c) Effects of r (bottom)



(a) *(b)* *(c)*

contrast, when the packet arrival rate is high, the cost gap gets larger.

Analysis of Total Signaling Costs

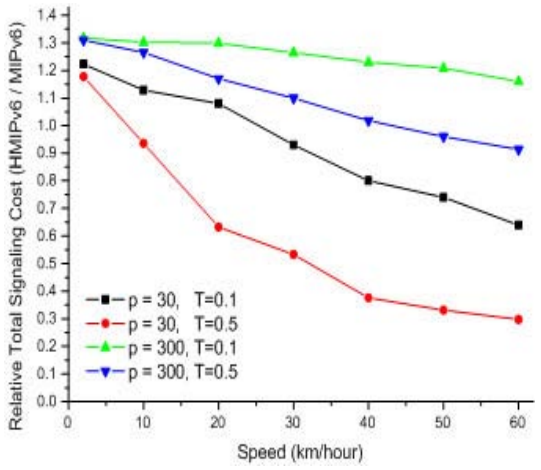
In this subsection, we evaluate the total signaling cost gain between MIPv6 and HMIPv6 by comparing the relative total signaling costs of the two protocols under the four parameter sets given in Table 2. This evaluation is investigated to show the variation in the relative total signaling costs of MIPv6 and HMIPv6 according to the change of *v*, *p*, and *T*. For the analysis, we define the relative total signaling cost of HMIPv6 as the ratio of the total signaling cost under HMIPv6 to that under MIPv6. Therefore, a relative total signaling cost of 1 means that the total signaling costs under the two protocols are exactly the same. As already mentioned, in order to evaluate the efficiency of IP mobility management protocols, the tradeoff relationship between the location update cost and the packet tunneling cost has to be taken into consideration (Xie, 2002). In this subsection, we will show the efficiency of MIPv6 and HMIPv6 by comparing the relative total signaling costs of the two protocols under the four parameter sets given in Table 2.

Figure 6 indicates the following several facts: As *v* decreases, the signaling cost gain of MIPv6

Table 2. Parameter set

set	*p*	*T*
1	30	0.1 hour
2	30	0.5 hour
3	300	0.1 hour
4	300	0.5 hour

Figure 6. Analysis of relative total signaling costs



over HMIPv6 gets larger, and this trends go into the reverse as *v* increases. In addition, under the same value of *v*, the cost gain of MIPv6 over HMIPv6 gets larger as *p* increases or as *T* is set to the smaller value. HMIPv6 aims to reduce the number of the BU messages in the backbone network by using the MAP. However, this does not imply any change to the periodic BR messages that an MN has to send to the HA and the CN, and the MN rather should send it to the MAP additionally. In addition, since the MAP acts as a local HA in HMIPv6, it receives all packets on behalf of the MNs it is serving and should tunnel the received packets to the MN. In other words, from the viewpoint of the signaling bandwidth consumption inside the domain, the signaling bandwidth consumption inside domain under HMIPv6 is generally larger than that under MIPv6, because of the additional periodic BR messages to the MAP and the packet tunneling at the MAP. In addition, this phenomenon becomes more prominent as an MN stays for a considerable time within a domain (i.e., when *v* is very small) or the incoming packet arrival rate is high. This is due to the fact that the domain residence time and packet arrival rate are proportional to the binding renewal cost and packet tunneling cost, respectively. These are the reasons why the gain of MIPv6 over HMIPv6 gets larger as *v* and *T* decrease or *p* increases. On the other hand, the cost gain of HMIPv6 over MIPv6 gets larger as *v* increases, and this phenomenon becomes more prominent as *p* decreases or as *T* is set to the larger value. The results shown in Figure 6 verify these facts. Note that when *v* is greater than or equal to 7 km/hour in Figure 6, the parameter set 2 is the case where the gain of HMIPv6 over MIPv6 is the largest under the four parameter sets, and the parameter set 3 is the case where the gain of MIPv6 over HMIPv6 is the largest, as shown in Figure 6.

CONCLUSION AND FUTURE WORK

In this paper, we proposed a novel analytical approach for the performance analysis of IPv6 mobility protocols. In order to evaluate the signaling load of the two protocols, we designed a user mobility model and network model. Then, based on these two models, we analytically derived the location update costs, packet tunneling costs, and total signaling costs generated by an MN during its average domain residence time under MIPv6 and HMIPv6. In addition, we investigated the effects of various mobility and traffic-related parameters on each derived costs. The analytical results provide a deep understanding of the overall performance of MIPv6 and HMIPv6, and demonstrate that as the average speed of an MN gets higher and the binding lifetime period is set to the larger value, or as its packet arrival rate gets lower, the total signaling cost generated by an MN during its average domain residence time under HMIPv6 will get relatively lower than that under MIPv6, and that under the reverse conditions, the total

signaling cost under MIPv6 will get relatively lower than that under HMIPv6.

Our future research directions are as follows. First, we intend to extend our analytical performance study to the other protocols, such as Fast Handovers for MIPv6 (FMIPv6) and Fast Handovers for HMIPv6 (FHMIPv6). Second, based on the modeling technique and results shown in this paper, we will focus on designing the adaptive mobility management scheme that enables an MN to selectively switch its mobility management scheme in HMIPv6 networks in order to minimize the total signaling cost according to its mobility/traffic history (Kong, 2005), and these works are underway.

Chapter 7.30
A Novel Fuzzy Scheduler for Mobile Ad Hoc Networks

S. Shanmugavel
Anna University, India

C. Gomathy
Deemed University, India

ABSTRACT

As mobile computing gains popularity, the need for ad hoc routing also continues to grow. In mobile ad hoc networks, the mobility of nodes and error prone nature of the wireless medium pose many challenges, including frequent route changes and packet losses. Such problems increase the packet delays and decrease the throughput. To meet with the dynamic queuing behaviour of Ad hoc networks, to provide QoS and hence to improve the performance, a scheduler can be used. This chapter presents a novel fuzzy based priority scheduler for mobile ad-hoc networks, to determine the priority of the packets. The performance of this scheduler is studied using GloMoSim and evaluated in terms of quantitative metrics such as packet delivery ratio, average end-to-end delay and throughput.

INTRODUCTION

A mobile ad hoc network is a cooperative engagement of mobile hosts or routers connected by wireless links. In the performance evaluation of a protocol, for an ad hoc network, the protocol should be tested under realistic conditions with representative data traffic models and realistic movement of mobile users. In order to thoroughly simulate a new protocol for an ad hoc network, it is very essential to use a mobility model that accurately represents the mobile nodes (MNs). MNs within an ad hoc network move from location to location. A mobility model should attempt to mimic the movements of the real MNs. Currently, there are two types of mobility models used in simulations of ad hoc networks: traces and synthetic models (Camp, Boleng, & Davies, 2002; Lin, Noubir, & Rajaraman, 2004). Traces are those mobility patterns that are observed in real-life systems.

Traces provide accurate information when they involve a large number of participants and a long observation period, but privacy issues will prohibit the collection and distribution of such statistics, and new environments cannot be easily modeled. Hence, in these situations, synthetic models are used. They realistically represent MNs without the use of traces. We consider here three of the synthetic models—namely, random walk, random way point, and random direction mobility models (Bettsetter, 2001).

The random walk mobility model is a widely used mobility model and, in this, the current speed and direction of MN is independent of its past speed and direction. It has a memory-less mobility pattern, because it retains no knowledge containing its past location and speed values. Here, we encounter unrealistic generation of movements such as sudden stopping, sharp turning, and completely random wandering.

The random waypoint mobility model includes pause times between changes in direction and speed. An MN begins by staying in one location for a certain period of time (Jardosh, 2003; Camp et al., 2002). Once this time expires, the MN chooses a random destination in the simulation area and a speed that is uniformly distributed between minspeed and maxspeed. The MN then travels towards the newly chosen destination at the selected speed. Upon arrival, the MN pauses for a specified time period before starting the process again. This is also a widely used model. The RWP model is similar to the random walk model if pause time is zero.

The random direction mobility model is a revised version of random walk, and it ensures that every node is assigned the same speed throughout the entire simulation. After a random direction is chosen in the range 0 to 2π, an MN begins moving. If the MN reaches a grid boundary, it bounces off the simulation border with an angle determined by the incoming direction. The MN then continues along this new path.

The choice of a mobility model can have a significant effect on the performance of an ad hoc network protocol. The performance of random walk, random waypoint, and random direction mobility models are compared. Dynamic source routing (DSR) protocol is chosen to be the routing protocol (Royer & Toh, 1999; Das, Castaneda, Yan, & Sengupta, 1998; Das, Perkins, & Royer, 2001). It determines the routes on demand. Here, the packet carries the full route that the packet should be able to traverse in its header.

DSR is chosen since it performs well in many performance evaluations of unicast protocols.

The performance metrics—namely, packet delivery ratio, end-to-end delay, average hop count, and protocol overhead—are used for comparison of these mobility models. The results prove that the random waypoint mobility model has the highest packet delivery ratio, lowest end-to-end delay, and lowest hop count (Camp et al., 2002). The random direction mobility model has the highest average hop count, highest end-to-end delay, and lowest packet delivery ratio since each MN moves to the border of the simulation area before changing its direction. The performance of the random walk model falls between these two. Hence to conclude, the random waypoint mobility model is used in many prominent simulation studies of ad hoc network protocols since it is flexible and it creates realistic mobility patterns for the way people might move in.

Research in the area of ad hoc networks has focused mainly on the routing protocols that decide the routing of packets hop by hop as efficiently as possible and medium access control (MAC), which indicates how to share the medium efficiently. But there is little focus towards the queuing dynamics in the nodes of the networks and on the effects scheduling algorithms in the queues of the nodes. Hence, we believe that choice of scheduling algorithm will certainly improve the performance of the ad hoc network. Here, the different scheduling algorithms and the network's

effect on mobile communication with the random waypoint mobility model are discussed.

We also design and analyze the performance of a fuzzy logic-based priority scheduler (FLPS), which combines the metrics and computes the crisp value of priority. The fuzzy algorithm for finding the priority of the packet based on some attributes of the packets is devised and coded in C language. The C code is linked with GloMoSim and is tested. It is found that the proposed fuzzy scheduler provides improved packet delivery ratio, reduced average end-to-end delay, and increased throughput when tested with various unicast routing protocols under different mobility conditions.

SCHEDULING ALGORITHMS

The ad hoc networks produce unique queuing dynamics due to the possible frequent transmission of control packets due to mobility, multi-hop forwarding of packets, and multiple roles of nodes as routers, sources, and sinks of data. The selection of the scheduling algorithms for mobile ad hoc networks is highly dependent on the queuing dynamics. These algorithms determine which queued packet to process next, and they have significant impact on the end-to-end performance. A scheduler for an ad hoc network is required to schedule the packets to reach the destination quickly, which are at the verge of expiry. The scheduler is positioned between the routing agent and the MAC layer. Without scheduling, packets will be processed in FIFO manner, and hence there are more chances that either more packets may be dropped or may not meet the quality of service (QoS) target.

Generally, in all algorithms, high priority is given to control packets. Different drop policies are used for data and control packets when the buffer is full. When the incoming packet is a data packet, the data packet is dropped. If it is a control packet, the last enqueued data packet is dropped. If all packets are control packets, the incoming control packet is dropped.

There are many scheduling algorithms proposed in literature. No priority scheduling services both control and data packet in FIFO order. Priority scheduling gives high priority to control packets, and data packets are serviced in FIFO order. When considering the effect of setting priorities to data packets, these schedulers give high priority to control packets (Chun & Baker, 2002). Their differences are in assigning priorities among data queues. Weighted hop and weighted distance scheduling methods use the distance metrics. Weighted hop scheduling gives higher weight to data packets that have fewer remaining hops to traverse. If the packet has fewer remaining hops, then it has to reach the destination quickly. The data packets can be stored in round-robin fashion. The remaining hops to traverse can be obtained from packet headers. In weighted distance scheduling, physical distance is used. It is also a weighted round-robin scheduler. It gives higher weight to data packets, which have shorter geographic distances. The remaining distance is the distance between a chosen next hop and a destination. Round-robin scheduling maintains per-flow queues. The flow can be identified by a source and destination pair. Here each flow queue is allowed to send one packet at a time in a round-robin fashion. In greedy scheduling scheme, each node sends its own data packets before forwarding those of other nodes (Luo, Lu, & Bhargavan, 2000). The other nodes' data packets are serviced in FIFO order. Two other schedulers are earliest deadline first (EDF) and virtual clock (VC) (Kanodia, Li, Sabharwal, Sadeghi, & Knightly, 2002). In EDF, a packet arriving at time t and having delay bound d has a deadline t + d. In virtual clock, a packet with size L of a flow with service rate r has priority index L/r plus the maximum of current time t and priority index of the flow's previous packet.

In these priority scheduling algorithms we considered, the parameters used to find the priority of packets are: remaining hops to traverse, remaining distance, per-flow queues, greediness of nodes, delay bound, and service rate. With the thorough study of ad hoc networks, and the above mentioned scheduling algorithms, it is found that a number of metrics can be combined into a single decision so as to find the crisp value of the priority of packets. Our solution to determine the priority index of the packets utilizes the fuzzy logic concept (Gomathy & Shanmugavel, 2004). It deals with the imprecise and uncertain information of the network parameters since ad hoc network is dynamic in nature. This is advantageous in the target system because the fuzzy logic system is flexible and capable of operating with imprecise data and hence can be used to model nonlinear functions with arbitrary complexity. The fuzzy inference process works in three stages: fuzzification, rule evaluation, and defuzzification. In the first stage the parameters of the system are fed into a fuzzifier, which transforms the real-time measurements into fuzzy sets. The second stage applies a set of fuzzy rules onto fuzzy input in order to compute fuzzy outputs. Finally, outputs are translated into crisp values.

QoS Provisioning

QoS provisioning is becoming a critical issue in designing wireless ad hoc networks due to the necessity of providing multimedia applications in such networks. These are typically delay sensitive and have high bandwidth requirements. It is a challenging task since the wireless channel is shared among adjacent hosts and network topology changes. Typical metrics for providing QoS include delay, loss rate bandwidth, and so forth. Here, in the design of scheduler, end-to-end delay and delivery ratio of packets are considered to analyze the performance of ad hoc networks and thus to provide QoS to the networks.

FUZZY LOGIC-BASED PRIORITY SCHEDULER (FLPS)

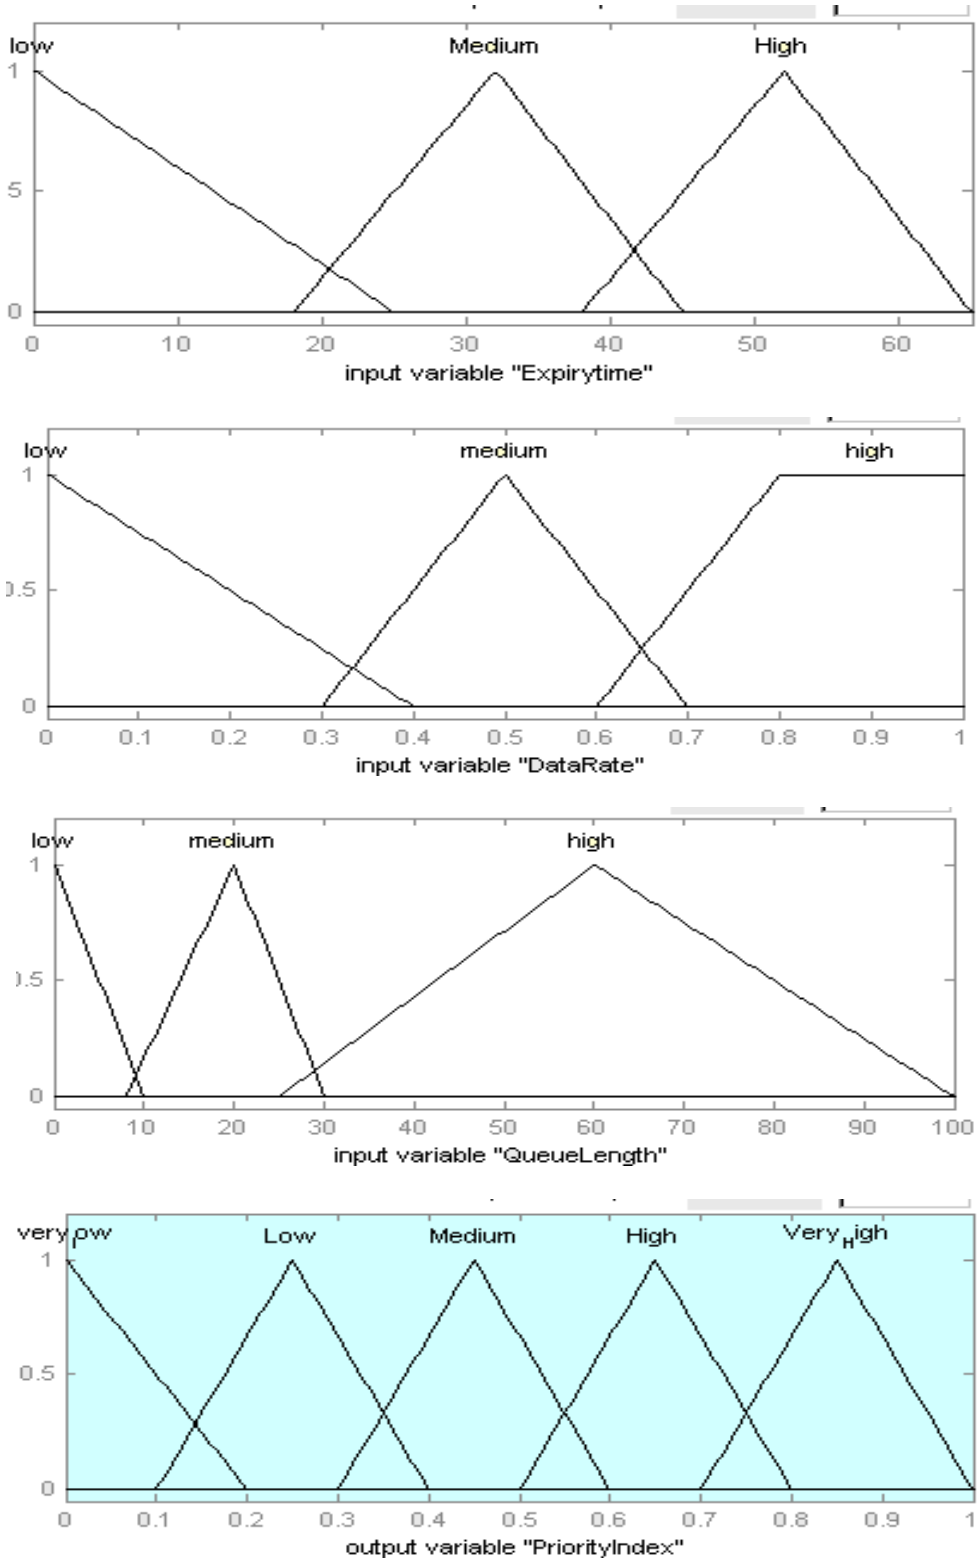
Fuzzy logic (FL) is a kind of artificial intelligence technology, which has the capability of mimicking how the field experts would make decisions. In networking area, there are a variety of traffic mixes, different traffic types, and long- and short-lived traffic flows. FL can incorporate networking expert knowledge to generate sensible solutions.

In order to improve the performance of scheduling algorithms, a mechanism using FL has been proposed to find the value of priority index of packets. The fuzzy logic-based priority scheduler aims to determine the priority index of data packets based on three input variables: data rate, expiry time of the packets, and queue length of the nodes. With these inputs, the fuzzification, rule evaluation, and defuzzification are performed. The following section describes the three processes.

Fuzzification

The three inputs are translated into fuzzy sets. The fuzzy sets contain elements that have a varying degree of membership in a set. Therefore, it is different from an ordinary set, where elements will only be considered as members of a class if they have full membership in that class. For example, if the expiry time is considered in an ordinary set, then it can only be either low or high and not both simultaneously, whereas in a fuzzy set, it can be classed as quite low, not so high, or medium and high. This indicates that the element in the fuzzy set can have membership in more that one set. The membership values are obtained by mapping the values obtained for a particular parameter onto a membership function, which will be used to determine the system outputs. This function is a curve or line that defines how each data or value is mapped onto a membership

Figure 1. Membership functions of input and output variables



value. We define here what are low L, medium M, and high H for each fuzzy set. Then by mapping the position of current input value onto the graph of the membership function, the input is allocated with a membership value in each set ranging from 0 to 1. Fuzzification of output parameter priority index is also performed, and five linguistic terms are attached to it. Figure 1 shows the membership function of the input and output variables for the FLPS.

Rule Evaluation

This stage involves feeding the fuzzy sets into an inference engine, where a set of fuzzy rules is applied. Fuzzy rules are usually defined as a set of possible scenarios in the form of if/then rules which determines the value of the priority index. Table 1 provides the summary of the decision-making logic. The first rule can be interpreted as: if the expiry time is low and data rate is low and queue length is low, then priority index is low. This indicates that, if expiry time of packets is low, it shows that packets are at the verge of expiry. And even if the data rate and number of packets in queue is low, the priority index is set to be low, so as to enable the packets to reach the destination quickly. The index value if very low indicates that packets are attached with high priority and will be scheduled immediately. If the index is very high, then packets are with lowest priority, and will be scheduled only after all high-priority packets are scheduled (Gomathy & Shanmugavel, 2004).

The rationale behind setting rules is that if the expiry time is low and both data rate and queue length are high, packets are attached with a very low priority index and hence possess high priority. Whereas if expiry time is high and both data rate and queue length are low, packets are attached

Table 1. Fuzzy rule base (D=data rate; Q=queue length)

Q D	L	M	H
Expiry Time – Low			
L	L	L	VL
M	VL	VL	VL
H	L	VL	VL
Expiry Time – Medium			
L	M	M	L
M	M	M	L
H	M	M	M
Expiry Time – High			
L	VH	VH	H
M	H	M	M
H	H	H	M

with higher priority index and hence possess low priority. These rules are then applied to fuzzy inputs and return the fuzzy outputs.

Defuzzification

At this stage the resultant fuzzy decision sets have to be converted into precise quantities. There exist several heuristic defuzzification methods such as max criterion, mean of maximum, and center of area or centroid method. In the FLPS, we consider the weighted average method of defuzzification to find the crisp output. The weighted average defuzzification technique can be expressed as:

$$x^* = \frac{\sum_i w_i m_i}{\sum_i w_i}$$

where x^* is the defuzzified output, m^i is the membership of the output of each rule, and w_i is the weight associated with each rule.

Example

Consider the scenario when the packets have an expiry time of 20 seconds, queue length of node the packet reaches is 50, and normalized data rate is 0.66 (normalized with respect to the channel capacity of 2 Mbps). For these set of inputs, the priority index is calculated as follows, which is done in three stages.

- **Fuzzification:** As seen from the figure, the expiry time of 20 seconds is fuzzified into low expiry with a degree of 0.2 and medium expiry with degree of 0.07. Queue length is fuzzified into high queue with degree 0.7142. Similarly, the data rate is fuzzified into medium rate with degree 0.2 and high rate with degree 0.3.
- **Rule Evaluation:** Now a series of if/then rules which are provided in the table are applied in order to determine the fuzzy outputs. An example of firing of rules is shown below.
  - If expiry time is low and data rate is medium and queue length is high, then priority index is very low.
  - If expiry time is medium and data rate is medium and queue length is high, then priority index is low.
  - If expiry time is low and data rate is high and queue length is high, then priority index is very low.
  - If expiry time is medium and data rate is high and queue length is high, then priority index is medium.

  Since the rules are connected by an AND operation, we calculate the minimum function—that is, min {0.2, 0.3, 0.7142} = 0.2, and we cut the fuzzy set very low of the output parameter priority index at this minimum level. Similar steps are done to determine the index of other rules. The four results of output overlap and they yield overall result.
- **Defuzzification:** The results are still a fuzzy set. Therefore we have to choose the representative crisp value for getting the final output. For this purpose, the weighted average method of defuzzification is used which yields a crisp value of P = 0.175. This value of P indicates that the packets are attached with high priority and will be scheduled immediately.

PERFORMANCE EVALUATION

The simulation for evaluating the proposed fuzzy scheduler is implemented using GloMoSim library. First, the input variables used in fuzzy logic C code are identified. Then the calculated priority index is used for scheduling the data packet. By this way of scheduling, the packets that are about to expire or the packets in highly congested

queues are given first priority for sending. As a result of this, the number of packets delivered to the client node, the end-to-end delay of the packet transmission, and the throughput improve.

The inputs to the fuzzy system are identified by a complete search of the GloMoSim environment. The input expiry time is the variable TTL, which is present in the network layer of the simulator. TTL stands for "time to live". If the packet suffers excessive delays and undergoes multi-hop, its TTL falls to zero. As a result of this, the packet is dropped. If this variable is used as an input to the scheduler for finding the priority index, a packet with a very low TTL value is given the highest priority. Hence due to this, the dropping of packets experiencing multi-hops gets reduced. The next input to the scheduler is the data rate of transmission and it is normalized. The third input to the scheduler is the queue length of the node in which the packet is present. If the packet is present in a highly crowded node, it suffers excessive delays and gets lost. So, such a packet is given a higher priority and hence it gets saved.

The priority index is calculated with the inputs obtained from the network layer. This is then added to the header associated with the packet. Hence whenever the packet reaches a node, its priority index is calculated and it is attached with it. Each node has three queues. Each queue in the node is sorted based on the priority index, and the packet with the lowest priority index (i.e., packet with the highest priority) is scheduled next, when the node gets the opportunity to send. By this method of scheduling, the overall performance increases.

Simulation Environment and Methodology

The simulation package GloMoSim is used to analyze and evaluate the performance of the proposed fuzzy scheduler. The GloMoSim (GLObal MObile information system SIMulator) provides a scalable simulation environment for wireless network systems. It is designed using the parallel discrete event simulation capability provided by PARSEC (PARallel Simulation Environment for Complex Systems) (Bargodia et al., 1999). It is a C-based simulation language developed by the parallel computing laboratory at UCLA (n.d.) for sequential and parallel execution of discrete event simulation model.

A network of mobile nodes is modeled and placed randomly within a 1000x1000-meter area. There were no network partitions throughout the simulation. Each simulation is executed for 600 seconds of simulation time. Transmission range is chosen to 250 meters. Multiple runs with different seed values were conducted for each scenario, and collected data was averaged over those runs. A free space propagation model was used in our experiments. A traffic generator was developed to simulate CBR sources. Data sessions with randomly selected sources and destinations were simulated. Each source transmits data packets at a minimum rate of four packets/second and a maximum rate of 10 packets/second. The data payload was chosen to be 512 bytes/second.

Performance Metrics

The *packet delivery ratio* is the ratio of the number of data packets actually delivered to the destinations to the number of data packets supposed to be received.

The *average end-to-end delay* indicates the end-to-end delay experienced by packets from source to destination. This includes the route discovery time, the queuing delay at node, the retransmission delay at the MAC layer, and the propagation and transfer time in the wireless channel.

Throughput is measured in bytes per second and serves as an effective performance metric.

The performance of the network with the fuzzy code (FLPS) and without the code (WS) is studied under and the routing protocols used in the simulator. The results are shown in Table 2 (Gomathy & Shanmugavel, 2004), showing that

Table 2.

PACKETS DELIVERED - FOR UNICAST PROTOCOLS, WITH FLPS AND WS

Routing Protocol		Packets Delivered	
		FLPS	WS
1.	AODV	33155	21818
2.	DSR	34503	21676
3.	WRP	32183	28373

THROUGHPUT - FOR UNICAST PROTOCOLS WITH FLPS AND WS

Routing Protocol		Throughput	
		FLPS	WS
1.	AODV	263347	233513
2.	DSR	269890	164680
3.	WRP	263841	225320

END TO END DELAY - FOR UNICAST PROTOCOLS WITH FLPS AND WS

Routing Protocol		Average End to end delay	
		FLPS	WS
1.	AODV	0.97	1.127
2.	DSR	0.09	1.49
3.	WRP	0.3	0.571

the proposed scheduler works well with the three routing protocols.

Scheduler Performance with Different MAC Layer Protocols: IEEE 802.11, CSMA, MACA

Experiments were performed to check the performance of the scheduler with different MAC layer protocols such as IEEE 802.11, CSMA, and MACA. In the IEEE 802.11 protocol, each node maintains the scheduling table by overhearing all the RTSs and CTSs transmitted by other nodes within its broadcast range. Here an acknowledgment (ACK) of transmission is required after successful reception of data packet. In CSMA, if the transmission medium is in use, the node waits. It is limited by the hidden and exposed

Figure 2. Packet delivery ratio vs. number of nodes

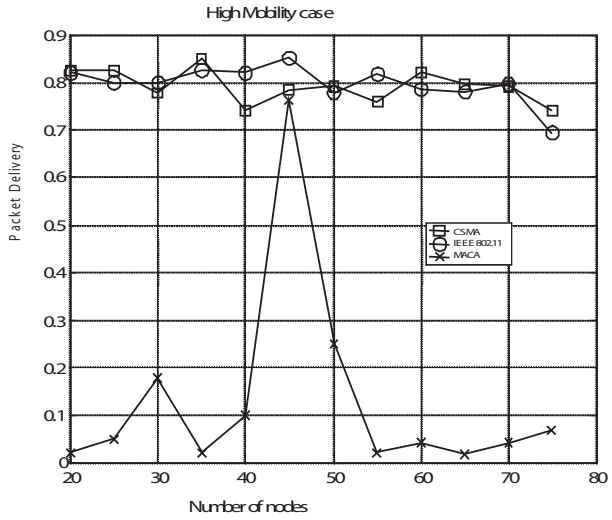


Figure 3. Average end-to-end delay as a function of number of nodes

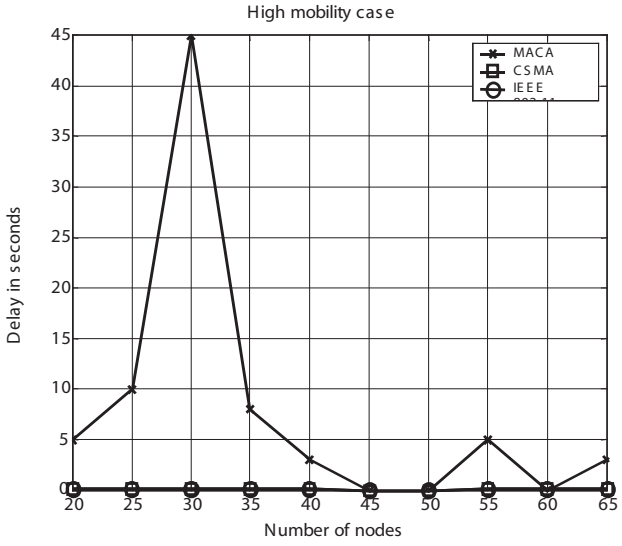

terminal problem. This can be solved by the use of RTS/CTS dialogue for collision avoidance. Hence IEEE 802.11 always shows a better performance as seen in Figures 2 and 3, compared to CSMA and MACA protocols (Gomathy & Shanmugavel, 2004). The collision avoidance mechanism in IEEE 802.11 aids in reducing the number of collisions, and hence more data packets reach the destination. Also in an exposed terminal scenario, both CSMA and MACA present poor performance behavior.

Scheduler Performance with Mobility: Two Nodes Transmitting at the Same Time to the Same Node

When two different nodes transmit at the same time to the same node with CSMA, less than half of the number of total packets is received by the receiving node due to collision. This scenario is presented for both MACA and IEEE 802.11 protocols. It is seen that a better behavior is obtained with IEEE 802.11. When used along with the scheduler, the performance with respect to throughput, packet delivery ratio, and delay improves further. The results are proved by experimenting with mobility changes under random waypoint condition in GloMoSim and are plotted. It is clear from the results that a fuzzy scheduler performs well with two nodes transmitting to the same node. Packet delivery ratio of the network with scheduler improves by 2-5%, as the mobility of the nodes varies from low to high range. The results are again verified for varieties of combinations of nodes, and results are averaged out (Gomathy & Shanmugavel, 2004). Similarly, there is an increase in throughput. There is a marked reduction in delay, which measures as low as 0.02 seconds under high mobility.

Variation in Network Size

In this simulation, the node mobility is set at 1m/s and network traffic load is made relatively heavy. The routing protocol is chosen to be AODV. Now the impact of node density on scheduler performance is studied. The packet delivery ratio is much improved as compared with that of one without scheduler, as seen in Figure 4. It is also seen that for lighter loads, the inclusion of the

Figure 4. Packet delivery ratio as a function of network size

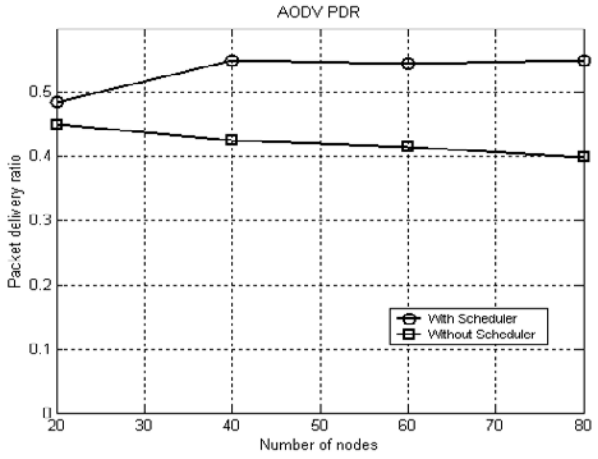

Figure 5. Average end-to-end delay vs. network size

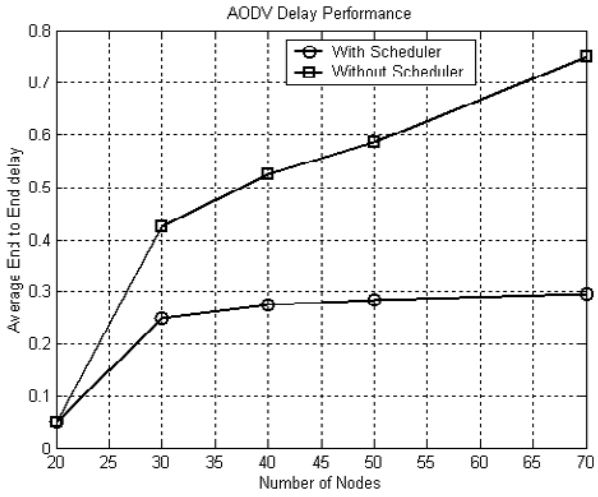

scheduler does not provide much improvement. But as traffic load increases, marked improvement is noticed in the performance. The average end-to-end delay performance proves that the end-to-end delay improves by 0.4 seconds when scheduler is included, as seen in Figure 5. This performance is achieved by the crisp calculation of the priority index including TTL as one of the inputs.

Variation in Mobility

In this simulation, each node is moved constantly with a predefined speed. The random waypoint mobility model is chosen for this study. The node movement speed or the mobility of the nodes is varied from 0 m/s to 10 m/s. The number of nodes is set as 30 and the routing protocol is selected to be DSR. From the results in Figure 6, it is evident that the packet delivery ratio is at the higher side for the network with scheduler. Even though the delivery ratio reduces as mobility approaches 10 m/s, there is always an increase of 10% in the performance of fuzzy scheduler (Gomathy & Shanmugavel, 2004)

In the fuzzy scheduler, there is a slight degradation in performance as the number of nodes increases above 70. This is due to the increase in number of hops the packets have to take to reach the destination. But still, the end-to-end delay is much smaller compared to that of the network without the scheduler. It can be inferred from Figure 7 that the fuzzy scheduler provides a superior performance in terms of the end-to-end delay. As the mobility varies from 0-10 m/s, the fuzzy scheduler provides an end-to-end delay reduced by around 0.1 sec. to 0.2 sec. The performance of the fuzzy scheduler is also tested by varying the pause time, for RWP mobility model, using the AODV routing algorithm.

The results prove that the network performs better when FPLS is included. Increasing pause time results in smoother transitions and hence

Figure 6. Packet delivery ratio vs. mobility

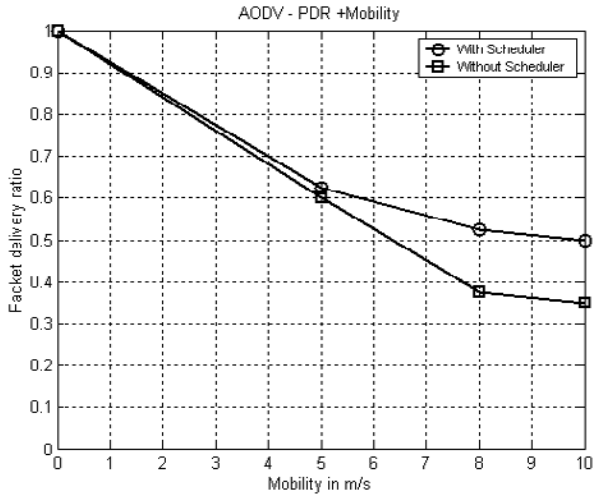

Figure 7. Average end-to-end delay vs. mobility of nodes

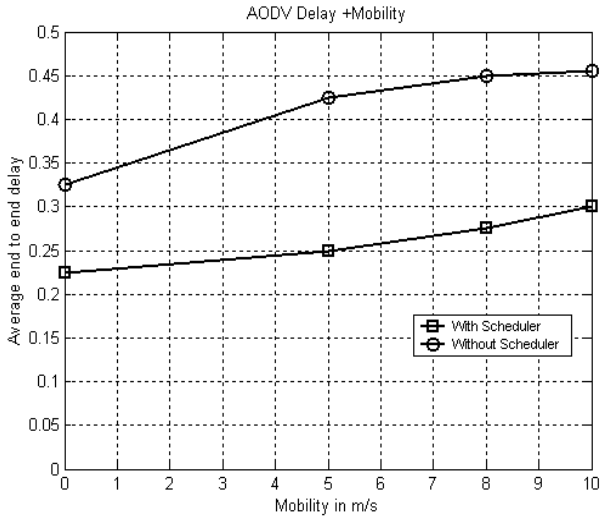

improves the performance parameters. As the mobility model is changed to random walk, with uniformly distributed speed, the throughput packet delivery ratio reduces a little and the end-to-end delay increases slightly. This is because the random walk mobility model is characterized by

the abrupt transitions in the direction and speed of nodes.

Scheduler Performance for Multicasting Protocols

Multicasting routing and packets forwarding in ad hoc networks is a fairly unexplored area. In today's network, data transmission between multiple senders and receivers is becoming increasingly important. Three multicast protocols are considered here for testing the proposed scheduler—ODMRP(On-Demand Multicast Routing Protocol), CAMP, and NTPMR (Node Transition Probability-based Multicast Routing) (Gomathy & Shanmugavel, 2005).

Variations in Mobility

In the mobility experiment, 20 nodes are multicast members and five sources transmit packets at the rate of two packets per second each. It is evident from the results that NTPMR provides higher packet delivery ratio as compared to ODMRP and CAMP. This is because NTPMR enables packets to travel distant destinations since a packet is sent to different neighbors during repeated encounters with a node. It is now proposed to include the fuzzy scheduler for these three protocols and test whether there is any improvement in packet delivery ratio. The packet delivery ratio (PDR) increases for all the three protocols. Hence it is verified that even at high mobility speeds, the routing protocols could be used when the fuzzy priority scheduler is included in these routing agents.

Multicast Group Size

The number of multicast members was varied to investigate the scalability of the protocol. The number of senders was fixed at five; the mobility speed at 1 m/s, network traffic rate at 10 packets per second, and the multicast group size was varied from 5 to 20 members. The routing effectiveness of the protocol as a function of multicast group size is now compared. For NTPMR, the packet delivery ratio is found to remain constant with increase in group size. Here the routing of packets does not depend on any forwarding group. CAMP performs better as the number of groups increases. Since the mesh becomes more massive with the growth of members, more redundant routes are formed. In ODMRP, as the number of receivers increases, the number of forwarding group nodes increases; this in turn increases the connectivity. With these results, the fuzzy scheduler is inserted in between the MAC layer and routing agent. The simulation is run and the results are presented. As seen from results, the NTPMR shows an increased performance of 3%. This is again due to the fact that, with already existing best performance, as the data scheduler is added, the packets at the verge of expiry are scheduled immediately. This increases the PDR by 3%. For ODMRP, the scheduler PDR characteristics are closer to the one without scheduler. Again in CAMPamp, the PDR improves by 5% due to the proper selection of a priority index. Thus it is also verified that the proposed scheduler performs well with multicast protocols (Gomathy & Shanmugavel, 2005).

CONCLUSION

This chapter addresses a fuzzy-based priority scheduling scheme, which improves the quality of service parameters in mobile ad hoc networks. The fuzzy scheduler algorithm attaches a priority index to each data packet in the queue of the node. It combines the input parameters such as queue length, data rate, and expiry time to find the priority index. The crisp priority index is calculated by the fuzzy scheduler based on the above inputs, which are derived from the network. The membership functions and rule bases of the fuzzy scheduler are carefully designed. The coding is done in C language and output is verified using MATLAB fuzzy logic toolbox

with FIS editor. Then the inputs are identified in the library of GloMoSim and the fuzzy scheduler is attached.

In this chapter, the performance of the fuzzy scheduler is studied for mobile ad hoc networks using GloMoSim simulator. It is found from the results that priority scheduling helps in effective routing of packets without much loss and with less delay. In a real network environment, where timely reception of each packet plays a crucial role, priority scheduling helps in effective transmission of packets. Based on the studies, we conclude that the proposed fuzzy-based scheduling algorithm performs better compared with the network performance without scheduler. The results are also verified for different unicast and multicast routing protocols under different mobility conditions and network size, with IEEE 802.11 as MAC protocol.

The future extension of the work could be to include the mobility rate, number of nodes in the transmission range, channel state conditions, and fairness among sources as inputs to the fuzzy scheduler, and investigate the effect on the overall performance of the network.

Narottam Chand
Indian Institute of Technology Roorkee, India

ABSTRACT

Caching at the mobile client is a potential technique that can reduce the number of uplink requests, lighten the server load, shorten the query latency and increase the data availability. A cache invalidation strategy ensures that any data item cached at a mobile client has same value as on the origin server. Traditional cache invalidation strategies make use of periodic broadcasting of invalidation reports (IRs) by the server. The IR approach suffers from long query latency, larger tuning time and poor utilization of bandwidth. Using updated invalidation report (UIR) method that replaces a small fraction of the recent updates, the query latency can be reduced. To improve upon the IR and UIR based strategies, this chapter presents a synchronous stateful cache maintenance technique called Update Report (UR). The proposed strategy outperforms the IR and UIR strategies by reducing the query latency, minimizing the disconnection overheads, optimizing the use of wireless channel and conserving the client energy.

INTRODUCTION

The tremendous growth in mobile hardware technology and wireless communication has increased the number of clients that access data remotely. Efficient data access in mobile computing is a

field of increasing importance for a wide range of mobile applications. Users of mobile devices wish to access dynamic data, such as stock quotes, news items, current traffic conditions, weather reports, e-mail, and video clips via wireless networks. However, limited battery power of mobile client and scarce wireless bandwidth hinder the full realization of ubiquitous data access in mobile computing. Caching at the mobile client can relieve bandwidth constraints imposed on wireless mobile computing. Copies of remote data can be kept in the local memory of the mobile client to substantially reduce user requests for retrieval of data from the origin server. This not only reduces the uplink and downlink bandwidth consumption, but also the average query latency. Caching frequently accessed data by a mobile client can also save its power used to retrieve the repeatedly requested data.

Cache invalidation strategy is used to ensure that the data items cached at a mobile client are consistent with those stored on the server. Depending on whether or not the server maintains the state of the mobile client's cache, the invalidation strategies are divided into two categories: the *stateful* server approach and the *stateless* server approach (Barbara & Imielinski, 1994; Tan, Cai, & Ooi, 2001). Barbara and Imielinski (1994) provide a solution where the server periodically broadcasts an invalidation report (IR) in which the changed data items are indicated. Rather than querying the server directly regarding the validation of cached copies, the clients can listen to these IRs over the wireless channel and use them to validate their local cache. The IR-based invalidation may be of two types: *synchronous* and *asynchronous.* In the synchronous method, the invalidation reports are broadcast periodically, whereas in the asynchronous method, the server broadcasts the reports only when some data changes. Because of the nature of periodic broadcast, synchronous methods provide a bound on the waiting time of the next report, whereas in an asynchronous invalidation report, there is no guarantee on how long the client must wait.

Clients use IRs to keep their cache consistent by discarding any obsolete data. If a query cannot be served locally—that is, a cache miss—the client issues an uplink query request for the data items. The IR-based solution is attractive because of its scalability, as the size of IR is independent of the number of clients. It is also energy efficient, as clients can exploit the periodicity of server broadcast to save power, in that mobile devices can operate in doze mode most of the time and only activate during broadcast. However, the solution suffers from the problem of long query latency since a client must listen to the next IR before answering a query. The problem has been tackled with the addition of *updated invalidation report (UIR)* by broadcasting a number of smaller reports (UIRs) between successive IRs (Cao, 2001, 2002a, 2002b, 2003). Each UIR contains information about most recently updated data items since the last IR. In case of cache hit, there is no need to wait for the next IR and hence the query latency is reduced. However, if there is a cache miss, the client still needs to wait for the data to be delivered. Thus, due to cache miss, the UIR strategy has the same query latency as IR strategy.

In IR strategy, if the disconnection time of a client is longer than a fixed period, the client should discard its entire cache even if some of the cached data may still be valid. This issue is addressed in Cao (2002a, 2002b), and Jing, Elmagarmid, Helal, and Alonso (1997). Chand, Joshi, and Misra (2005) have demonstrated more efficient handling of arbitrarily long client disconnection.

To overcome the limitations of existing cache invalidation strategies, we present a synchronous stateful caching strategy where cache consistency is maintained by periodically broadcasting *update reports (URs)* and *request reports (RRs).* The central design of our strategy includes reducing the query latency, improving the cache hit ratio, minimizing the client disconnection overheads, utilizing the wireless channel better, and conserving the client energy. The track of cached

items for each client is maintained at the home mobile support station in the form of *cache state information (CSI*). Use of CSI reduces the size of IR by filtering out non-cached items and handles long disconnection. In various IR-based strategies (Kahol, Khurana, Gupta, & Srimani, 2001; Jing et al., 1997; Barbara & Imielinski, 1994; Chuang & Hsu, 2004), even though many clients cache the same updated data item, all of them have to query the server and get the data separately from the server. It wastes a large amount of wireless bandwidth and client battery energy. To minimize uplink requests and downlink broadcasts, we use a broadcast strategy, called update report (UR) (Chand et al., 2005), where all the recently updated/requested items are broadcast immediately after the invalidation report (IR). To further reduce query latency, the strategy uses *request reports (RRs)*, where all the recently requested items are broadcast after the UIR. Selective tuning is used to conserve the client energy.

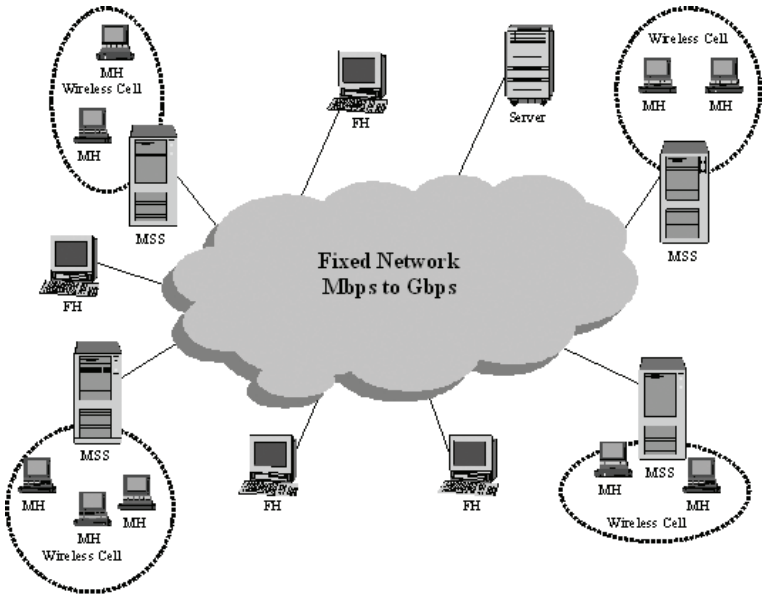
THE PROPOSED CACHE INVALIDATION STRATEGY

In this section, we present our UR-based synchronous stateful caching strategy.

UR Caching Model

As shown in Figure 1, the model consists of two distinct sets of entities: *Mobile Hosts (MHs)* and *Fixed Hosts (FHs).* Some of the fixed hosts, called *Mobile Support Stations (MSSs),* are augmented with a wireless interface in order to communicate with the mobile hosts, which are located within a radio coverage called a cell. Each cell is associated with an id for identification purpose. MSSs are also known as *Base Stations (BSs).* An MSS acts like a gateway between a fixed network and a wireless network. An MH communicates with a fixed host/server via an MSS over a wireless

Figure 1. UR caching model



communication link. The communication is asymmetric (i.e., the uplink bandwidth is much less than that of downlink). The MSSs communicate among themselves over a wired channel and the communication is transparent to a client. A fixed network has a large bandwidth (order of Mbps or Gbps), while the bandwidth of the wireless channel is low (19.2 Kbps-10 Mbps). An MH can move within a cell or between cells while retaining its network connection. When an MH moves from one cell to another (called handoff), its wireless connection is switched to the new cell. An MH either connects to an MSS through a wireless link or disconnects from the MSS by operating in a 'power save' mode (Kahol et al., 2001).

The database D is a collection of N data items with ids: d_1, d_2, …, d_N. A data item is the basic unit for update and query. For each data item d_i, two timestamps t_i and t_i^r are maintained: t_i is the most recent *timestamp* when d_i got updated at the server and t_i^r, called *latest request time*, represents the most recent time when d_i was last requested by any client. MHs only issue simple requests to read the most recent copy of a data item. In order to serve a request sent from a client, the MSS needs to communicate with the database server to retrieve the data items. Caching techniques may also be applied at MSS. Since the communication between the database server and MSSs are through wired link, we assume traditional techniques can be used to maintain cache consistency. Since the communication between the MSS and the database server is transparent to the clients, from the client point of view, the MSS is the same as the database server.

Frequently accessed data items are cached on the client side. We assume that the cache at the mobile client is a nonvolatile memory such as a hard disk so that after a long disconnection, the contents of the cache can still be retrieved. When caching is used, data consistency issues must be addressed. We assume the *latest value* consistency model (Cao, 2002a, 2002b), which is widely used in dissemination-based information systems.

To ensure cache consistency, the server broadcasts UR every L seconds and it also broadcasts (m-1) RRs between two URs. Every active client listens to the report (UR/RR) and invalidates its cache accordingly. To answer a query, the client listens to the IR/UIR part of the next report (UR/RR) and decides its cache validity. If there is a valid cached copy of the requested item, the client returns the item immediately. Otherwise, it sends a query request to the server through the uplink. The simulation architecture of the proposed model is shown in Figure 2.

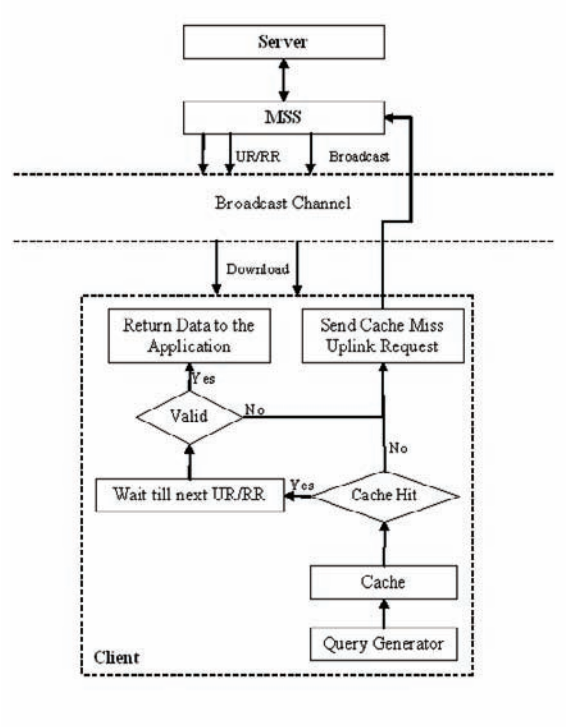
To keep the information about cached items for each MH, a cache state information (CSI) is maintained at the home MSS. The CSI is the list of cached data item ids by the host. For each item d_i a cache count n_i is also maintained at the home MSS. Thus, n_i denotes the number of clients who have cached the item d_i in that particular cell. When a client sends a data request, the MSS updates the relevant counters and the corresponding CSI, and forwards the request to the server.

In order to save energy, an MH may power off most of the times and only turns on during the report broadcast time. Moreover, an MH may be in the power save mode for a long time and it may miss some reports.

The following assumptions are made:

- Database D is a collection of N data items. An item is identified by a unique id d_i ($1 \le i \le N$). D_i denotes the actual data of an item with id d_i. Each item has the same size S_{data} (in bits).
- Each cell has a single MSS such that cell A is managed by MSS_A. Each MSS broadcasts UR every L seconds and RR every L/m seconds.
- A unique host identifier is assigned to each MH in the system. The system has a total of M hosts, and MH_i ($1 \le i \le M$) is a host identifier. Each mobile host moves freely. We use the terms host and client interchangeably.

Figure 2. Simulation architecture



- Each MH has a cache space for C data items.
- CSI stored in the local disk of home MSS maintains the state information for a host. An MH informs its MSS before it stores any data item in its local cache and the MSS updates the CSI accordingly.
- The server is reliable—that is, it handles the failure with some fault tolerance techniques.

Cache State Information to Reduce the Report Size

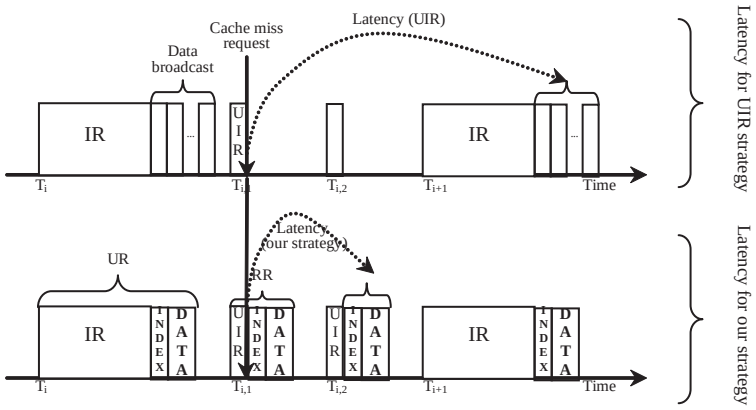
In a stateless strategy when an item updates at the server, its id is broadcast as part of IR irrespective of whether the item has been cached or not. Including an item as part of IR, which has not been cached by any client, makes poor utilization of the available wireless bandwidth. It also increases the client energy consumption since users have to listen to the broadcast channel for a longer duration to download the report. To filter out from a report all those recently updated items that are not cached by any client, we have used a stateful approach in our strategy.

To keep the information about cached items, for each MH a *cache state information (CSI)* is maintained at the home MSS. Consider a cell with H hosts (MH_i, $1 \le i \le H$), at any given time. For any j, CSI_j for MH_j, as maintained on its home MSS, keeps track of what data has been locally cached at MH_j. In general, if $d_k \in CSI_j$, then the client MH_j has cached the item d_k. When an item updates, it will be added as part of a report (UR/RR) at the server. The MSS, upon receiving the report from the server, removes all those items from the IR that are not cached by any client (i.e., with cache count 0) and thus broadcasts reduced report in its cell. When a client moves to a new cell, the copy of its CSI is replicated at the new MSS.

Reducing the Query Latency

In UIR-based caching strategy, the server aggregates data requests from all its clients over the whole invalidation interval (L seconds) and broadcasts the requested data after each IR. This aggregation of requests tremendously reduces the number of data broadcasts and thus makes efficient utilization of the downlink channel. The reduction in the number of broadcasts is at the expense of increased query latency, since a client has to wait longer to download the requested data item. In UIR scheme, the requested data are scheduled for broadcast after the next IR, thus due to cache miss, the expected query latency is L/2 seconds. To reduce the query latency due to cache miss, the UR strategy broadcasts the recently requested data items after the next report

Figure 3. Reducing the query latency



(IR/UIR), whichever arrives earlier, such that the expected query latency is L/(2*m) seconds instead of L/2 seconds. In general, $T_{i,k}$ represents the time of k^{th} RR after the i^{th} UR. When a client receives a cache miss request between $T_{i,1}$ and $T_{i,2}$, it cannot answer the query until T_{i+1} in the UIR approach, but it can answer the query at $T_{i,2}$ in UR approach (see Figure 3). UIR, followed by the broadcast of recently requested data, constitutes *request report (RR).* At interval time $T_{i,k}$, $RR_{i,k}$ is constructed as follows:

$UIR_{i,k}$	$RR\_INDEX_{i,k}$	$RR\_DATA_{i,k}$

$$UIR_{i,k} = \{d_x | (d_x \in D) \wedge (T_{i,0} < t_x \leq T_{i,k}) \wedge (n_x > 0)\} \; (0 < k < m)$$

$$RR\_INDEX_{i,k} = \{d_x | (T_{i,k-1} < t^r_x \leq T_{i,k})\}$$

$$RR\_DATA_{i,k} = \{D_x | d_x \in RR\_INDEX_{i,k}\}$$

This distribution of query replies also reduces the impact of data broadcast on other downlink traffic. To make the selective tuning possible for the clients, the server broadcasts the index information RR_INDEX before the broadcast of actual data. Since the query replies are distributed, the size of the index in our strategy is much smaller than in the UIR strategy.

Improving Wireless Channel Utilization

To reduce the number of uplink requests and downlink broadcasts, we introduce the concept of update report (UR) (Chand et al., 2004). Update reports (URs) are broadcast synchronously with period L.

At interval T_i, the structure of UR_i is as follows:

IR_i	UR_INDEX_i	UR_DATA_i

$$IR_i = \{(d_x, t_x) | (d_x \in D) \wedge (n_x > 0) \wedge (T_i - w*L < t_x \leq T_i)\}$$

$$UR\_INDEX_i = \{d_x | ((T_{i-1} < t_x \leq T_i) \wedge (n_x > 0)) \vee (T_{i-1,m-1} < t^r_x \leq T_i)\}$$

$$UR\_DATA_i = \{D_x | d_x \in UR\_INDEX_i\}$$

UR_INDEX_i defines the order in which data appears in UR_DATA_i. Within UR_INDEX and RR_INDEX, the items are arranged in non-decreasing order of their cache count. This ordering of broadcast items further reduces the query latency (Chand et al., 2004).

IR contains the update history of past w broadcast intervals, whereas UR_DATA contains the actual data value for the items that have been updated during previous UR interval and the items that have been requested during the last RR interval. In our strategy the contents of URs broadcast in different cells depend upon the cache state of the clients lying within a cell, and hence the broadcast URs may be inhomogeneous. In most IR-based algorithms (Kahol et al., 2001; Jing et al., 1997; Barbara & Imielinski, 1994), updating a data item that has been cached may generate many uplink requests and downlink broadcasts, and thus make poor utilization of available wireless bandwidth. This is due to the reason that when an item is updated and IR is broadcast, each client who has cached that item will generate an uplink request for the item and the server responds to each request by broadcasting the item. For example, for an item with id d_x which is cached by n_x clients, there will be n_x uplink requests and n_x downlink broadcasts due to update. We address the problem by asking the server to broadcast all the data items that have been recently requested or updated and are cached by one or more clients. If a client observes that the server is broadcasting an item which is an invalid entry in its local cache, it will download the item. Otherwise, the client may have to send another request to the server, and the server will have to broadcast the data again in the future. So in comparison to n_x uplink requests and downlink broadcasts for an updated item, our strategy makes only single broadcast without any uplink request.

Due to data update at the server, UR strategy has same number of uplink requests and downlink broadcasts as in UIR strategy. Also, during one RR interval, due to cache miss an item may have been requested by many clients, but our scheme broadcasts the item only once. In comparison to UIR strategy, our strategy further improves the wireless channel utilization by using *delayed uplink (DU)* technique as follows.

To improve the efficiency of uplink channel due to cache miss, when an item d_x is requested by a client at time $T_{i,j}$ $(1 \le j \le m\text{-}1)$, in UR strategy the client would download $RR\_INDEX_{i,j}$ to see if the server has planned the broadcast of item d_x. If $d_x \in RR\_INDEX_{i,j}$, the client would download D_x and the item id d_x is piggybacked when a new request is sent to the server; otherwise the client sends an uplink request to the server for d_x. This saving in uplink request also reduces query latency as the client receives the item sooner. Thus, reducing the number of uplink requests and downlink broadcasts due to recent updates or cache misses, UR strategy heavily saves on wireless bandwidth.

Synchronous Broadcasting to Conserve Client Energy

In asynchronous invalidation methodology, there is no guarantee on how long the client must wait for the next report, and hence the clients are in doze mode and may lose some of the reports, thus compromising the cache consistency or further increasing the query latency. By broadcasting UR and RR periodically, we use a synchronous approach where clients may wake up during the UR/RR broadcast time and selectively tune in to the channel to save power. After broadcasting IR/UIR, the server broadcasts UR_INDEX/RR_INDEX followed by the broadcast of actual data UR_DATA/RR_DATA. Every client listens to the report (IR/UIR) if not disconnected. At the end of report, the client downloads index and locates the interesting item that will come, and listens to the channel at that time to download the data. This strategy saves power since the client selectively tunes to the channel and can stay in doze mode most of time.

Handling Client Disconnection

Since a UR broadcasts information about the items that have been updated during past w*L time, our strategy handles the disconnection of clients less than w*L without any additional overhead. When a client reconnects after a disconnection time longer than w*L, it sends an uplink request with the last received UR time stamp T_l (before disconnection) to the home MSS. On receipt of the request, the MSS constructs a binary vector *DIV* called *disconnection information vector*. DIV is of size C bits and contains the validity information about the cached items by the client. For a client MH_i, the MSS constructs DIV_i as follows:

1. Scan the CSI_i for the list of cached items. If $d_j \in CSI_i$, MH_i has cached the item d_j otherwise not ($1 \le j \le N$).
2. For an item d_j which is cached by client MH_i, compare its last update timestamp (t_j) with T_l. If $t_j > T_l$, the item d_j has been updated since MH_i received the last UR before disconnection. In case t_j satisfies the above condition (i.e., $t_j > T_l$), then set $DIV_i[k] = 1$, where MH_i has stored item d_j at k^{th} cache location ($1 \le k \le C$). If $t_j \le T_l$, then set $DIV_i[k] = 0$.

Step 1 gives the list of items that have been cached by the client, and step 2 checks whether the particular cached item has been updated when the client was in disconnection mode. Step 2 is repeated for all the cached items by the client MH_i. The number of bits in DIV_i is C and is equal to the number of items cached by MH_i.

Once the DIV_i has been constructed, the server sends DIV_i to MH_i over the downlink channel. After downloading DIV_i, MH_i finds whether a particular cached item is valid or not. If $DIV_i[k] = 1$, then the k^{th} cached item is invalid, otherwise it is still valid. After checking for each cached item, the client will send an uplink request for all the invalid items, and the server responds by broadcasting the requested items during and following UR/RR.

As compared to UIR strategy (Cao, 2001, 2002a, 2002b, 2003), which handles disconnection by sending the ids for updated items, our strategy uses only one bit for an item, thus reducing the reconnection overheads tremendously. For our strategy, the reconnection overhead is C bits, which is very low as compared to UIR. Because of the smaller size of overheads, our strategy is also very much effective in terms of bandwidth utilization, client tuning time, and energy consumption.

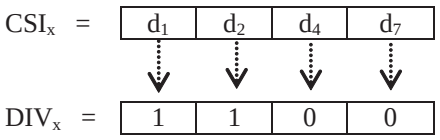
An Example

Consider a database having 10 items with the last update timestamp t_i as follows:

d_i	1	2	3	4	5	6	7	8	9	10
t_i	20	16	17	13	5	6	2	9	23	19

Consider a host MH_x of cache size C = 4 that has cached the items with id d_1, d_2, d_4, and d_7. Let MH_x be disconnected at time 17 such that it has received the last UR at $T_l = 15$ and wakes up at time 30.

Then:



While MH_x receives DIV_x, it is interpreted as: 1st cached item where d_1 is invalid, and 2nd cached item where d_2 is invalid, whereas d_4 and d_7 are still valid. The reconnection overhead for our strategy is 4 bits.

For UIR, the overhead = number of cached items invalidated during disconnection*item id size (S_{id}). Generally S_{id} = 32 bits, therefore the overhead value = 64 bits.

CONCLUSION AND FUTURE DIRECTION

This chapter investigates the cache invalidation issue in a realistic mobile environment, where there exist resource-poor mobile clients, data updates, asymmetric low-quality wireless channel, and client disconnections. UR-based cache invalidation strategy has been proposed that reduces the query latency as compared to existing IR and UIR strategies. The UR strategy employs selective tuning to conserve the client's battery power. Frequent client disconnection is one of the main features in a mobile computing environment. To cater for such an environment, a disconnection information vector (DIV) based algorithm has been proposed that maintains cache consistency at the mobile client with very low overhead as compared to existing strategies. The ad hoc mode of operation, which is now available with new-generation wireless interfaces, makes possible peer-to-peer (P2P) caching in which mobile clients can access data items from the cache in their neighboring peers. Extension of the proposed strategy to peer-enabled caching is a consideration during our future research.

Chapter 7.32
Ensuring Serializability for Mobile-Client Data Caching

Shin Parker

IMPORTANCE OF ENSURING SERIALIZABILITY IN MOBILE ENVIRONMENTS

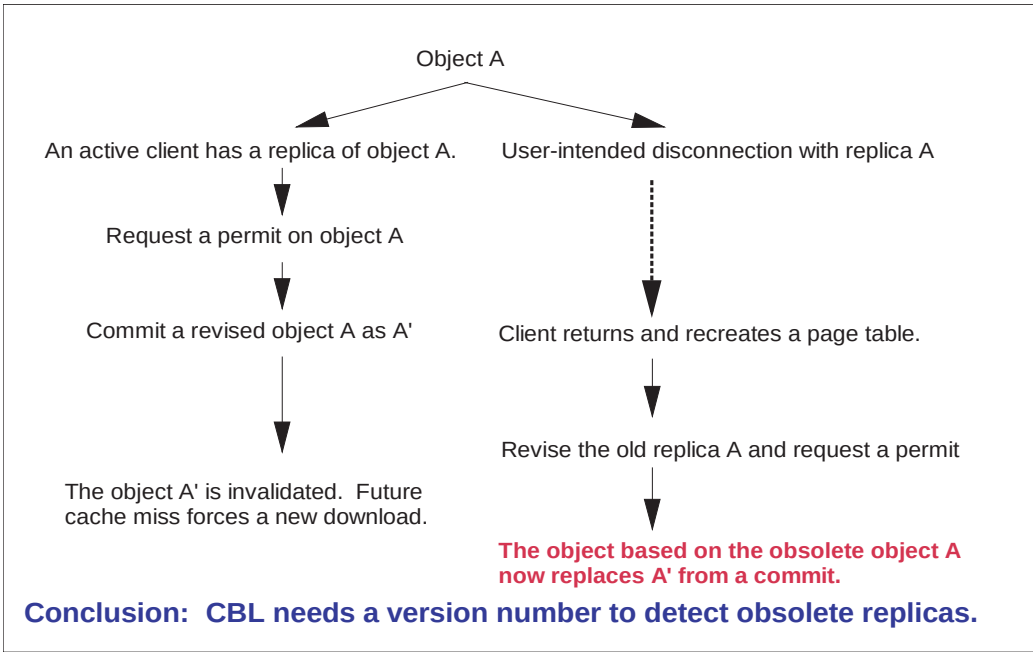
Data management in mobile computing has emerged as a major research area, and it has found many applications. This research has produced interesting results in areas such as data dissemination over limited bandwidth channels, location-dependent querying of data, and advanced interfaces for mobile computers (Barbara, 1999). However, handling multimedia objects in mobile environments faces numerous challenges. Traditional methods developed for transaction processing (Silberschatz, Korth & Sudarshan, 2001) such as concurrency control and recovery mechanisms may no longer work correctly in mobile environments. To illustrate the important aspects that need to be considered and provide a solution for these important yet "tricky" issues in this article, we focus on an important topic of data management in mobile computing, which is concerned with how to ensure serializability for mobile-client data caching. New solutions are needed in dealing with caching multimedia data for mobile clients, for example, a cooperative cache architecture was proposed in Lau, Kumar, and Vankatesh (2002). The particular aspect considered in this article is that when managing a large number of multimedia objects within mobile client-server computing environments, there may be multiple physical copies of the same data object in client caches with the server as the primary owner of all data objects. Invalid-access prevention policy protocols developed in traditional DBMS environment will not work correctly in the new environment, thus, have to be extended to ensure that the serializability involving data updates is achieved in mobile environments. The research by Parker and Chen (2004) performed the analysis, proposed three extended protocols, and conducted experimental studies under the invalid-access prevention policy

in mobile environments to meet the serializability requirement in a mobile client/server environment that deals with multimedia objects. These three protocols, referred to as extended server-based two-phase locking (ES2PL), extended call back locking (ECBL), and extended optimistic two-phase locking (EO2PL) protocols, have included additional attributes to ensure multimedia object serializability in mobile client/server computing environments. In this article, we examine this issue, present key ideas behind the solution, and discuss related issues in a broader context.

BACKGROUND

In a typical client-server computing architecture, there may exist multiple physical copies of the same data object at the same time in the network with the server as the primary owner of all data objects. The existence of multiple copies of the same multimedia object in client caches is possible when there is no data conflict in the network. In managing multiple clients' concurrent read/write operations on a multimedia object, no transactions that accessed the old version should be allowed to commit. This is the basis of the invalid-access prevention policy, from which several protocols have been proposed. The purpose of these protocols is to create an illusion of a single, logical, multimedia data object in the face of multiple physical copies in the client/server network when a data conflict situation arises. When the server becomes aware of a network-wide data conflict, it initiates a cache consistency request to remote clients on behalf of the transaction that caused the data conflict. Three well-known invalid-access prevention protocols are Server-based Two-Phase

Figure 1. CBL failure analysis tree in a mobile environment



Locking (S2PL), Call-Back Locking (CBL), and Optimistic Two-Phase Locking (O2PL).

In order to extend these policies to the mobile environment, we should understand that there are four key constraints of mobility which forced the development of specialized techniques, namely, unpredictable variation in network quality, lowered trust and robustness of mobile elements, limitations on local resources imposed by weight and size constraints, and concern for battery power consumption (Satyanarayanan, 1996). The inherent limitations of mobile computing systems present a challenge to the traditional problems of database management, especially when the client/server communication is unexpectedly severed from the client site. The standard policy does not enforce the serializability to the mobile computing environment. Transactions executing under an avoidance-based scheme must obey the Read-Once Write-All (ROWA) principle, which guarantees the correctness of the data from the client cache under the CBL or the O2PL protocol. The standard CBL and O2PL protocols cannot guarantee the currency of the mobile clients' cache copies or prevent serializability violations when they reconnect to the network. Figures 1 illustrates how error conditions (appearing toward the end of the figure) arise after mobile clients properly exit the client application when the traditional CBL protocol is used.

FUNDAMENTAL ISSUES AND APPROACHES TO DEALING WITH THESE ISSUES

In order to extend invalid-access prevention policy protocols to mobile environments, there are three fundamental issues that need to be addressed for mobile-client multimedia data caching, namely:

- to transform multimedia objects from databases' persistent data type to the clients' persistent data type;
- to handle client-server communication for multimedia objects; and
- to deal with the impact of mobility, particularly to deal with the case when the client-server communication is unexpectedly severed from the client site.

Research work from various authors (Breitbart et al., 1999; Franklin, Carey & Livny, 1997; Jensen & Lomer, 2001; Pacitti, Minet & Simon, 1999; Shanmugasundaram et al., 1999; Schuldt, 2001) have contributed to the investigation of aspects related to ensuring serializability of data management. Based on these studies, Parker and Chen (2004) have conducted a more recent research to deal with the three issues mentioned above and developed algorithms to achieve extended invalid-access prevention protocols. The basic ideas of this research are summarized below.

First, in order to prevent the serializability failure scenario described above, we summarize important features of the extended invalid-access prevention policy protocols for the mobile client/server environments that guarantee the serializability. As shown in Table 1, an X denotes an attribute under the standard invalid-access prevention policy, while a bold-face **X** as an additional attribute under the extended invalid-access prevention policy. The revised algorithms for extended invalid-access prevention policy protocols are developed based on these considerations.

As an example of these attributes, here we take a brief look at the important role of the page table. To detect or avoid invalid-accesses from all transactions, all clients and the server each need to keep a separate table to detect or avoid data conflict situations. For clients, page tables are the current inventories of their cached multimedia objects. For the server, a page table is the information about their active constituent clients to detect or avoid data conflicts in the network. Figure 2 depicts a proper page table procedure for logical invalidations to deal with serializability problems through page table consistency check.

Table 1. Extended invalid-access prevention policy

ATTRIBUTE	S2PL	O2PL	CBL
Version Numbers	X	**X**	**X**

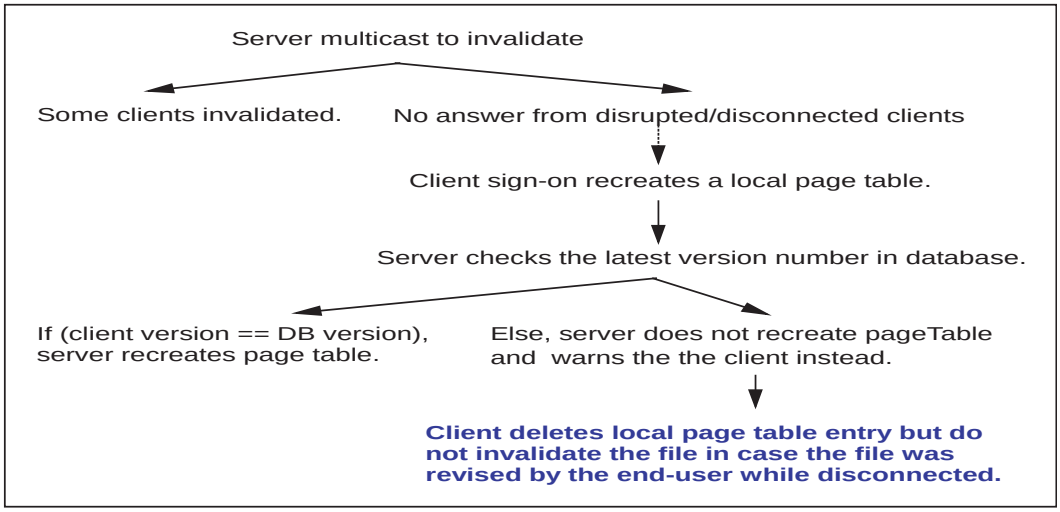
Server knows who has locks	X	X	X
Server knows who has what objects		X	X

EXTENDING TRADITIONAL PROTOCOLS: BASIC IDEA AND RESULTS OF EXPERIMENTS

To illustrate the basic ideas involved in extending standard protocols, let us take a look at the case of extended O2PL algorithm with dynamic replication. In its original form, the O2PL protocol defers the write declaration until the end of a transaction's execution phase. Dynamic replication is a natural choice for the O2PL because when the server issues a write lock after multicasting

Figure 2. Consistency check of the page table



to all cached remote clients of the same object, the server already has an updated object at hand from the committing client. Just before the server commits the new object to the database with an exclusive lock, there are two copies of the new version object in the network, the server's binary array variable and the local client's new-version cache copy and only one primary copy of the old version object in the database.

The correctness criterion in the replicated database is one-copy serializability (Holiday, Agrawal & Abbadi, 2002) under the ROWA principle where write operations must write to all copies before the transaction can complete. This is accomplished via the server's multicast transmission to a subset of active clients after the primary new-version copy is safely stored in the database.

The primary copy of an object is with the server, and the replicas are at client caches for read transactions. For write transactions, the primary copy is at the transaction's originating site temporarily. After commit operations, however, the server becomes the primary site, and the originating client becomes one of the replicated sites. The server then multicasts the replica to remote clients with the previous version object. When a client downloads an object explicitly, a local lock is given automatically, but the end user can release the local lock manually. Local locks will not be automatically given after dynamic replications.

To enforce the network-wide unique object ID, the server application will verify the uniqueness of the file name at the insert transaction, and the client application will verify that the file name is not altered at the commit transaction as an early abort step.

RESULT OF EXPERIMENTS ON EXTENDED PROTOCOLS

The three extended protocols have been implemented, and comparative studies through experiments have been conducted. Below is the result

of an experiment where identical transactions of four clients are used, each with two multimedia objects (one small size and the other 15 times as large). Table 2 summarizes the number of messages clients sent to the server, total kilobytes of the messages, the number of the server aborts, and the abort rate which is the percentage of aborts from the entire number of messages clients sent to the server. Any dynamic replications do not count toward the messages sent since clients do not send any messages to the server for them. All client-initiated abort messages, such as the permit abort in the ECBL or the lock abort in the ES2PL, are counted toward the MESSAGE, not the ABORT.

Experiments have shown that extended invalid-access prevention policy algorithms enforce a guaranteed serializability of multimedia objects in RDBMS applications under a mobile client/server environment. As for the pros and cons of each extended algorithm, we have the following general observations. Extended S2PL protocol brings the lowest number of client messages to the server but at the highest server abort rate leaving the network with multiple versions. Extended CBL protocol with invalidation carries the highest number of client messages sent to the server and a moderate server abort rate in the expense of reliability. Extended O2PL protocol with replication offers a moderate number of client messages sent to the server with the lowest server abort rate that may make it desirable for most applications.

FUTURE TRENDS

Due to its importance for data management in a mobile environment, techniques for ensuring serializability in dealing with multiple copies of multimedia objects should be further explored. New solutions are needed for existing problems in new environments, and new problems emerge, demanding solutions, as well. In this article, we have deliberately focused on a well-selected specific topic to show the need for an in-depth study of dealing with mobility in databases involving multimedia objects. However, the methodology used here can be extended to many other topics in regard to data management in a mobile computing environment. The key to success in such studies lies in a good understanding of important features of mobile environments, as well as in-

Table 2. Comparison of extended invalid-access prevention policy protocols

*** Total size of client messages**

herent limitations of involved resources in such environments.

In addition, ensuring serializability has implications beyond guaranteeing correctness of transaction execution in a mobile environment. For example, based on the work reported above, Parker, Chen, and Sheng (2004) further identified four core areas of issues to be studied in database-centered mobile data mining, with an emphasis on issues related to DBMS implementation such as query processing and transaction processing. Other aspects related to data mining techniques and distributed or mobile (or even pervasive) computing environments have also been explored (e.g., Kargupta & Joshi, 2001; Lim et al., 2003; Liu, Kargupta & Ryan, 2004; Saygin & Ulusoy, 2002).

There are many other database issues related to mobile computing, such as location-dependent queries (Dunham, Helal & Balakrishnan, 1997; Seydim, Dunham & Kumar, 2001; Yan, Chen & Zhu, 2001). In addition, many issues related to mobile computing can be examined in a more general context of pervasive computing (or ubiquitous computing). Satyanarayanan (1996, 2001) discussed several important issues and future directions on pervasive computing. A wide range of data management aspects should be explored in the future, with the following as sample topics:

- Infrastructure for mobile computing research
- User interface management for pervasive devices
- Data models for mobile information systems
- Mobile database management and mobility-aware data servers
- Mobile transaction and workflow management and models
- Data and process migration, replication/ caching and recovery
- Moving objects and location-aware data management
- Adaptability and stability of pervasive systems in ever-changing wireless environments
- Quality of service (QOS) mechanism for mobile data management

CONCLUSION

As noted earlier, handling multimedia objects in mobile environments faces numerous challenges. Traditional methods developed for transaction processing such as concurrency control and recovery mechanisms may no longer work correctly in mobile environments. In this article, we have focused on a specific issue to ensure serializability for mobile-client data caching. We have explained why the traditional approaches need to be revised and demonstrated the basic idea of extended approaches. Extending from this particular study, we have also discussed related issues in a more general perspective. As indicated in the Future Trends section , there are numerous challenging issues to be resolved in the near future.

KEY TERMS

Call-Back Locking (CBL): CBL is an avoidance-based protocol that supports inter-transactional page caching. Transactions executing under an avoidance-based scheme must obey the read-once write-all (ROWA) replica management approach, which guarantees the correctness of data from the client cache by enforcing that all existing copies of an updated object have the same value when an updating transaction commits.

Data Management for Mobile Computing: Numerous database management issues exist in mobile computing environments, such as resource management and system support, representation/dissemination/management of information, location management, as well as others. Various new techniques for cache management, data replication, data broadcasting, transaction processing, failure recovery, as well as database security, have been developed. Applications of these techniques have been found distributed mobile database systems; mobile information systems; advanced mobile computing applications; and the Internet. Yet there are still many other issues need to be dealt with, such as the problem described in this article.

Invalid Access Prevention Policy: The invalid-access prevention policy requires that in order to manage multiple clients' concurrent read/write operations in the client/server architecture, no transactions that access stale multimedia data should be allowed to commit. In general, there are two different approaches to achieve this policy. The detection-based (lazy) policy ensures the validity of accessed multimedia data, and the avoidance-based (eager) policy ensures that invalid multimedia data is preemptively removed from the client caches.

Multimedia Database: A particular challenge for a multimedia database is the ability of dealing with multimedia data types. Retrieval of structured data from databases is typically handled by a database management system (DBMS), while retrieval of unstructured data from databases requires techniques developed for information retrieval (IR). (A survey on content-based retrieval for multimedia databases can be found in Yoshitaka and Ichikawa, A survey on content-based retrieval for multimedia databases, *IEEE Transactions of Knowledge and Data Engineering, 11*(1), pp. 81-93, 1999.) Yet the rigid resource requirement demands more advanced techniques in dealing with multimedia objects in a mobile computing environment.

Optimistic Two-Phase Locking (O2PL): This is avoidance-based and is more optimistic about the existence of data contention in the network than CBL. It defers the write intention declaration until the end of a transaction's execution phase. Under the ROWA protocol, an interaction with the server is required only at client cache-miss or for committing its cache copy under the O2PL. As in CBL, all clients must inform the server when they erase a page from their buffer so that the server can update its page list.

Pervasive Computing (or Ubiquitous Computing): Pervasive computing "has as its goal the enhancing of computer use by making many computers available throughout the physical environment, but making them effectively invisible to the user" (Mark Weiser, Hot topics: Ubiquitous computing, *IEEE Computer*, October 1993, p. 000). Pervasive computing is the trend towards increasingly ubiquitous, connected computing devices in the environment. As the result of a convergence of advanced electronic (particularly, mobile wireless) technologies and the Internet,

pervasive computing is becoming a new trend of contemporary technology.

Serializability: Serializability requires that a schedule for executing concurrent transactions in a DBMS is equivalent to one that executes the transactions serially in a certain order.

Server-Based Two-Phase Locking (S2PL): The S2PL uses a detection-based algorithm and supports inter-transaction caching. It validates cached pages synchronously on a transaction's initial access to the page. Before a transaction is allowed to commit, it must first access the primary copies from the server on each data item that it has read at the client. The new value must be installed at the client if the client's cache version is outdated. The server is aware of a list of clients who requested locks only, and no broadcast is used by the server to communicate with clients.

Chapter 7.33
Mobile Caching for Location-Based Services

Jianliang Xu
Hong Kong Baptist University, Hong Kong

INTRODUCTION

Location-based services (LBS) are services that answer queries based on the locations with which the queries are associate; normally the locations where the queries are issued. With a variety of promising applications, such as local information access (e.g., traffic reports, news, and navigation maps) and nearest neighbor queries (e.g., finding the nearest restaurants) (Barbara, 1999; Ren & Dunham, 2000; D. L. Lee, Lee, Xu, & Zheng, 2002; W. C. Lee, Xu, & Zheng, 2004), LBS is emerging as an integral part of daily life.

The greatest potential of LBS is met in a mobile computing environment, where users enjoy unrestricted mobility and ubiquitous information access. For example, a traveler could issue a query like "Find the nearest hotel with a room rate below $100" from a wireless portable device in the middle of a journey. To answer such a query, however, three major challenges have to be overcome:

- **Constrained Mobile Environments:** Users in a mobile environment suffer from various constraints, such as scarce bandwidth, low-quality communication, frequent network disconnections, and limited local resources. These constraints pose a great challenge for the provision of LBS to mobile users.
- **Spatial Data:** In LBS, the answers to a query associated with different locations may be different. That is, query results are dependent on spatial properties of queries. For a query bound with a certain query location, the query result should be relevant to the query as well as valid for the bound location. This requirement adds additional complexity to traditional data management techniques such as data placement, indexing, and query processing (D. L. Lee, 2002).
- **User Movement:** The fact that a mobile user may change its location makes some tasks in LBS, such as query scheduling and cache management, particularly tough. For example, suppose that a mobile user issues a query "Find the nearest restaurant" at loca-

tion *A*. If the query is not scheduled timely enough on the server, the user has moved to location *B* when he or she gets the answer *R*. However, *R* is no longer the nearest restaurant at location *B*.

Caching has been a commonly used technique for improving data access performance in a mobile computing environment (Acharya, Alonso, Franklin, & Zdonik, 1995). There are several advantages for caching data on mobile clients:

- It improves data access latency since a portion of queries, if not all, can be satisfied locally.
- It helps save energy since wireless communication is required only for cache-miss queries.
- It reduces contention on the narrow-bandwidth wireless channel and off-loads workload from the server; as such, the system throughput is improved.
- It improves data availability in circumstances where clients are disconnected or weakly connected because cached data can be used to answer queries.

However, as discussed above, the *constrains* of mobile computing environments, the *spatial* property of location-dependent data, and the *mobility* of mobile users have opened up many new research problems in client caching for LBS. This chapter discusses the research issues arising from caching of location-dependent data in a mobile environment and briefly describes several state-of-the-art solutions.

BACKGROUND

Location Model

Location plays a central role in LBS. A location needs to be specified explicitly or implicitly for any information access. The available mechanisms for identifying locations of mobile users are based on two models:

- **Geometric Model:** A location is specified as an *n*-dimensional coordinate (typically, $n = 2$ or 3); for example , the latitude/longitude pair returned by the global positioning system (GPS). The main advantage of the geometric model is its compatibility across heterogeneous systems. However, providing such fine-grained location information may involve considerable cost and complexity.
- **Symbolic Model:** The location space is divided into disjointed zones, each of which is identified by a unique name. Examples are the Cricket system (Priyantha, Chakraborty, & Balakrishnan, 2000) and the cellular infrastructure. The symbolic model is in general cheaper to deploy than the geometric model because of the lower cost of employing a coarser location granularity. Also, being discrete and well-structured, location information based on the symbolic model is easier to manage.

For ease of illustration, two notions are defined: *valid scope* and *valid scope distribution*. A dataset is a collection of data instances. The *valid scope* of a data instance is defined as the area within which this instance is the only answer with respect to a location-dependent query. With the symbolic location model, a valid scope is represented by a set of logical zone ids. With the geometric location model, a valid scope often takes the shape of a polygon in a two-dimensional space. Since a query may return different instances at different locations, it is associated with a set of valid scopes, which collectively is called the *scope distribution* of the query. To illustrate, consider a four-cell system with a wireless-cell-based location model. Suppose that the nearby restaurant for cell 1 and cell 2 is instance *X*, and the nearby restaurant for cell 3 and cell 4 is instance *Y*. Then,

the valid scope of X is {1, 2}, the valid scope of Y is {3, 4}, and the scope distribution of the nearby restaurant query is {{1, 2}, {3, 4}}.

Client Caching Model

There is a cache management module in the client. Whenever an application issues a query, the local cache manager first checks whether the desired data item is in the cache. If it is a cache hit, the cache manager still needs to validate the consistency of the cached item with the master copy at the server. This process is called *cache validation*. In general, data inconsistency is incurred by data updates at the server (called *temporal-dependent invalidation*). For location-dependent information in a mobile environment, cache inconsistency can also be caused by location change of a client (called *location-dependent invalidation*). If it is a cache hit but the cached content is obsolete or invalid, or it is a cache miss, the cache manager requests the data from the server via on-demand access. When the requested data item arrives, the cache manager returns it to the user and retains a copy in the cache. The issue of *cache replacement* arises when the free cache space is not enough to accommodate a data item to be cached. It determines the victim data item(s) to be dropped from the cache in order to allocate sufficient cache space for the incoming data item.

Survey of Related Work

This section reviews the existing studies on cache invalidation and replacement strategies for mobile clients. Most of them were designed for general data services and only a few addressed the caching issues for location-dependent data. Temporal-dependent invalidation has been studied for many years (Barbara & Imielinski, 1994; Cao, 2000; Wu, Yu, & Chen, 1996). To carry out temporal-dependent invalidation, the server keeps track of the update history (for a reasonable length of time) and sends it, in the form of an invalidation report (IR), to the clients, either by periodic/aperiodic broadcasting or upon individual requests from the clients. In the basic IR approach, the server broadcasts a list of IDs for the items that have been changed within a history window. The mobile client, if active, listens to the IRs and updates its cache accordingly. Most existing temporal-dependent invalidation schemes are variations of the basic IR approach. They differ from one another mainly in the organization of IR contents and the mechanism of uplink checking. A good survey can be found in Tan et al. (2001).

Semantic data caching has been suggested for managing location-dependent query results (Dar, Franklin, Jonsson, Srivatava, & Tan, 1996; Lee, Leong, & Si, 1999), where a cached result is described with the location associated with the query. Unfortunately, the possibility was not explored that a cached data value may be valid for queries issued from locations different from that associated with the original query. As demonstrated in Zheng, Xu, and Lee (2002), the exploration of this possibility can significantly enhance the performance of location-dependent data caching. As a matter of fact, the invalidation information in the proposed methods (to be discussed later in this chapter) can be considered a kind of semantic description, which could improve cache hit rates.

Cache replacement policies for wireless environments were first studied in the *broadcast disk* project (Acharya et al., 1995; Acharya, Franklin, & Zdonik, 1996). In Acharya et al. (1995), the PIX policy takes into consideration both data access probability and broadcast frequency during replacement. In Khanna and Liberatore (2000), the Gray scheme makes replacement decisions based on both data access history and retrieval delay. Motivated by a realistic broadcast environment, an optimal cache replacement policy, called Min-SAUD, was investigated in Xu, Hu, Lee, and Lee (2004). The Min-SAUD policy incorporates

various factors that affect cache performance, that is, access probability, retrieval delay, item size, update frequency, and cache validation delay.

In the studies on location-dependent data caching, data-distance based cache replacement policies, Manhattan distance (Dar et al., 1996) and FAR (Ren & Dunham, 2000), have been proposed. Under these two policies, the data that is farthest away from the client's current location is removed during replacement. However, data distance was considered alone and not integrated with other factors such as access probability. Moreover, they did not consider the factor of valid scope area.

CACHING FOR LOCATION-BASED SERVICES

Location-Dependent Cache Invalidation

When the client moves around, location-dependent data cached at a mobile client may become invalid with respect to the new location. The procedure of verifying the validity of location-dependent data with respect to the current location is referred to as *location-dependent cache invalidation*. To perform location-dependent invalidation efficiently, the idea is to make use of validity information of data instances. Specifically, the server delivers the valid scope along with a data instance to a mobile client and the client caches the data as well as its valid scope for later validity checking. The strategy involves two issues, namely validity checking time and validity information organization. Since a query result depends on the location specified with the query only, it is suggested to perform validity checking for a cached data instance until it is queried. For validity information organization, a number of schemes have been proposed (Zheng et al., 2002; Xu, Tang, & Lee, 2003). The proposed schemes can be classified into two categories according to the underlying location model employed. This section introduces two methods, that is, implicit scope information (ISI) and caching-efficiency-based method (CEB), for a symbolic and geometric location model respectively.

Implicit Scope Information (ISI)

Assume a wireless-cell-ID-based symbolic location model. Under the ISI scheme, the server enumerates the scope distributions of all items and numbers them sequentially. The valid scopes within a scope distribution are also numbered sequentially. For any instance of data item *i*, its valid scope is specified by a 2-tuple (SDN_i, SN_i), where SDN_i is the scope distribution number and SN_i denotes the scope number within this distribution. The 2-tuple is attached to a data instance as its valid scope. For example, suppose there are three different scope distributions (see Table 1) and data item 4 follows distribution 3. If item 4 is cached from cell 6 (i.e., CID = 6), then SDN_4 = 3 and SN_4 = 3. This implies that item 4's instance is valid in cells 6 and 7 only.

It can be observed that the size of the validity information for a data instance is small and independent of the actual number of cells in which the instance is valid. Another observation is that a set of data items may share the same scope distribution. As such, the number of scope distributions could be much smaller than the number of items in the database.

At the server-side, a *location-dependent IR* is periodically broadcast in each cell. It consists of the ordered valid scope numbers (SN) for each scope distribution in the cell. For example, in cell 8, the server broadcasts {8, 3, 4} to mobile clients, where the three numbers are the SN values in cell 8 for scope distributions 1, 2, and 3, respectively (see Table 1).

The validity checking algorithm for item *i* works as follows. After retrieving a location-dependent IR, the client compares the cached SN_i with the SDN_i-th SN in the location-dependent IR received. If they are the same, the cached data

Table 1. An example of data items with different distributions

Cell ID	1	2	3	4	5	6	7	8	9	10	11	12
Scope Distribution (SDN) #1	1	2	3	4	5	6	7	8	9	10	11	12
Scope Distribution (SDN) #2	1			2			3			4		
Scope Distribution (SDN) #3	1			2		3		4			5	

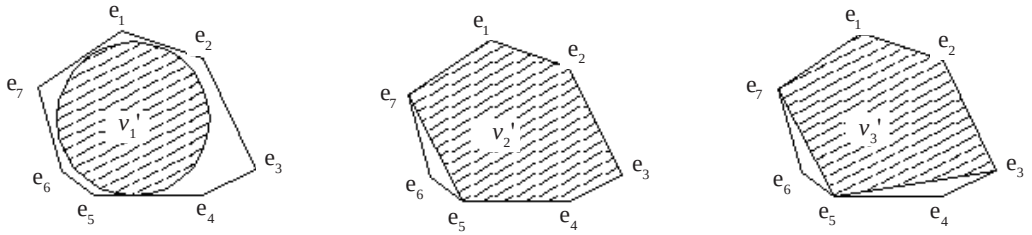
instance is valid. Otherwise, the data instance is invalid. For example, in cell 8, the client checks for the cached instance of data item 4 whose $SDN_4 = 3$ and $SN_4 = 3$. In the broadcast report, the SDN_4-th (i.e., third) *SN* equals to 4. Therefore, the client knows that the cached instance is invalid. The performance analysis conducted in Xu et al. (2003) shows that the ISI method performs close to an optimal strategy which assumes perfect location information is available on mobile clients.

Caching-Efficiency-Based Method (CEB)

This section discusses location-dependent cache invalidation strategies for a geometric location model. Under this model, there are two basic schemes for representing valid scopes, that is, *polygonal endpoints* and *approximate circle* (Zheng et al., 2002). However, these two schemes perform poorly due to either high overhead or imprecision of the invalidation information. To enhance performance, a generic *caching-efficiency-based* (CEB) method for balancing the overhead and the knowledge of valid scopes was proposed in Zheng et al. (2002).

In the CEB method, a new metric *caching efficiency* was introduced. Suppose that the valid scope of a data instance is *v*, and v_i' is a subregion contained in *v* (see Figure 1). Let *s* be the data size, $A(v_i')$ the area of any scope of v_i', and $O(v_i')$ the storage overhead needed to record the scope v_i'. The caching efficiency of the data instance with respect to a scope v_i' is defined as follows:

Figure 1. An example of possible candidate valid scopes ($v = p(e_1,e_2,...,e_7)$)



(a)v_1'=inscribed circle of *v* (b)$v_2' = p(e_1, e_2, e_3, e_4, e_5, e_7)$ (c)$v_3' = p(e_1, e_2, e_3, e_5, e_7)$

$$E(v_i') = \frac{A(v_i')/A(v)}{(s + O(v_i')/s} = \frac{A(v_i')s}{A(v)(s + O(v_i')} \quad (1)$$

Let v_i' be the approximated scope information stored in the client cache. Assuming that the cache size is infinite and the probabilities of a client issuing queries at different locations are uniform, $A(v_i')$ / $A(v)$ is the data instance's cache hit ratio when the client issues the query within the valid scope v. In contrast, $(s + O(v_i'))$ / s is the normalized overhead for achieving such a hit ratio. The rationale behind this definition is as follows. When none of the invalidation information is cached, $E(v_i')$ is 0 because the cached data is completely useless; $E(v_i')$ increases with more invalidation information attached. However, if too much overhead is therefore introduced, $E(v_i')$ would decrease again. Thus, a generic method for balancing the overhead and the precision of invalidation information works as follows:

- For a data instance with a valid scope of v, given a candidate valid scope set $V' = \{v_1', v_2', ..., v_k'\}$, $v_i' \subseteq v$, $1 \le i \le k$, the CEB method chooses the scope v_i' that maximizes caching efficiency $E(v_i')$ as the valid scope to be attached to the instance.

Figure 1 illustrates an example where the valid scope of the data instance is $v = p(e_1,e_2,...,e_7)$, and v_1', v_2', v_3' are three different subregions of v, $A(v_1')$ / $A(v)$ = 0.788, $A(v_2')$ / $A(v)$ = 0.970, and $A(v_3')$ / $A(v)$ = 0.910 . Assume that the data size s is 128 bytes, 8 bytes are needed to represent an endpoint, and 4 bytes for the radius of an inscribed circle; hence $O(v)$ = 56, $O(v_1')$ = 12, $O(v_2')$ = 48, and $O(v_3')$= 40. Thus, $E(v)$ = 0.696, $E(v_1')$ = 0.721, $E(v_2')$ = 0.706, and $E(v_3')$= 0.694. As a result, v_1' is chosen as the valid scope to be attached to the data instance. The simulation based evaluation demonstrates that the CEB method is very effective and outperforms other invalidation methods (Zheng et al., 2002).

Cache Replacement Policies

Because a mobile client has only limited cache space, cache replacement is another important issue to be tackled in client cache management. In traditional cache replacement policies, access probability is considered the most important factor that affects cache performance. A probability-based policy is to replace the data with the least access probability. However, in LBS, besides access probability, there are two other factors, namely *data distance* and *valid scope area*, which have to be considered in cache replacement strategies.

Generally, a promising cache replacement policy should choose as its victim the data item with a low access probability, a small valid scope area, and a long distance if data distance is also an influential factor. This section presents two cost-based cache replacement policies, PA and PAID, which integrate the three factors that are supposed to affect cache performance. The discussions are based on a geometric location model.

- **Probability Area (PA):** As the name suggests, the cost of a data instance under this policy is defined as the product of the access probability of the data item and the area of the attached valid scope. That is, the cost function for data instance j of item i is as follows:

$$c_{i,j} = p_i \cdot A(v'_{i,j}), \quad (2)$$

  where p_i is the access probability of item i and $A(v'_{i,j})$ is the area of the attached valid scope $v'_{i,j}$ for data instance j. The PA policy chooses the data with the least cost as its victim for cache replacement.
- **Probability Area Inverse Distance (PAID):** Compared with PA, this scheme further integrates the data distance factor. For the PAID policy, the cost function for

data instance j of item i is defined as follows:

$$c_{i,j} = \frac{p_i \cdot A(v'_{i,j})}{D(v'_{i,j})}, \qquad (3)$$

where p_i and $A(v'_{i,j})$ are defined the same as above, and $D(v'_{i,j})$ is the distance between the current location and the valid scope $v'_{i,j}$. Similar to PA, PAID ejects the data with the least cost during each replacement.

Zheng et al. (2002) have evaluated the performance of PA and PAID and demonstrated that PA and PAID substantially outperform the existing policies including LRU and FAR. In particular, consideration of the valid scope area improves performance in all settings, and consideration of the moving direction in calculating data distance is effective only for short query intervals and short moving intervals.

FUTURE TRENDS

Caching of location-dependent data opens up a new dimension of research in mobile computing. As for future work, per user based adaptive techniques can be developed since mobile clients may have different movement patterns. Besides cache invalidation and replacement schemes, it is interesting to investigate *cache prefetching* which preloads data onto the mobile client cache by taking advantage of user mobility. Furthermore, how to incorporate location-dependent data invalidation schemes and semantic caching would be an interesting topic. In addition, battery power is a scarce resource in a mobile computing environment; it is believed that power-aware cache management deserves further in-depth study.

CONCLUSION

LBS has been emerging as the result of technological advances in high-speed wireless networks, personal portable devices, and location positioning techniques. This chapter discussed client cache management issues for LBS. Two location-dependent cache invalidation methods, that is, ISI and CEB, are introduced. The cache replacement issue for location-dependent data was also investigated. Two cache replacement policies, that is, PA and PAID that consider the factors of valid scope area (for both methods) and data distance (for PAID only) and combine these factors with access probability, were presented. With an increasing popularity of LBS, caching of location-dependent data remains a fertile research area that aims to overcome inherent constraints (including power, bandwidth, storage, etc.) in a mobile environment.

KEY TERMS

Cache Invalidation: The procedure of validating whether the cached data is consistent with the master copy at the server.

Cache Replacement: The procedure of finding the victim data item(s) to be dropped from the cache in order to allocate sufficient cache space for an incoming data item.

Location-Based Services (LBS): The services that answer queries based on the locations with which the queries are associate.

Location-Dependent Cache Invalidation: The procedure of verifying the validity of cached location-dependent data with respect to the current location.

Mobile Client: A portable device that is augmented with a wireless communication interface.

Valid Scope: The area within which the data instance is the only answer with respect to a location-dependent query.

Valid Scope Distribution: The collective set of valid scopes for a data item.

Wireless Cell: The radio coverage area in which a mobile client can communicate with the wireless infrastructure.

Chapter 7.34
Location-Aware Query Resolution for Location-Based Mobile Commerce:
Performance Evaluation and Optimization

James E. Wyse
Memorial University of Newfoundland, Canada

ABSTRACT

Location-based mobile commerce incorporates location-aware technologies, wire-free connectivity, and locationalized Web-based services to support the processing of location-referent transactions. In order to provide usable transaction processing services to mobile consumers, location-referent transactions require timely resolution of queries bearing transaction-related locational criteria. This research evaluates Wyse's location-aware method of resolving these queries. Results obtained in simulated mobile commerce circumstances (1) reveal the query resolution behavior of the location-aware method, (2) confirm the method's potential to improve the timeliness of transactional support provided to mobile consumers, and (3) identify the method-related adjustments required to maintain optimal levels of query resolution performance. The article also proposes and provides a preliminary evaluation of a heuristic that may be used in efficiently determining the method-related adjustments needed in order to maximize query resolution performance.

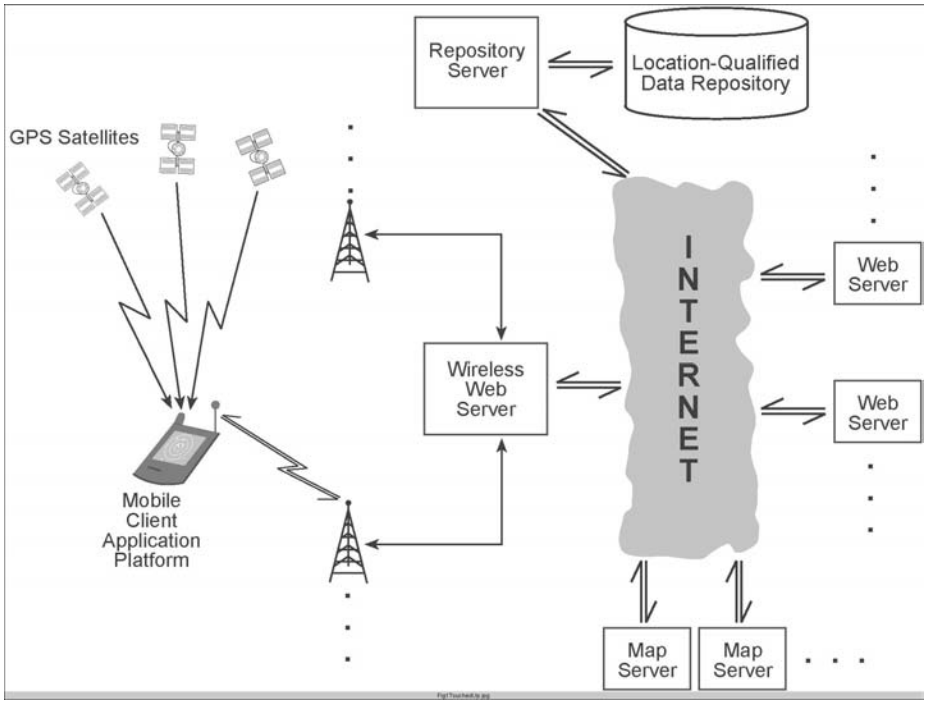
INTRODUCTION

Recent years have witnessed the emergence of transaction-supporting devices directed toward the mobile consumer. Devices range from simple handsets in mobile/cellular phone systems to those involving the convergence of palm-top computing, location-determining technology, and wireless Internet connectivity. Minimally,

devices utilized by mobile consumers must incorporate wireless communication capabilities that permit a significant degree of mobility (Leung & Atypas, 2001; Santami, Leow, Lim, & Goh, 2003). Yuan and Zhang (2003) assert that mobile devices with capabilities extending beyond wireless communication to include those that support location awareness add a "much emphasised … new dimension for value creation" (p. 41) to mobile commerce. Location awareness refers to the capability of a device to obtain data about geographical position and then to use the data to retrieve, select, and report information with respect to that position (Butz, Bauss, & Kruger, 2000). Figure 1 illustrates a location-aware mobile commerce (mcommerce) context in which location-aware applications operating on mobile, GPS-enabled, handheld computing devices avail of wireless connectivity to access a variety of Internet-based servers providing information and functionality to support the transactional activities of mobile consumers.

An essential component in large-scale, location-aware, mobility-supporting applications is a specialized database of transaction-supporting information (Location-Qualified Data Repository, Figure 1). Locational content from the repository is required for the resolution of queries arising from location-referent transactions, transactions in which the relative geographical locations of the prospective transactional parties is a material transactional concern. Siau, Lim, and Shen (2001) and, later, Siau and Shen (2003) call for research on improving the processing of transactional queries in circumstances "where users are constantly on the move and few [end user device] computing resources are available" (p. 13). The research reported here responds to this call; it is

Figure 1. Illustrative configuration of m-commerce components



concerned with the timely processing of queries initiated by location-variant (on-the-move) consumers operating resource-limited devices that must rely on centralized repositories of location-qualified information.

The emergence of m-commerce has spawned several streams of research in areas related to the components shown in Figure 1. Some recent studies with respect to these components have been conducted in such areas as mobile user location determination (McGuire, Plataniotis, & Venetsanopoulos, 2005; Quintero, 2005; Samaan & Karmouch, 2005), mobile device interface design (Lee & Benbasat, 2004), mobile business application design (Gebauer & Shaw, 2004; Khungar & Reikki, 2005), and mobility-related wireless connectivity (Chao, Tseng, & Wang, 2005; Chou & Shin, 2005; Cinque, Cotroneo, & Russo, 2005; Lin, Juang, & Lin, 2005; Xu, Shen, & Mark, 2005; Yeung & Kwok, 2005). Research in areas related to mobile commerce has also addressed in various ways the issue of query resolution in mobile computing environments. Kottkamp and Zukunft (1998) developed and evaluated a mobility aware cost model for location-aware query optimization in the context of mobile user location management; Choy, Kwan, and Hong (2000) proposed a distributed database system architecture to support query processing in mobile geographical applications; Lee and Ke (2001) conducted a cost analysis of strategies for query processing in a mobile commerce environment; Lee, Xu, Zheng, and Lee (2002) and Huang, Lin, and Deng (2005) dealt with the validity of query results and the efficiency of query processing through improved mobile device cache management; while Wyse (2003) proposed a location-aware method of locations repository management to support m-commerce transactions. It is the latter area that is addressed here; specifically, this article examines the extent to which query resolution time is affected by implementing Wyse's (2003) location-aware method (LAM) of managing a server-based locational repository.

A synopsis of LAM is provided in Appendix A. The method employs the linkcell construct as a means of transforming locational coordinates in geographical space to spatially-oriented table names in relational space. A specialized search method operates on the transformation to resolve location-referent queries. Results from Wyse's (2003) work suggest that the method significantly improves query resolution performance over that realized from the use of naïve enumerative methods. However, the work notes that the location-aware method's performance was evaluated in limited circumstances (small repository sizes, fixed geographical coverage, limited business categorization) and also points out that the effect of variations in linkcell size on resolution performance remains unexamined. Wyse (2003) also contemplated the existence of a linkcell size that would optimize query resolution performance but offered no approach that would result in its determination.

These contemplations and limitations give rise to four questions to be addressed by the research reported here: (1) Will the location-aware method yield resolution performance profiles consistent with those previously observed when greater repository sizes, larger variations in geographical coverage, and differing business category sets are used? (2) How is linkcell size related to query resolution performance? (3) Is there a specific linkcell size that will optimize resolution performance? and (4) How might an optimal linkcell size be determined? Before providing results that address these questions, some discussion is warranted on the nature of the problem for which the location-aware method is proposed as a solution.

THE REPOSITORY MANAGEMENT PROBLEM

Mobile consumers frequently require information presented in some consumer-centric proximity

pattern on the locations of businesses offering products and services in a specified business category. Consumer-centric information may be requested in relation to questions such as *Where is the nearest health food outlet? How far away am I from a golf course? Where am I situated in relation to a medical facility?* The queries arising from such questions must incorporate both a product/service criterion (e.g., medical facility) and a consumer-centric, distance-related criterion (e.g., nearest). Two distinctions between product/service-related criteria and consumer-centric, distance-related criteria have implications for the management of locational repositories. First, product/service-related criteria are invariant with respect to a mobile consumer's location, while consumer-centric, distance-related criteria are not. Nievergelt and Widmayer (1997) recognize the distinction between the two types of criteria and point out its efficiency-related implication: "Spatial data differs from all other types of data in important respects. Objects are embedded in an Euclidean space … and most queries involve proximity rather than intrinsic properties of the objects to be retrieved. Thus, data structures developed for conventional database systems are unlikely to be efficient" (p. 186). The issue of efficiency is readily seen in the second distinction: product-service attribute values are patently resident in a repository, while consumer-centric, distance-related attribute values must be derived from the locational attributes of both the consumer and the business location offering a consumer-targeted product or service. Thus, each change in a consumer's geographical position in general will necessitate a redetermination of values for an appropriate consumer-centric, distance-related attribute.

The requirement to continually requery a repository and redetermine a consumer-centric proximity pattern places an extensive burden on server-side repository functionality. For a given level of computational capability, continual requerying and redetermination eventually results in service time degradation as repository sizes increase and/or as the number of consumers increases and/or as consumers more frequently change geographic positions. Increased repository size (i.e., a richer set of locations from which the mobile consumer may obtain information on targeted products or services) would likely attract greater numbers of mobile consumers. In turn, greater numbers of consumers would likely motivate the construction of larger, more richly populated repositories, which then would attract even more consumers (Lee, Zhu, & Hu, 2005). Thus, a cycle is created wherein repository sizes will increase and, in the absence of mitigating investments in computational capability, result in a degradation of the service times experienced by consumers accessing the repository. Thus, an important challenge facing those who are tasked with managing large-scale locational repositories is one of minimizing the increase (i.e., degradation) in the service times realized by mobile consumers while at same time enriching (i.e., enlarging) the location-qualified data repository available to mobile consumers.

SOLUTION APPROACHES

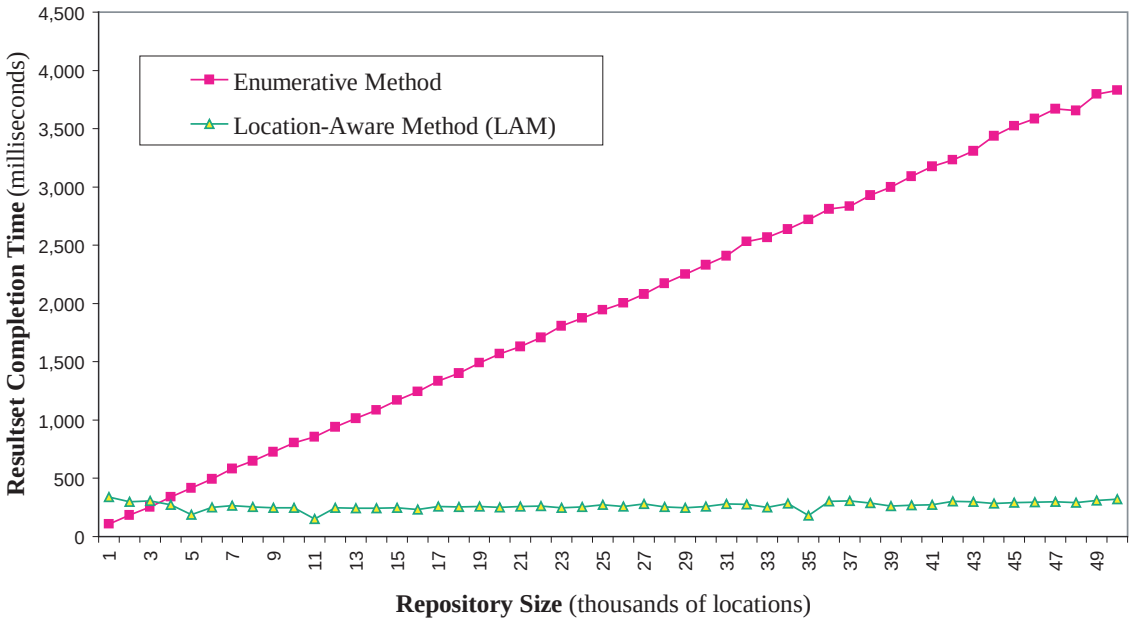
The nature of queries initiated by mobile consumers (e.g., Where's the nearest health food outlet?) suggests that the problem of query resolution is conceptually similar to the nearest neighbor (NN) problem, a problem that has received considerable attention in computational geometry. Formally, solutions to the NN problem incorporate constructs and procedures that, when given a set P of n points and a query point q, result in $p \in P$ such that for all $p' \in P$ we have $d(p, q) \leq d(p', q)$ where $d(p', q)$ is the distance between p' and q (Cary, 2001). Several works have developed NN solution algorithms. Arnon, Efrat, Indyk, and Samet (1999), Lee (1999), and Cary (2001) propose solutions from computational geometry, while Kuznetsov (2000) proposes a solution based on

the space-filling curves developed by Sierpinski (1912) and Hilbert (Butz, 1969, 1971). These algorithms yield solution times that improve upon those realized from naïve enumerative methods; however, the solution time derived for each algorithm's execution is positively related to *n*, the number of points in the set *P*.

A mapping of the terms of the NN problem to aspects of the problem of managing location-qualified data repositories gives *n* as the repository size, *P* as the repository, *q* as the mobile consumer's location, *p* as the nearest location, and $d(p', q)$ as the distance-related attribute needed to resolve the consumer's query. This mapping formalizes the dependency of this attribute on both the consumer's location (q) and the locational attributes contained in the repository for each location, p'. Furthermore, the condition that $d(p, q) \leq d(p', q)$, for all $p' \in P$, implies that new distance-related attribute values are required for all records whenever there is any change in the consumer's location (q). This condition in combination with algorithm solution times that are related positively to repository size (n) corroborates the assessment reached in the previous section that the service times associated with mobile consumer access to location-qualified data repositories will degrade as repository size is increased.

An important aspect of mitigating service time degradation is the use of a retrieval algorithm that does not require a determination of $d(p', q)$, for all $p' \in P$. In other words, new distance-related attribute values need not be calculated for all locations in the repository whenever a new q is encountered (i.e., whenever the mobile consumer changes location). The solution algorithms developed in computational geometry generally take this approach; however, these algorithms have

Figure 2. Resultset completion times for enumerative and location-aware methods by repository size



Source: Wyse (2003), p. 135. Reproduced with the permission of Inderscience Publishers.

solution times that increase, albeit in varying ways, as the size of the set P increases. In this report, the location-aware solution approach to be examined also does not require a determination of $d(p', q)$, for all $p' \in P$. As shown by the LAM curve in Figure 2, the method appears capable of producing resultset completion times (RCTs) that, for practical purposes, are invariant with respect to repository size.[1] Thus, LAM implementations would appear to be useful in mitigating the service time degradation attributable to increases in repository size that otherwise would be realized from implementing an enumerative method of query resolution. The Enumerative Method curve shown in Figure 2 illustrates the degradation that otherwise would occur.[2]

Although the goal of the location-aware method's solution algorithm essentially is the same as that for the NN solution algorithms of computational geometry, the method does not draw upon that discipline's constructs and procedures. Instead, as seen in Appendix A, the method relies upon relational database constructs and functionality combined with the structure of a commonly used convention for designating geographical position (latitude and longitude) to construct and manipulate specialized relational tables (linkcells). Previous work used a simulation-based methodology to demonstrate that the location-aware method is a potential solution (illustrated by the LAM curve in Figure 2) to an important problem (illustrated by the Enumerative curve in Figure 2) associated with managing locational repositories. In what follows, the location-aware method is evaluated in simulated circumstances that extend beyond those of previous work. Also, in contrast to previous work, an important task here is determining the existence of a specific (optimal) linkcell construction that would maximize the resolution performance of queries associated with location-referent transactions.

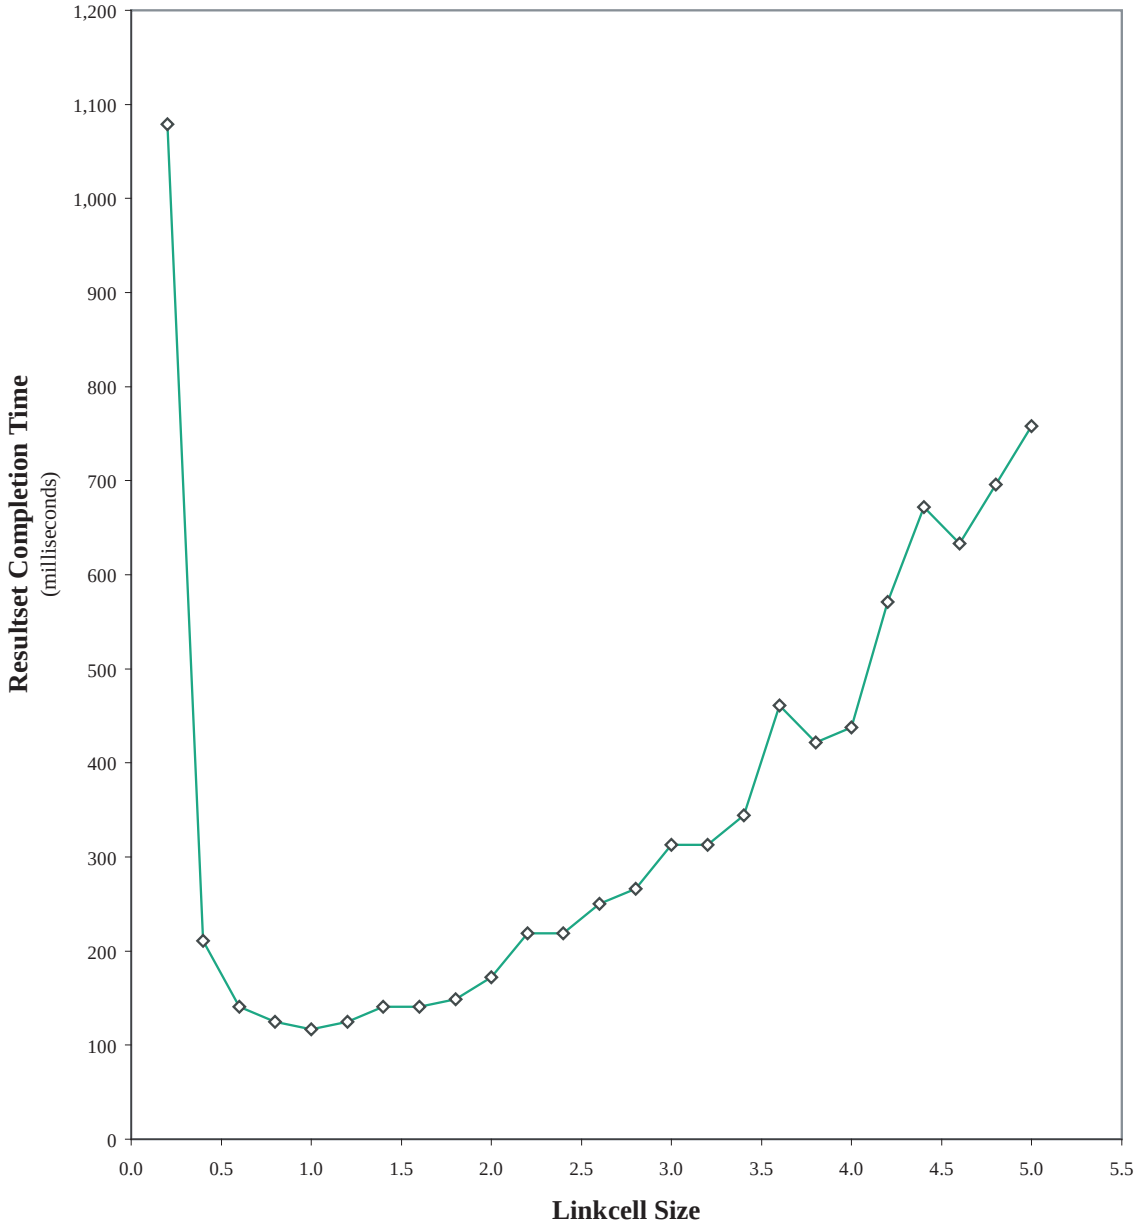
OPTIMAL LINKCELL SIZE DETERMINATION: METHODS AND MEASURES

Appendix A discusses the formulation of the linkcell construct and defines linkcell size. The appendix also notes that changes in linkcell size result in redistributions of repository locations among linkcells and that these redistributions may have a substantial impact on query resolution performance. Wyse's (2003) work on simulated locational repositories used a single linkcell size of 1.0 for all of the various analyses that were conducted, and beyond noting that other linkcell sizes could be used, the work provided little guidance on searching for an optimal linkcell size. Thus, a brute force search strategy was employed in preliminary work here wherein linkcell size (arbitrarily) took an initial value of 0.2 and then was incremented successively (also arbitrarily) by 0.2. This sequence of linkcell sizes was imposed on a series of simulated repository scenarios, each of which consisted of a selected number of randomly generated locations, a selected area of geographical coverage, and a selected number of product-service categories. Resultset completion times (RCTs) were determined at each linkcell size based on queries initiated from 100 randomly chosen locations within the selected geographical area. As previously noted, RCT values indicate the time taken to extract a set of repository locations that represent a resolution of a consumer-initiated query.

Figures 3 and 4 show results from two of the many scenarios on which a brute force search was carried out. All scenarios revealed what appeared to be an optimal linkcell size; however, the optimal value was not generally the same across the scenarios. An optimal linkcell size of 1.0 was revealed for the scenario in Figure 3, while an optimal linkcell size of 0.8 was revealed for the scenario in Figure 4. In its comparison of RCT

performance profiles for the Enumerative and LAM methods, Figure 4 illustrates that a poorly chosen linkcell size (e.g., 5.0) could result not just in RCTs that are far removed from optimal values but also in the complete loss of any query resolution performance advantage attributable to LAM. Table 1 provides the results of an analysis of the scenario whose RCT profile appears in Figure 3.

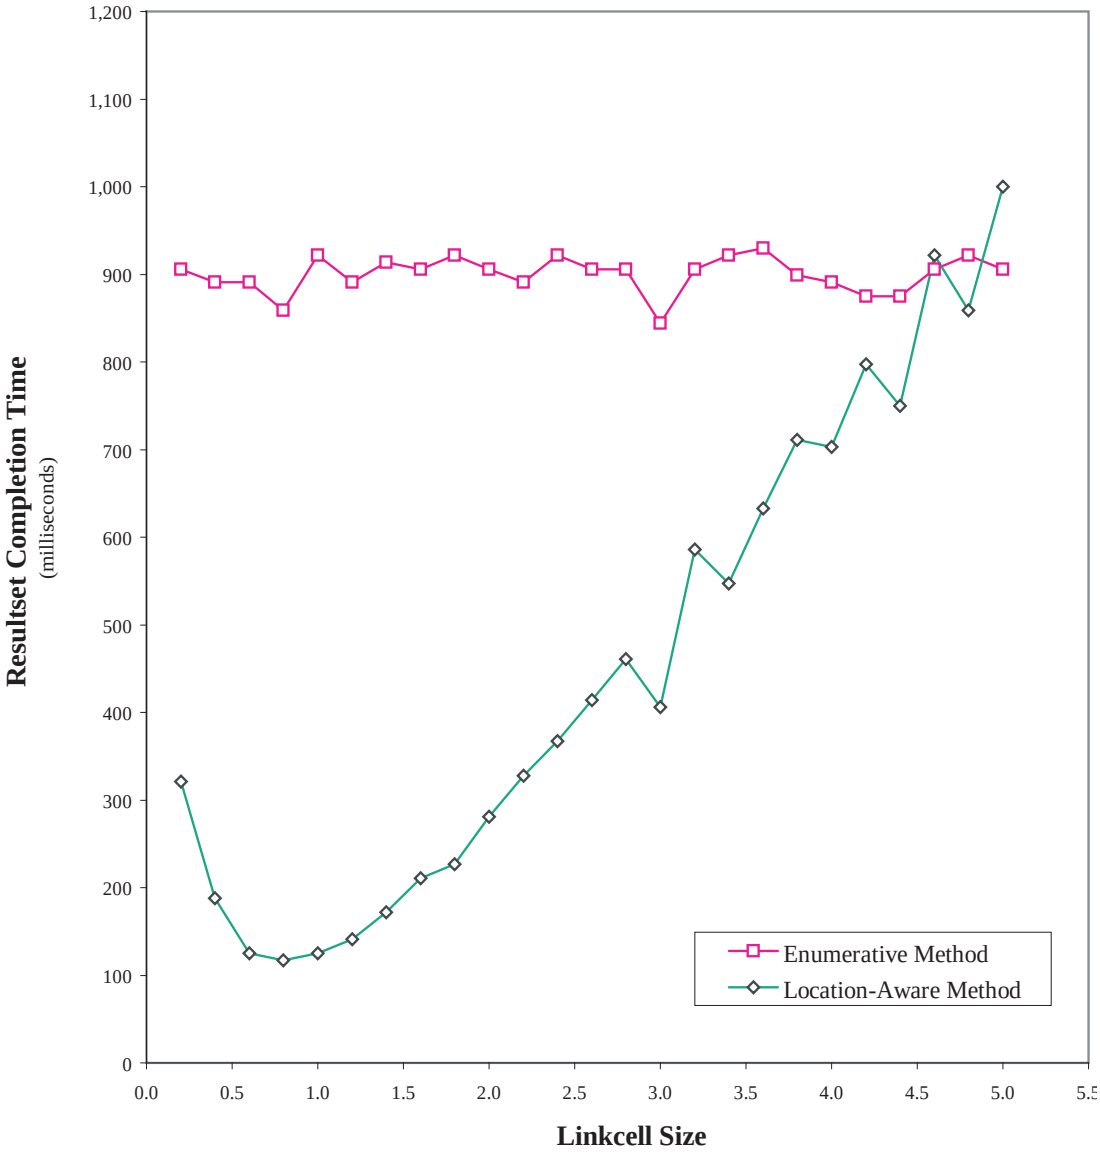
Figure 3. LAM resultset completion times (RCT_L) by linkcell size (Repository: 100,000 locations, 100 product-service categories, area N30° to N50° and W070° to W130°)



The following discussion of the table's content will provide more detail on the simulation-based methodology used to (1) obtain resultset completion times, (2) explain the mechanism underlying the existence of an optimal linkcell size, and (3) illustrate the trade-offs in repository space consumption required to realize LAM-related gains in query resolution performance.

The methodology used to generate the RCT curves in Figures 3 and 4 is similar to the simula-

Figure 4. Resultset completion times for location-aware and enumerative methods by linkcell size (Repository: 100,000 locations, 200 product-service categories, area N35° to N45° and W080° to W110°)



tion-based approach used in Wyse's (2003) evaluative work on the location-aware method. Software called the Linkcell Performance Analyzer (LPA) was developed that (1) generates locational repositories with varying numbers of locations ranging over various geographical areas and referencing different product-service category lists; (2) creates linkcell sets based on repository locations with respect to a specified linkcell size; (3) assembles and processes simulated queries bearing randomly assigned product-service criteria for randomly located consumers; (4) resolves the location-referent queries using both enumerative (E) and location-aware (L) methods; and (5) determines resultset completion times (RCT_E and RCT_L) for each method. Table 1 provides LPA-generated results associated with the RCT_L values plotted in Figure 3. The first column shows the series of linkcell sizes (from 0.2 to 5.0) for the plot's horizontal axis. Columns 6 through 10 report RCT_L statistics derived from simulated queries originating from 100 randomly chosen mobile consumer locations. All five statistics reveal their lowest resultset completion time values at a linkcell size

of 1.0, a result reflected in the plot of RCT_L's 50th percentile values, as shown in Figure 3.[3]

The results shown in Columns 2, 3, and 4 of Table 1 help to explain why an optimal linkcell size can be expected to exist. Column 2 indicates the maximum number of linkcells that may be created for each linkcell size, a quantity that varies from 30,000 linkcells for a linkcell size of 0.2 down to 48 linkcells for a linkcell size of 5.0. The numbers in Column 2 are the result of allocating the linkcell size along the (arbitrarily chosen) horizontal and vertical extents that encompass a repository's locations. For a linkcell size of 0.2, the chosen extents potentially result in 30,000 relational tables (linkcells), a number that is the product of 300 linkcell size intervals along the repository's horizontal extent (W070° to W130°) and 100 linkcell size intervals along its vertical extent (N30° to N50°).[4] Not all of the maximum number of relational tables may be actually created. Appendix A's discussion on linkcell creation indicates that a relational table corresponding to a linkcell only comes into existence when its name is derived from a repository location. Thus, the number of linkcells actually generated from a repository's locations may be less than the maximum potential number of linkcells. Such an outcome is seen in Column 3 of Table 1, where, for a linkcell size of 0.2, only 28,923 of the 30,000 possible linkcells actually were created.

Column 4 of Table 1 reports the mean number of linkcell entries for each linkcell size and is obtained by dividing the total number of repository locations (100,000, in this case) by the number of linkcells (Column 3) created from those locations. Comparing Columns 3 and 4 will help to reveal why an optimal linkcell size exists. Note that small linkcell sizes result in the generation of large numbers of small relational tables, while large linkcell sizes result in the generation of small numbers of large relational tables. Consequently, as linkcells initially increase in size, query resolution times will improve, because fewer relational tables have to be examined in order to find a location in the targeted product-service category; however, with each increase in linkcell size, query resolution times also will degrade, because more relational table entries have to be examined in order to find a location in the targeted product-service category. The optimal linkcell size corresponds to the size at which the RCT gains from processing fewer linkcells begin to be overwhelmed by the RCT losses incurred from processing linkcells with greater numbers of linkcell entries. The RCT statistics in Columns 6 through 10 of Table 1 indicate that such gains and losses combine to reveal an optimal linkcell size of 1.0.

The generation of a relational table for each linkcell results in the database containing a location-qualified data repository that is larger than the database for the same repository without linkcells. Column 11 of Table 1 shows the disk space consumed by the location-qualified repository for each linkcell size. A linkcell size of 0.2 results in the generation of 28,923 linkcells and requires disk storage of approximately 358 MB, an amount of storage that is almost 47 times the 7.7 MB storage amount consumed by the repository without linkcells (referred to as Repository x-Linkcells in Column 12 of Table 1). At the other end of the linkcell range, a linkcell size of 5.0 results in the generation of 48 linkcells and requires 11.0 MB of storage, or 1.4 times as much storage as the repository x-linkcells. At the observed optimal linkcell size of 1.0, the repository requires 2.9 times the storage required by the repository x-linkcells. In general, disk storage consumption (manifested here by repository xlinkcell multiples) varies across the scenarios investigated. With respect to the results shown in Figure 4, the optimal linkcell size requires a repository that is 2.0 times the repository x-linkcells. Thus, service-level performance gains from using the location-aware method come at a repository space cost that may be several multiples of that required when using the enumerative method.

The fifth column of Table 1 reports the probability $P_{TC}(S)$ that a linkcell of size S contains an

entry for a location in the product-service category that is targeted by the mobile consumer. For example, if a mobile consumer initiates a query about the nearest medical facility, which has been assigned, for instance, a product-service code of *C016*, then the targeted category TC is *C016*, and with reference to the results in Table 1 for a linkcell size of 0.2, we see that $P_{C016}(0.2)$ is 0.03. Note that *C016* is one of the 100 product-service categories used to qualify the 100,000 locations in Table 1's repository scenario. As will be explained next, values for $P_{TC}(S)$ were generated to facilitate the search for optimal linkcell sizes in a way that is more computationally efficient and managerially usable than searches using brute force methods.

Formally, the probability that a linkcell contains a location in the targeted product-service category TC is given by:

$$P_{TC}(S) = 1 - (1 - n_{TC}/N)^{N/CS} \qquad (I)$$

where n_{TC} is the number of locations in the repository with product-service code TC,
N is the total number of locations contained in the repository,
C_S is the number of linkcells of size S created from the repository's N locations, and
N/C_S is the mean number of entries per linkcell.

Equation (I) was formulated on the following basis:

(1) As noted in Appendix A, the manner in which linkcells are created, populated, and destroyed results in one and only one linkcell entry for each repository location. Thus, the probability that any linkcell entry bears the targeted product-service code is the ratio of the number of locations in the repository in the targeted product-service category to the total number of locations in the repository in all product-service categories, or n_{TC} /N.

(2) As also noted in Appendix A during its discussions on repository structure, each location in the repository is qualified by one and only one product-service code. Thus, each linkcell entry either bears the targeted product-service code or it does not. Consequently, if the probability that a linkcell entry bears TC is n_{TC} /N, then the probability that a linkcell entry does not bear TC is (1 - n_{TC} /N).

(3) The probability that none of a linkcell's entries bears the targeted code is given by the product of the probabilities that each linkcell entry does not bear the targeted code, or in other terms, (1 – n_{TC} /N) x (1 – n_{TC} /N) x …. x (1 – n_{TC} /N), which may be estimated by $(1 - n_{TC}/N)^{N/CS}$.

(4) Hence, the probability that at least one of the linkcell entries bears the targeted code is $(1 - (1 - n_{TC}/N)^{N/CS})$, which is the right-hand side of Equation (I).

An important assumption underlining Equation (I) is the independence of the probabilities of occurrence of repository entries in the same product-service category with respect to geographical location. Since the repositories used here are generated based on a uniform distribution of locations within specified geographical boundaries, the assumption of independent probabilities in this respect is not an unreasonable one, given the simulated circumstances employed here. However, as discussed later in this article, this assumed distribution of locations may not hold in many practical mcommerce circumstances.

An examination of various repository scenarios indicated the potential usefulness of Equation (I) in identifying optimal linkcell sizes more efficiently and conveniently than doing so using a brute force identification approach. Instead of starting the search for an optimal linkcell size at some arbitrary point, the search was started at the linkcell size S that results in a value of $P_{TC}(S)$ that

is close to 0.5.[5] Letting $S_{0.5}$ denote the linkcell size such that $P_{TC}(S_{0.5}) \cong 0.5$, then for smaller linkcell sizes ($S < S_{0.5}$), a linkcell examined during a LAM search probably does not contain a location in the consumer-targeted category; however, for larger linkcell sizes ($S > S_{0.5}$), an examined linkcell probably does contain a consumer-targeted location. Thus, somewhere in the vicinity of $S_{0.5}$, it starts to become likely that a linkcell contains a consumer-targeted location, and consequently, searches for RCT minima that begin at $S_{0.5}$ are likely to more quickly identify an optimal linkcell size than would brute search methods.

An analysis of selected repository scenarios suggested that searches initiated at a linkcell size of $S_{0.5}$ were effective in quickly identifying optimal linkcell sizes. In the case of the repository scenario associated with Table 1 and Figure 3, Equation (I) yields $S_{0.5} \cong 0.9$ as the starting linkcell size. The optimal linkcell size revealed by brute force is close by at 1.0. With respect to repository scenario associated with Figure 4, Equation (I) yields $S_{0.5} \cong 0.7$, a linkcell size that is close to the 0.8 linkcell size revealed by brute force. Application of Equation (I) in the context of these two and various other repository scenarios indicated its usefulness in improving the efficiency of optimal linkcell size identification. However, the repository scenarios were chosen arbitrarily, and the results of their analysis provide only a rough indication of both the existence of linkcell size optima and Equation (I)'s managerial usefulness in optima identification.

In the following sections, more comprehensive and rigorous assessments of the existence of linkcell size optima are reported with respect to (1) changes in repository size, (2) variations in a repository's geographical coverage, and (3) differences in the product-service code sets used to qualify a repository's locations. A simulation-based methodology is used wherein RCT curves like those seen in Figures 3 and 4 are constructed. The methodology is similar to that used previously but with three differences: (1) RCT curves are based on finer linkcell size increments (0.1 vs. 0.2); (2) RCT values are obtained using a greater number of randomized consumer-initiated queries (200 vs. 100); and (3) the $S_{0.5}$-method is used to initiate a brute force search for linkcell size optima.

LINKCELL SIZE OPTIMA AND REPOSITORY SIZE VARIABILITY

Figure 5 plots resultset completion times (RCTs) for repositories that range in size from 20,000 to 500,000 locations. Each point is the 50th percentile of RCTs for 200 queries issued by mobile consumers from randomly selected geographical locations. Table 2 presents linkcell sizes, P_{TC} values, and RCTs for the repositories associated with Figure 5. The geographical coverage area and the number of product-service categories remained fixed for all repository sizes. Three RCT curves are shown in Figure 5(a): (1) the RCT_E values plotted in the topmost curve (and shown in Column 5 of Table 2) are the result of using enumerative query resolution; (2) the RCT_L values plotted in the bottom curve (and shown in Column 6 of Table 2) are the result of using location-aware query resolution and doing so at each repository's observed optimal linkcell size (seen in Column 3 of Table 2); and, (3) the RCT_L values plotted in the middle curve are the result of using location-aware query resolution, but here, the linkcell size is the same for all repository sizes and is set to the observed optimal linkcell size (3.3) for a repository size of 20,000 locations (note the first linkcell size shown in Column 3 of Table 2).

Managerially, the middle curve in Figure 5 reflects a circumstance in which linkcell size is set to its optimal value with respect to some initial repository size and then remains unchanged (unmanaged) as repository growth occurs. The results indicate that an unmanaged linkcell size results in query resolution time deterioration as a repository grows in size. As seen from the point

500,000	0.6	0.9	0.80	4741	141	0.7	156

on the curve for a 500,000-location repository, RCT_L eventually reaches 953 ms when linkcell size remains unmanaged (i.e., unoptimized), a query resolution time that is almost seven times the RCT_L of 141 ms for a managed (i.e., optimized) linkcell size. This outcome suggests that in order to continually realize optimal query resolution performance, linkcell size must be adjusted as repository size changes.

The observed optimal linkcell size S_{OPT} was identified for each repository size as the linkcell size corresponding to the minimum observed RCT. The search for S_{OPT} began at a linkcell size of $S_{0.5}$ (determined from Equation (I)) and then was expanded above and below $S_{0.5}$ in increments of 0.1 until an RCT minimum was discernable. Table 2 shows $S_{0.5}$ (Column 2) and the observed optimal linkcell size S_{OPT} (Column 3) for each repository size. Comparisons of the values of $S_{0.5}$ and S_{OPT} provide an indication of the usefulness of $S_{0.5}$ in the identification of S_{OPT}. Of the 25 repository sizes, $S_{0.5}$ is within 0.3 for 22 of them and never exceeds 0.7 for any of them. Furthermore, for 24 of the 25 repository sizes, S_{OPT} >=

$S_{0.5}$, a result consistent with the previously noted implication of Equation (I) that when $S > S_{0.5}$, a linkcell examined in the course of a location-aware search probably contains a location in the consumer-targeted category. Column 4 of Table 2 shows values for $P_{TC}(S_{OPT})$, the probability that a linkcell contains a consumer-targeted location at the observed optimal linkcell size. These probability figures are consistent with the expectation that optimal linkcell sizes would be rarely observed at a $P_{TC}(S_{OPT})$ value that is substantially below 0.50.

A comparison of the RCT curves in Figure 5(a) indicates that the methodology used to identify S_{OPT} yields linkcell sizes that result in query resolution performance that is not only superior to the conventional enumerative methodology but also substantively independent of repository size. Although these two outcomes are managerially important, the methodology by which they are realized is likely to be regarded as cumbersome and inconvenient by those tasked with repository management. Thus, a simpler method was sought that would be more readily applicable in practical circumstances. In the course of the investigation, it was observed that the use of linkcell sizes derived from Equation (I) with $P_{TC}(S)$ set to the mean value of $P_{TC}(S_{OPT})$ results in RCT values that, for practical purposes, very closely approximate the minimal RCT values associated with optimal linkcell sizes. With respect to the probability values in Column 4 of Table 2, the mean value of $P_{TC}(S_{OPT})$ is 0.63. Column 7 of Table 2 shows the linkcell sizes that result from setting Equation (I) = 0.63 and solving for S. Column 8 presents the RCT values that result from using the linkcell sizes in Column 7. The bottom curve in Figure 5(b) is a plot of Column 8's RCT values. A comparison of Columns 8 and 6 in Table 2 or, equivalently, a comparison of the bottom curves in Figures 5(a) and 5(b) reveals minimal differences in query resolution performance across the examined range of repository sizes.

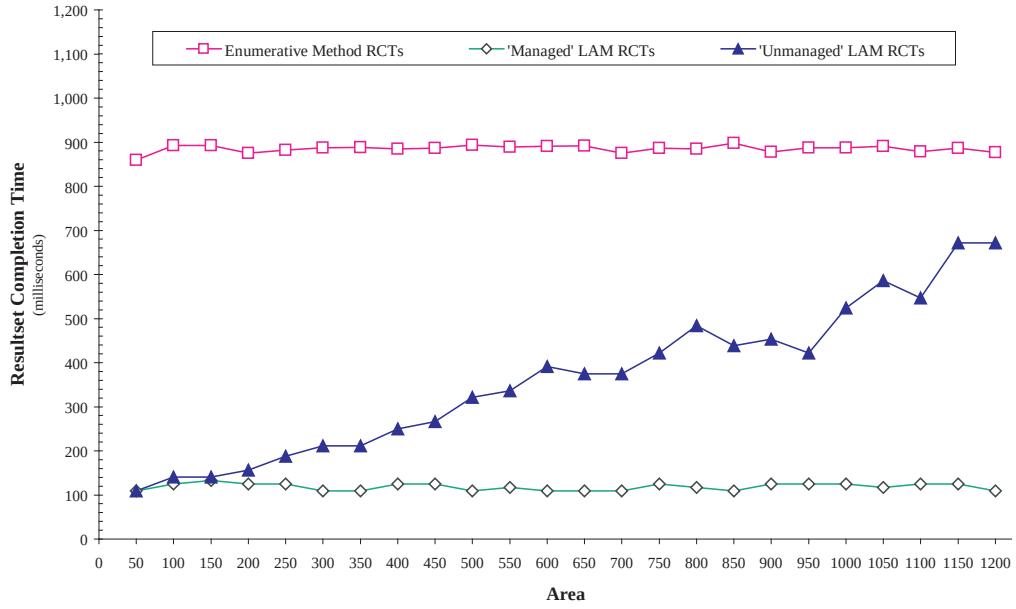
The outcomes associated with $P_{TC}(S) = 0.63$ suggest that it may be the basis for a practical method of directly identifying performance-optimizing linkcell sizes and one with considerable potential to simplify the repository manager's task of linkcell size determination. Furthermore, the method is structured to an extent that it may be captured in a software module in a straightforward manner. Although this method of linkcell size identification is more convenient and considerably less cumbersome than both the brute force method and the $S_{0.5}$method, its applicability relies heavily on the validity of setting $P_{TC}(S)$ = mean value of $P_{TC}(S_{OPT})$ as a basis for estimating optimal linkcell sizes. The next two sections provide further assessments of validity in this respect through examinations of circumstances in which (1) geographical area is varied and (2) different product-service code sets are used to qualify the repository's locations. Consistent with the methodological approach used previously, optimal linkcell sizes are identified in both cases, first by the method of constructing RCT curves at successive incremental linkcell sizes in the region of $S_{0.5}$ (i.e., the $S_{0.5}$method) and, second, by the method of determining linkcell sizes with reference to the mean value of $P_{TC}(S_{OPT})$.

LINKCELL SIZE OPTIMA AND AREA VARIABILITY

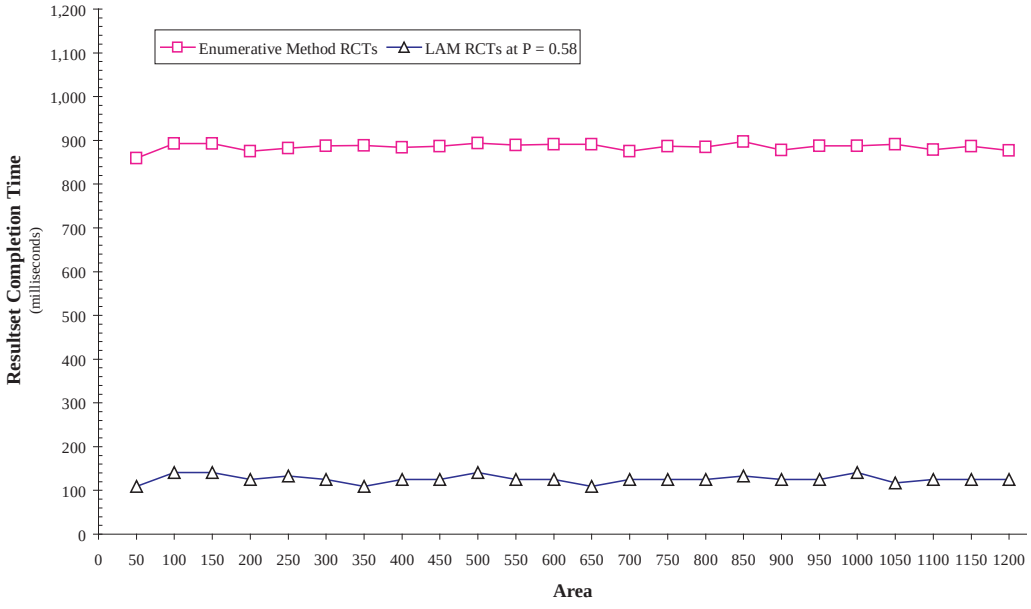
Figure 6 plots resultset completion times for a 100,000-location repository whose area of geographical coverage varies over a sequence of 24 areas of increasing size beginning (arbitrarily) with an area bounded by N35° to N40° and W095° to W105° (or 5 degrees of latitude by 10 degrees of longitude) and ending (arbitrarily) with area bounded by N30° to N50° and W070° to W130° (or 20 degrees of latitude by 60 degrees of longitude). For convenience, the areas of increasing size are shown in Figure 6 by the product of their latitu-

Figure 6. Resultset completion times by geographical area

(a) RCT_E, "Unmanaged" RCT_L, and "Managed" RCT_L



(b) RCT_E and RCT_L at Mean $P_{TC}(S_{OPT})$



dinal and longitudinal extents (50, 100, 150, …, 1200). Note that in contrast to the results seen in Figure 5, RCT_E values in this case are essentially invariant with respect to geographical area. A consideration of the enumerative method's procedural details will reveal that although changes in either the number of locations or the number of product-service codes will affect query resolution time, changes in geographical area will not. Changes in geographical area affect the range of values over which the coordinates of locations will vary; however, there is no additional computational burden placed on the enumerative method when different coordinate values are assigned to the same repository locations. Thus, RCT_E values are substantively invariant with respect to geographical area.

Three curves are shown in Figure 6(a): (1) the topmost curve is the result of using the enumerative method; (2) the bottom curve is the result of using the location-aware method and doing so for each area's observed optimal linkcell size; and (3) the middle curve is the result of using the location-aware method with the linkcell size unchanged for all areas from the optimal linkcell size (0.3) for the smallest area. The third curve reflects a circumstance in which linkcell size is set at its optimal value with respect to some arbitrary area and then remains unchanged (unmanaged) as the repository's area of geographical coverage is enlarged. Here, as before, unmanaged linkcell sizes result in query resolution time degradation. As seen from the point on the RCT curve for the largest area, RCT_L eventually reaches 672 ms when linkcell sizes remain unoptimized, a query resolution time that is more than six times the RCT_L of 109 ms for an optimized linkcell size.

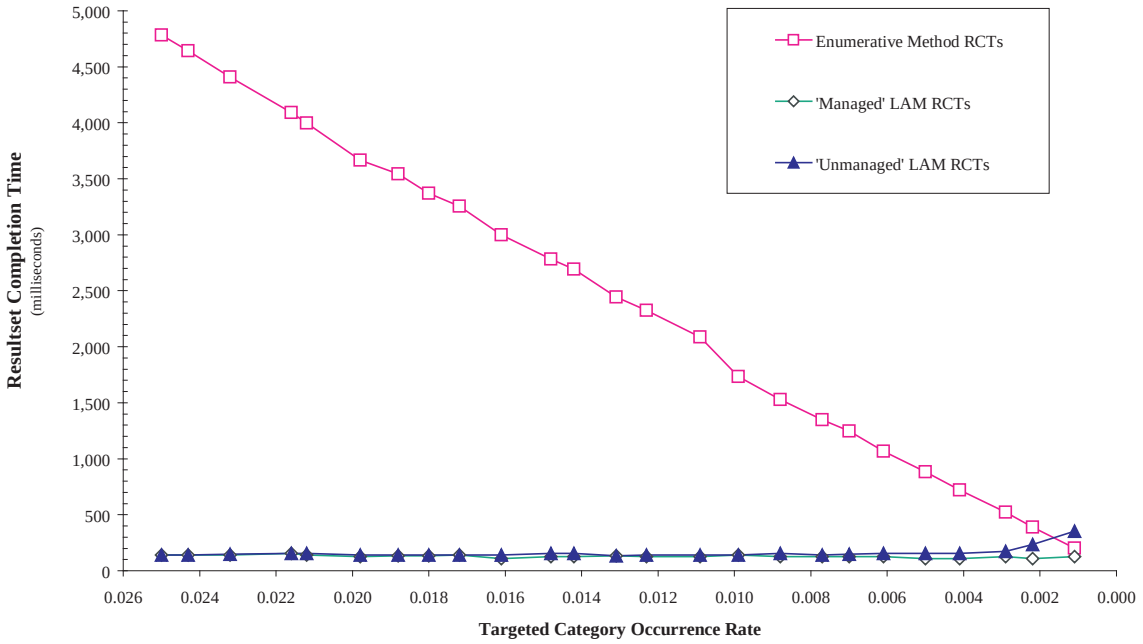
The results presented in Figure 6 (a) indicate that in the observed range of geographical coverage, the location-aware method yields query resolution performance that is superior to the enumerative method. However, the results also indicate that linkcell size must be adjusted appropriately in order to maintain this performance as the area of geographical coverage changes. As previously discussed with respect to repository size, this leads to a consideration of how the burden associated with determining linkcell size optima may be lightened by using the method of assigning sizes with reference to the mean value of $P_{TC}(S_{OPT})$. For the 24 areas associated with the results shown in Figure 6, the mean of $P_{TC}(S_{OPT})$ is 0.58. The bottom curve in Figure 6(b) shows the RCT_L values that result for each of the 24 areas when a linkcell size S is determined by setting Equation (I) =0.58. The curve suggests that as was seen previously for repository size, the application of this method results in linkcell sizes giving query resolution performance that is approximately the same as the performance realized when linkcell sizes are determined by the more cumbersome method of constructing RCT curves at successive incremental linkcell sizes in the region of $S_{0.5}$. Thus, the method of assigning linkcell sizes with reference to the mean value of $P_{TC}(S_{OPT})$ appears to be as useful in the context of variations in geographical area as it is for variations in repository size. Next, the method is assessed with respect to variations in the rate of occurrence of a specific product-service code or, in other words, with respect to using different product-service category sets to qualify repository locations.

LINKCELL SIZE OPTIMA AND TARGETED CATEGORY OCCURRENCE RATE VARIABILITY

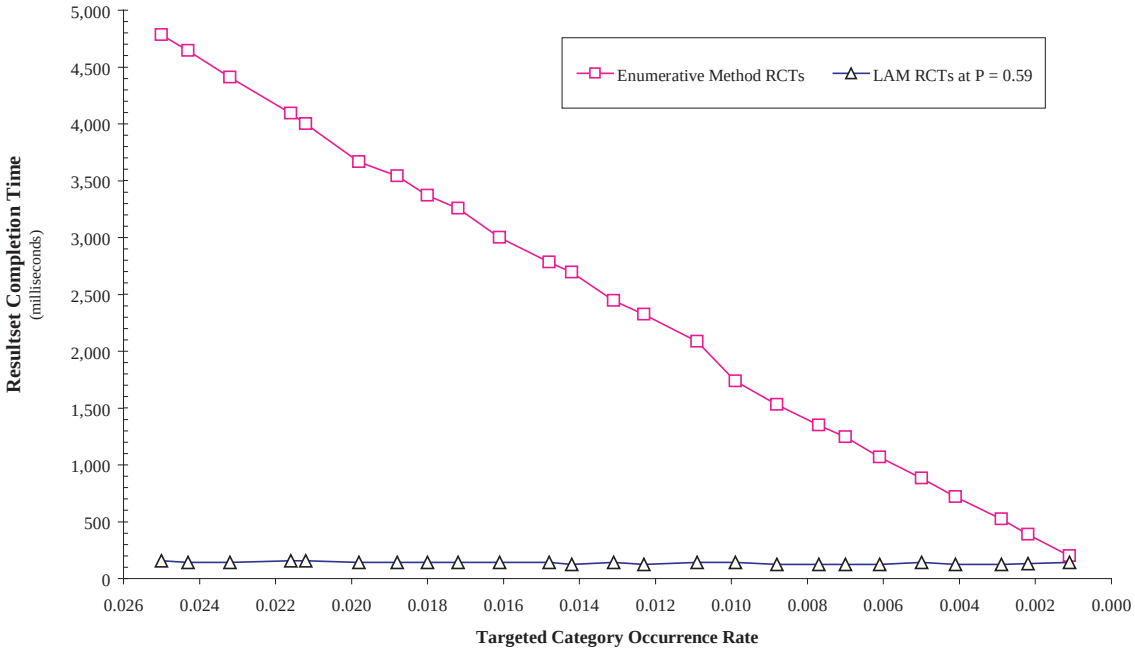
Figure 7 plots RCTs for variations in targeted category occurrence rate (TCOR) for a 100,000-location repository whose locations are distributed over a fixed geographical area (the largest of those in Figure 6). TCOR refers to the portion of a repository's locations falling into the product-service category that is targeted by a mobile consumer's query. The results seen previously in Figures 5 and 6 are based on repositories in which

Figure 7. Resultset completion times by targeted category occurrence rate

(a) RCT_E, "Unmanaged" RCT_L, and "Managed" RCT_L



(b) RCT_E and RCT_L at Mean $P_{TC}(S_{OPT})$



the product-service category attribute for each location was assigned randomly from a set of 200 product-service category codes {C001, C002, …, C200}. This, in effect, resulted in the rate with which each product-service code occurs across a repository's locations of 1/200 or, equivalently, a fixed TCOR of 0.005. The RCT values shown in Figure 7 correspond to TCOR rates that vary from 0.0250 to 0.0011. The first TCOR value indicates that 0.250 of a repository's locations bear a product-service category code matching a specific consumer-targeted category and corresponds to using a set of 40 product-service codes wherein each code occurs with equal frequency across the repository's locations. The latter TCOR value indicates that 0.0011 of a repository's locations bear a product-service category code matching a specific consumer-targeted category and corresponds to using a set of 909 equally occurring product-service codes.[6]

Figure 7(a) presents the usual three curves: (1) the topmost curve shows enumerative results; (2) the bottom curve shows optimized LAM results; and (3) the middle curve shows unmanaged LAM results. As before, the third curve reflects a circumstance in which linkcell size is set to an optimal value with respect to some initial TCOR value (0.0250, in this case) and then remains unadjusted as TCOR is changed. It is readily seen that in this case, unmanaged linkcell sizes have little appreciable effect on query resolution performance except at the smallest TCOR levels. Not until TCOR reaches 0.002 (500 product-service categories) is there a substantive separation of the two curves. The separation attains a managerially significant level in the vicinity of 0.001 (1,000 product-service categories), in which RCT_L eventually reaches 352 ms, a query resolution time that not only exceeds RCT_E but is also 2.5 times the optimized RCT_L value of 141ms.

As with the analyses respecting repository size and geographical area, TCOR-related analysis also leads to a consideration of how the repository manager's burden associated with determining linkcell size optima may be lightened by using the method of assigning sizes with reference to the mean value of $P_{TC}(S_{OPT})$. For the 24 TCOR values associated with the results shown in Figure 7, the mean of $P_{TC}(S_{OPT})$ is 0.59. The bottom curve in Figure 7(b) shows the RCT_L values that result for each of the 24 TCOR values when a linkcell size S is derived from Equation (I) = 0.59. The curve suggests, as was seen previously for repository size and geographical area, that the application of this method produces linkcell sizes resulting in query resolution performance that is approximately the same as the performance realized when linkcell sizes are determined by the $S_{0.5}$-method. Thus, the method of assigning linkcell sizes with reference to the mean value of $P_{TC}(S_{OPT})$ appears to be as valid in the TCOR context as it is in the previous two contexts.

LINKCELL SIZE DETERMINATION IN PRACTICAL M-COMMERCE OPERATIONAL CIRCUMSTANCES

The results obtained from the mean value approach to estimating optimal linkcell size in all three contexts, along with the observation that the three mean values (0.63, 0.58, and 0.59) are close to their average value of 0.60, suggest that reasonably valid estimates for optimal linkcell sizes may be obtained for practical purposes in a wide range of circumstances on the basis that:

$$P_{TC}(S) = 1 - (1 - n_{TC}/N)^{N/CS} = 0.6 \qquad \text{(II)}$$

The validity of Equation (II)'s use in linkcell size determination was assessed further by revisiting the RCT_L curves with linkcell sizes determined using Equation (II). Doing so yields query resolution performance profiles that are essentially the same as those shown in Figures 5(b), 6(b), and 7(b). Although the linkcell sizes identified through Equation (II) generally differed from those identified by the $S_{0.5}$-method, differ-

ences were minimal, and the resulting values for S always fell in a range of linkcell sizes associated with a region of minimal RCT values. Regions in this respect may be discerned in Figures 3 and 4; minimal RCT values are seen in the region in Figure 3 where linkcells vary in size from about 0.8 to 1.2 and in Figure 4 for sizes from about 0.5 to 1.0. These results, along with those seen previously, form the basis for proposing that Equation (II) represents, to this point, a heuristic with some potential to assist repository managers in realizing close-to-optimal query resolution performance and, ultimately, improved support to the location-referent transactions initiated by mobile consumers.

FURTHER WORK

Although the query resolution optimization methods used here appear to be potentially useful in realizing m-commerce service-level improvements, further work is needed in several respects. Preliminary results obtained when the location-aware method is implemented on a different computing platform reveal essentially the same RCT-linkcell size relationships that are reported here but with different RCT values. Such differences are expected and are largely attributable to differences in computational speed; however, further work is needed in order to confirm the validity of the results obtained across a greater variety of computing platforms and operational environments.

Although the major dimensions (repository size, geographical area, product-service category) associated with a location-qualified data repository in an m-commerce operational setting were addressed here, LAM's performance and the methods by which it may be optimized should be assessed in a wider variety of dimensional circumstances. For example, preliminary results from situations in which mobile consumers initiate location-referent queries from locations that are well beyond a repository's geographical boundaries suggest that values greater than 0.6 should be used to identify optimal linkcell sizes. However, these results also suggest that $P_{TC}(S) \rightarrow 0.6$ as a consumer's geographical position approaches the repository's boundaries. Further work in this respect will validate the method's applicability and assess its performance when repositories with highly localized information are used to support the location-referent queries of remotely located consumers.

Finally, the robustness of $P_{TC}(S)$'s application in circumstances that relax the assumption of a uniform distribution of locations in the same product-service category requires further examination. Product and service providers of similar type often choose locations in a non-independent, proximal fashion (e.g., law firms in legal districts, fast-food services in shopping mall food courts, retail petroleum outlets at highway intersections, etc.). Consequently, pending the outcome of further research in this respect, the use of uniform distributions of locations should be considered an important limitation on the applicability of this study's results in practical mcommerce operational settings.

CONCLUSION

Although any application of the research reported here must be done with an appreciation of its limitations and/or await the outcome of further work, the results obtained address to varying extents the four questions posed at the beginning of this article. With respect to question (1), the query resolution performance profiles observed in previous work for an invariant linkcell size are not inconsistent with those observed here. However, the present study's variant linkcell size combined with its examination of larger repository sizes, variability in geographical area, and differing product-service code sets permitted the observation of appreciable performance

degradation in unmanaged circumstances. With respect to question (2), the relationship of query resolution time to linkcell size reflects the varying dominance of two types of retrieval tasks: (1) the processing of relatively large numbers of generally smaller relational tables when linkcell sizes are small and (2) the processing of relatively small numbers of generally larger relational tables when linkcell sizes are large. The interplay of the two retrieval task types consistently produces U-shaped performance curves similar to those presented earlier in this article.

With respect to question (3), the U-shaped relationship between query resolution time and linkcell size always revealed a distinct minima or narrow region of minima indicative of the existence of a specific linkcell size that could be associated with maximum query resolution performance. Finally, with respect to question (4), the optimal linkcell size may be determined in three ways: (1) by brute force, (2) by the $S_{0.5}$-method, and (3) by solving for S such that $P_{TC}(S) = 0.6$. While the first two linkcell size determination methods were effective in revealing optimal linkcell sizes, the logistics associated with their application limits the feasibility of their deployment in practical mcommerce settings. The third method is considerably less burdensome to deploy, and results suggest that it is a useful linkcell size determination heuristic; however, further work is needed in order to assess its robustness in the face of departures from underlying assumptions and its predictive ability in a wider range of mcommerce circumstances.

ENDNOTES

1 Resultset Completion (RCT) is the time required to extract a set of repository locations that represents a resolution of a consumer-initiated query.

2 The Enumerative Method of query resolution used both in Wyse's (2003) work and in the work here is a method that (1) selects repository locations in the consumer-targeted, product-service category, (2) calculates consumer-relative distances for each of the selected locations, (3) orders the selected locations in ascending order by consumer-relative distance, and (4) presents the first N ordered locations as the resultset that resolves the consumer's query about the nearest N locations (N = 3, in the case of Figure 2).

3 Wyse (2003) used mean RCT values as the primary statistic to measure query resolution performance. The work here has chosen to use 50th percentile RCT values as the primary performance measurement statistic, a choice that (1) minimizes the disproportionate impact of the infrequent occurrence of very large query resolution times and (2) is consistent with widely used approaches to measuring and monitoring the response time performance for computer-based transaction processing.

4 Formally, the number of linkcells C_S for linkcell size S is given by:

$$C_S = ([UVL/S] - [LVL/S] + 1)([LHL/S] - [RHL/S] + 1)$$

where UVL and LVL represent the upper and lower limits, respectively, of the vertical extent of the geographical area covered by the repository's locations, and LHL and RHL represent the left and right limits, respectively, of the area's horizontal extent. Note that [ ] denotes the greatest integer function.

5 The phrase *close to* is used deliberately, since the integrally valued components of $P_{TC}(S)$, primarily C_S, result in values for $P_{TC}(S)$ that rarely will equal 0.5.

6 Two observations with respect to Figure 7 are worthy of note: (1) query resolution times are measured at unequal TCOR intervals, and (2) RCT_E values decline as TCORs become smaller (or, equivalently, product-service code sets become larger). With respect to the first observation, the TCOR value of 0.0011 (or 909 equally occurring product-service codes) resulted when LPA was supplied with a TCOR of 0.0010 (or 1,000 equally occurring product-service codes) and then asked to generate a repository in which locations are randomly assigned a product-service code. This randomized assignment results in realized (or output) TCORs that are close to, but generally different from,

supplied (or input) TCORs. Thus, unlike the RCT values seen in Figures 5 and 6, those in Figure 7 generally do not occur at equal intervals. With respect to the second observation, note that increases in the number of product-service codes for a given repository size will result in fewer repository locations in each product-service category, including the category matching the category criteria on a consumer's query. A consideration of the enumerative method's procedural details will reveal that this circumstance results in fewer instances in which consumer-relative distances must be determined as well as in smaller resultsets that must be sorted. Thus, as TCORs become smaller, the enumerative method completes its work faster, an outcome reflected in the downward sloping curve for RCT_E.

APPENDIX A: THE LOCATION-AWARE METHOD (LAM)

A synopsis of LAM's fundamental components is given in the following with respect to (1) the requisite structure of a location-qualified data repository, (2) a formulation of the linkcell construct, (3) the general tasks of linkcell management (creation, modification, and destruction), and (4) the method's linkcell-based retrieval process. Although LAM's essentials are disclosed here, many of the method's details are not presented. A more comprehensive description may be found in Wyse (2003).

Repository Structure: The solution approach assumes that the location-qualified data repository is a relational database table containing a tuple for each repository location minimally consisting of four attributes: (1) a unique identifier for the location; (2) a horizontal coordinate (e.g., the location's longitude); (3) a vertical coordinate (e.g., the location's latitude); and (4) a code that qualifies each location in terms of its product or service offering. Table A1 provides a sample repository segment.

The Linkcell Construct: LAM relies on a set of auxiliary relational tables referred to as linkcells, which contain subsets of repository content and take relational table names derived from the coordinates of repository locations. Figure A1 illustrates the relationship between a repository's locations and its linkcells. Linkcells are generated based on the existence of repository locations within the area covered by the linkcell. A linkcell's name is derived from the coordinates of any location situated within the linkcell. In order to illustrate how this is accomplished, note L_i's coordinates in Figure A1. Truncating the fractional part of each coordinate yields the linkcell name. Thus, the name for the linkcell containing location L_i is H07V02. The same linkcell name also would be derived from the other two locations contained in the linkcell with L_i.

Formally, a linkcell with the relational table name HNNVMM will contain all repository locations with horizontal coordinate values HNN.0 through HNN.999··· and vertical coordinate values VMM.0 through VMM.999···. Each linkcell in its relational table form contains a tuple for each of the repository locations encompassed by the linkcell's

boundaries. Linkcells, manifested as relational tables, could appear as shown in Table A2 (with longitudes treated as horizontal coordinates and latitudes treated as vertical coordinates).

Linkcells may be varied in size through coordinate scaling. For example, if L_i's positional coordinates are scaled by 10, for example, from (H07.530, V02.321) to (H075.30, V023.21), then L_i's linkcell name becomes H075V023, and the linkcell now relates to a smaller geographical area. The smaller area in this instance consists of vertical and horizontal extents that are $1/10^{th}$ of the respective extents of the original linkcell. (It also should be noted that the coordinate scaling factor for a linkcell's horizontal component may differ from the factor used for its vertical component.) The use of a different linkcell size does not affect the relative positions of a repository's locations; however, using a different linkcell size results in a redistribution of a repository's locations among the linkcells. As seen in the results reported here, redistributions attributable to changes in linkcell size often have a substantial impact on query resolution performance.

Linkcell Creation, Modification, and Destruction: Whenever a location is added to the repository, a linkcell name is derived from the location's horizontal and vertical coordinates. The derived name is used in order to query the repository about the existence of a corresponding linkcell (relational table). If the linkcell exists, the location's identifier and category code are placed in the linkcell. If the linkcell does not exist, it is created using the name derived from the location's coordinates, and then, the location's identifier and category code are placed in the newly created linkcell. Whenever a location is removed from the repository, a linkcell name is derived from the location's coordinates. Since the location had been previously added to the repository, it is assumed that a linkcell with the derived name already exists. If the location to be removed is the only remaining location in the linkcell, then the linkcell is destroyed. If the linkcell contains

other location identifiers, then only the attribute tuple for the location to be removed is deleted, and the linkcell is not destroyed. Thus, linkcells (manifested as relational tables) are created, destroyed, and modified dynamically, based on repository changes.

Retrieval Procedure: The procedure relies on two types of linkcells: (1) the Core Linkcell and (2) the Cursor Linkcell. The Core Linkcell obtains its name using the method described previously but not from the coordinates of any repository location; instead, from the coordinates of the

consumer's location. The structure of the linkcell construct and its manifestation as a relational table implies that once the Core Linkcell's name is obtained, the search procedure is immediately aware of the existence or non-existence of any repository locations in the immediate vicinity of the consumer. Once derived, the Core Linkcell name remains unchanged; however, the Cursor Linkcell takes on a sequence of linkcell names that effectively moves it in search of other locations in the vicinity of the consumer.

The procedure begins by setting the Cursor Linkcell name to the Core Linkcell name and then checking for the existence of a linkcell with the same name as the Cursor Linkcell. If the linkcell exists, its contents are examined for locations with a category code equal to that sought by the query. When a sought-after location is found, its attributes are placed in the query's resultset. The procedure then expands the search area by generating a sequence of Cursor Linkcell names. This is done by systematically changing the numeric sections of the Cursor Linkcell's name using a sequence that "moves" the Cursor Linkcell around the Core Linkcell in a clockwise pattern. Whenever the Cursor Linkcell is assigned a new name, it checks for the existence of a linkcell with its currently assigned name. If the linkcell exists, then its contents are examined, and the actions outlined previously are performed, resulting in further locations being accumulated in the query resultset. The numbers in parenthesis in Figure A2 indicate the sequence in which relational table names are generated and examined in the course of a clockwise movement of the Cursor Linkcell. The search area may be expanded further by moving the Cursor Linkcell through a layer of linkcells on the outer periphery of the linkcells previously examined. This outward-spiraling, clockwise-moving process continues until the sought-after number of locations is found.

Chapter 7.35
Data Dissemination in Mobile Environments

Panayotis Fouliras
University of Macedonia, Greece

ABSTRACT

Data dissemination today represents one of the cornerstones of network-based services and even more so for mobile environments. This becomes more important for large volumes of multimedia data such as video, which have the additional constraints of speedy, accurate, and isochronous delivery often to thousands of clients. In this chapter, we focus on video streaming with emphasis on the mobile environment, first outlining the related issues and then the most important of the existing proposals employing a simple but concise classification. New trends are included such as overlay and p2p network-based methods. The advantages and disadvantages for each proposal are also presented so that the reader can better appreciate their relative value.

INTRODUCTION

A well-established fact throughout history is that many social endeavors require dissemination of information to a large audience in a fast, reliable, and cost-effective way. For example, mass education could not have been possible without paper and typography. Therefore, the main factors for the success of any data dissemination effort are supporting technology and low cost.

The rapid evolution of computers and networks has allowed the creation of the Internet with a myriad of services, all based on rapid and low cost data dissemination. During recent years, we have witnessed a similar revolution in mobile devices, both in relation to their processing power as well as their respective network infrastructure. Typical representatives of such networks are the 802.11x for LANs and GSM for WANs.

In this context, it is not surprising that the main effort has been focusing on the dissemination of multimedia content–especially audio and video, since the popularity of such services is high, with RTP the de-facto protocol for multimedia data transfer on the Internet. Although both audio and video have strict requirements in terms of packet jitter (the variability of packet delays within the same packet stream), video additionally requires

significant amount of bandwidth due to its data size. Moreover, a typical user requires multimedia to be played in real-time, (i.e., shortly after his request, instead of waiting for the complete file to be downloaded; this is commonly referred to as *multimedia streaming.*

In most cases, it is assumed that the item in demand is already stored at some server(s) from where the clients may request it. Nevertheless, if the item is popular and the client population very large, additional methods must be devised in order to avoid a possible drain of available resources. Simple additional services such as fast forward (FF) and rewind (RW) are difficult to support, let alone interactive video. Moreover, the case of asymmetric links (different upstream and downstream bandwidth) can introduce more problems. Also, if the item on demand is not previously stored but represents an ongoing event, many of the proposed techniques are not feasible.

In the case of mobile networks, the situation is further aggravated, since the probability of packet loss is higher and the variation in device capabilities is larger than in the case of desktop computers. Furthermore, ad-hoc networks are introduced, where it is straightforward to follow the bazaar model, under which a client may enter a wall mart and receive or even exchange videos in real time from other clients, such as specially targeted promotions, based on its profile. Such a model complicates the problem even further.

In this chapter, we are focusing on video streaming, since video is the most popular and demanding multimedia data type (Sripanidkulchai, Ganjam, Maggs, & Zhang, 2004). In the following sections, we are identifying the key issues, present metrics to measure the efficiency of some of the most important proposals and perform a comparative evaluation in order to provide an adequate guide to the appropriate solutions.

ISSUES

As stated earlier, streaming popular multimedia content with large size such as video has been a challenging problem, since a large client population demands the same item to be delivered and played out within a short period of time. This period should be smaller that the time t_w a client would be willing to wait after it made its request. Typically there are on average a constant number of requests over a long time period, which suggests that a single broadcast should suffice for each batch of requests. However, the capabilities of all entities involved (server, clients, and network) are finite and often of varying degree (e.g., effective available network and client bandwidth). Hence the issues and challenges involved can be summarized as follows:

- What should the broadcasting schedule of the server be so that the maximum number of clients' requests is satisfied without having them wait more than t_w?
- How can overall network bandwidth be minimized?
- How can the network infrastructure be minimally affected?
- How can the clients assist if at all?
- What are the security considerations?

In the case of mobile networks, the mobile devices are the clients; the rest of the network typically is static, leading to a mixed, hybrid result. Nevertheless, there are exceptions to this rule, such as the ad hoc networks. Hence, for mobile clients there are some additional issues:

- Mobile clients may leave or appear to leave a session due to higher probability of packet loss. How does such a system recover from this situation?

- How can redirection (or *handoff*) take place without any disruption in play out quality?
- How can the bazaar model be accommodated?

BACKGROUND

In general, without prior knowledge on how the data is provided by the server, a client has to send a request to the server. The server then either directly delivers the data (on demand service) or replies with the broadcast channel access information (e.g., channel identifier, estimated access time, etc.). In the latter case, if the mobile client decides so, it monitors the broadcast channels (Hu, Lee, & Lee, 1998). In both cases, there have been many proposals, many of which are also suitable for mobile clients. Nevertheless, many proposals regarding mobile networks are not suitable for the multimedia dissemination. For example, Coda is a file replication system, Bayou a database replication system and Roam a slightly more scalable general file replication system (Ratner, Reiher, & Popek, 2004), all of which do not assume strict temporal requirements.

The basic elements which comprise a dissemination system are the server(s), the clients, and the intermittent network. Depending on which of these is the focus, the various proposals can be classified into two broad categories: Proposals regarding the server organization and its broadcast schedule, and those regarding modifications in the intermittent network or client model of computation and communication.

Proposals According to Server Organization and Broadcasting Schedule

Let us first examine the various proposals in terms of the server(s) organization and broadcasting schedule. These can be classified in two broad classes, namely *push*-based scheduling (or *proactive*) and *pull*-based scheduling (or *reactive*). Under the first class, the clients continuously monitor the broadcast process from the server and retrieve the required data without explicit requests, whereas under the second class the clients make explicit requests which are used by the server to make a schedule which satisfies them. Typically, a hybrid combination of the two is employed with push-based scheduling for popular and pull-based scheduling for less popular items (Guo, Das, & Pinotti, 2001).

Proposals for Popular Videos

For the case of pushed-based scheduling broadcasting schedules of the so-called *periodic broadcasting* type are usually employed: The server organizes each item in segments of appropriate size, which it broadcasts periodically. Interested clients simply start downloading from the beginning of the first segment and play it out immediately. The clients must be able to preload some segments of the item and be capable of downlink bandwidth higher than that for a single video stream. Obviously this scheme works for popular videos, assuming there is adequate bandwidth at the server in relation to the amount and size of items broadcasted.

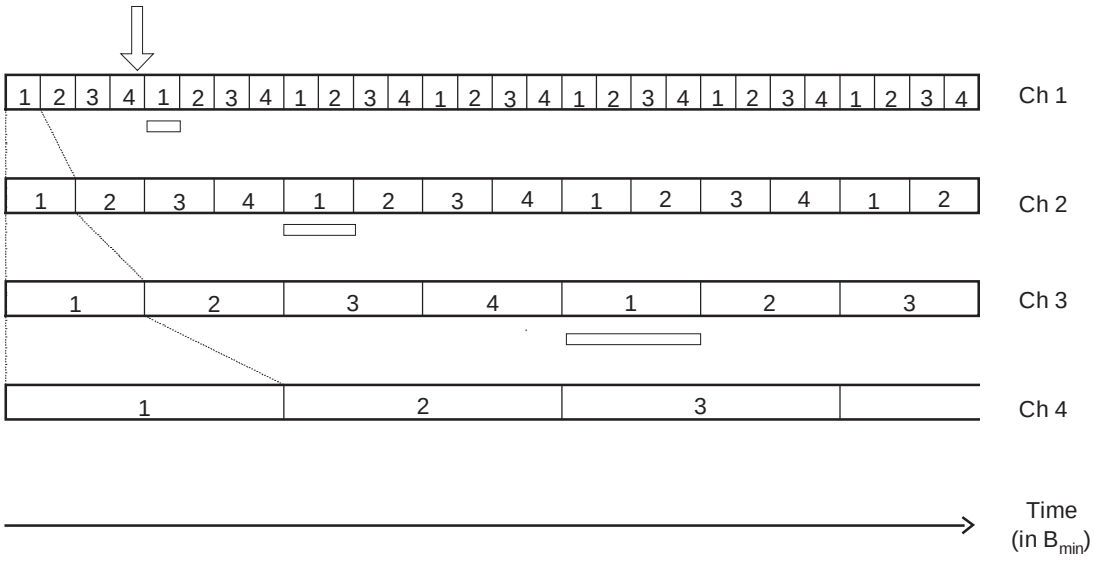
Pyramid broadcasting (PB) (Viswanathan & Imielinski, 1995) has been the first proposal in this category. Here, each client is capable of downloading from up to two channels simultaneously. The video is segmented in s segments of increasing size, so that $s_{i+1}=\alpha \cdot s_i$, where $\alpha = \frac{B}{MK}$ and B is the total server bandwidth expressed in terms of the minimum bandwidth b_{min} required to play out a single item, M the total number of videos and K the total number of virtual server channels. Each channel broadcasts a separate segment of the same video periodically, at a speed higher than b_{min}. Thus, with M=4, K=4 and B=32,

we have α=2, which means that each successive segment is twice the size of the previous one. Each segment is broadcasted continuously from a dedicated channel as depicted in Figure 1. In our example, each server channel has bandwidth $B'=B/K=8 \cdot b_{min}$, which means that the clients must have a download bandwidth of $16 \cdot b_{min}$.

If D is the duration of the video, then the waiting time of a client is at most $M \cdot s_1/B'$. With D = 120 and $K = M = 4$, we have $M \cdot s_1/B' = 4 \cdot 8/8 = 4$ time units. Each segment from the first channel requires 1 time unit to be downloaded, but has a play out time of 8 units. Consider the case that a client requests video 1 at the time indicated by the thick vertical arrow. Here the first three segments to be downloaded are indicated by small grey rectangles. By the time the client has played out half of the first segment from channel 1 it will start downloading the second segment from channel 2 and so on. The obvious drawback of this scheme is that it requires a very large download bandwidth at the client as well as a large buffer to store the preloaded segments (as high as 70% of the video).

In order to address these problems, other methods have been proposed, such as *permutation-based pyramid broadcasting* (PPB) (Aggarwal, Wolf, & Yu, 1996) and *skyscraper broadcasting* (SB) (Hua & Sheu, 1997). Under PPB each of the K channels is multiplexed into P subchannels with P times lower rate, where the client may alternate the selection of subchannel during download. However, the buffer requirements are still high (about 50% of the video) and synchronization is difficult. Under SB, two channels are used for downloading, but with a rate equal to the playing rate B_{min}. Relative segment sizes are 1, 2, 2, 5, 5, 12, 12, 25, 25,…W, where W the width of the skyscraper. This leads to much lower demand on the client, but is inefficient in terms of server bandwidth. The latter goal is achieved by *fast broadcasting* (FB) (Juhn & Tseng, 1998) which

Figure 1. Example of pyramid broadcasting with 4 videos and 4 channels



divides the video into segments of geometric series, with K channels of B_{min} bandwidth, but where the clients download from *all K* channels.

Yet another important variation is *harmonic broadcasting* (HB) (Juhn & Tseng, 1997) which divides the video in segments of equal size and broadcasts them on K successive channels of bandwidth B_{min}/i, where $i = 1,\ldots K$. The client downloads from all channels as soon as the first segment has started downloading. The client download bandwidth is thus equal to the server's and the buffer requirements low (about 37% of the total video). However, the timing requirements may not be met, which is a serious drawback. Other variations exist that solve this problem with the same requirements (Paris, Carter, & Long, 1998) or are hybrid versions of the schemes discussed so far, with approximately the same cost in resources as well as efficiency.

Proposals for Less Popular Videos or Varying Request Pattern

In the case of less popular videos or of a varying request pattern pulled-based or reactive methods are more appropriate. More specifically, the server gathers clients' requests within a specific time interval $t_{in} < t_w$. In the simplest case all requests are for the beginning of the same video, although they may be for different videos or for different parts of the same video (e.g., after a FF or RW). For each group (*batch*) of similar requests a new broadcast is scheduled by reserving a separate server channel, (*batching*). With a video duration t_D a maximum of $\lceil t_D/t_{in} \rceil$ server channels are required for a single video assuming multicast.

The most important proposals for *static* multicast batching are: *first-come-first-served* (FCFS) where the oldest batch is served first, *maximum-queue-length-first* (MQLF) where the batch containing the largest amount of requests is served first, reducing average system throughput by being unfair and *maximum-factor-queue-length* (MFQL) where the batch containing the largest amount of requests for some video weighted by the factor $1/\sqrt{f_i}$ is selected, where f_i is the access frequency of the particular video. In this way the popular videos are not always favored (Hua, Tantaoui, & Tavanapong, 2004).

A common drawback of the proposals above is that client requests which miss a particular video broadcasting schedule cannot hope for a reasonably quick service time, in a relatively busy server. Hence, *dynamic* multicast proposals have emerged, which allow the existing multicast tree for the same video to be extended in order to include late requests. The most notable proposals are *patching*, *bandwidth skimming*, and *chaining*.

Patching (Hua, Cai, & Sheu, 1998) and its variations allow a late client to join an existing multicast stream and buffer it, while simultaneously the missing portion is delivered by the server via a separate patching stream. The latter is of short duration, thus quickly releasing the bandwidth used by the server. Should the clients arrive towards the end of the normal stream broadcast, a new normal broadcast is scheduled instead of a patch one. In more recent variations it is also possible to have double patching, where a patching stream is created on top of a previous patching stream, but requires more bandwidth on both the client(s) and the server and synchronization is more difficult to achieve.

The main idea in Bandwidth Skimming (Eager, Vernon, & Zahorjan, 2000) is for clients to download a multicast stream, while reserving a small portion of their download bandwidth (*skim*) in order to listen to the closest active stream other than theirs. In this way, hierarchical merging of the various streams is possible to achieve. It has been shown that it is better than patching in terms of server bandwidth utilization, though more complex to implement.

Chaining (Sheu, Hua, & Tavanapong, 1997) on the other hand is essentially a pipeline of clients, operating in a peer-to-peer scheme, where the server is at the root of the pipeline. New clients are added at the bottom of the tree,

receiving the first portion of the requested video. If an appropriate pipeline does not exist, a new one is created by having the server feed the new clients directly. This scheme reduces the server bandwidth and is scalable, but it requires a collaborative environment and implementation is a challenge, especially for clients who are in the middle of a pipeline and suddenly lose network connection or simply decide to withdraw. It also requires substantial upload bandwidth to exist at the clients, so it is not generally suitable for asymmetric connections.

Proposals According to Network and Client Organization

Proxies and Content Distribution Networks

Proxies have been used for decades for delivering all sorts of data and especially on the Web, with considerable success. Hence there have been proposals for their use for multimedia dissemination. Actually, some of the p2p proposals discussed later represent a form of proxies, since they cache part of the data they receive for use by their peers. A more general form of this approach, however, involves dedicated proxies strategically placed so that they are more effective.

Wang, Sen, Adler, and Towsley, (2004) base their proposal on the principle of prefix proxy cache allocation in order to reduce the aggregate network bandwidth cost and startup delays at the clients. Although they report substantial savings in transmission cost, this is based on the assumption that all clients request a video from its beginning.

A more comprehensive study based on Akamai's streaming network appears in (Sripanidkulchai, Ganjam, Maggs, & Zhang, 2004). The latter is a static overlay composed of edge nodes located close to the clients and intermediate nodes that take streams from the original content publisher and split and replicate them to the edge nodes. This scheme effectively constitutes a content distribution network (CDN), used not only for multimedia, but other traffic as well. It is reported that under several techniques and assumptions tested, application end-point architectures have enough resources, inherent stability and can support large-scale groups. Hence, such proposals (including p2p) are promising for real-world applications. Client buffers and uplink bandwidth can contribute significantly if it is possible to use them.

Multicast Overlay Networks

Most of the proposals so far work for multicast broadcasts. This suggests that the network infrastructure supports IP multicasting completely. Unfortunately, most routers in the Internet do not support multicast routing. As the experience from MBone (multicast backbone) (Kurose, & Ross, 2004) shows, an overlay virtual network interconnecting "islands" of multicasting-capable routers must be established over the existing Internet using the rest of the routers as end-points of "tunnels." Nevertheless, since IP multicasting is still a best effort service and therefore unsuitable for multimedia streaming, appropriate reservation of resources at the participating routers is necessary. The signaling protocol of choice is RSVP under which potential receivers signal their intention to join the multicast tree. This is a defacto part of the Intserv mechanism proposed by IETF. However, this solution does not scale well. A similar proposal but with better scaling is DiffServ which has still to be deployed in numbers (Kurose, & Ross, 2004).

A more recent trend is to create an overlay multicast network at the application layer, using unicast transmissions. Although worse than pure multicast in theory, it has been an active area of research due to its relative simplicity, scalability and the complete absence of necessity for modifications at the network level. Thus, the complexity is now placed at the end points, (i.e.,

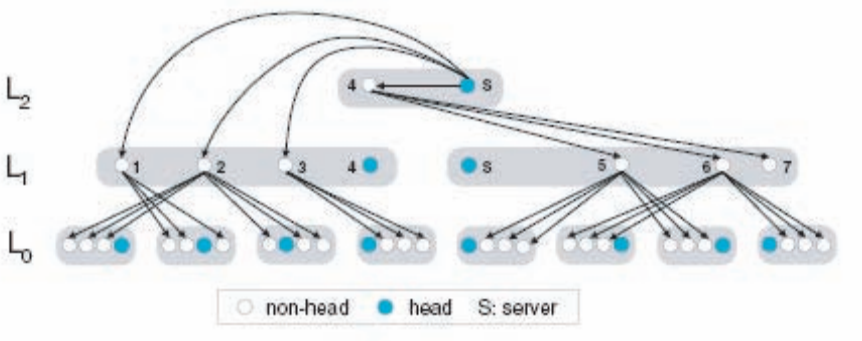
the participating clients and server(s)) and the popular point-to-point (p2p) computation model can be employed in most cases. Asymmetric connections must still include uplink connections of adequate bandwidth in order to support the p2p principle.

Variations include P2Cast (Guo, Suh, Kurose, & Towsley, 2003) which essentially is patching in the p2p environment: Late clients receive the patch stream(s) from old clients, by having two download streams, namely the normal and the patch stream. Any failure of the parent involves the source (the initial server), which makes the whole mechanism vulnerable and prone to bottlenecks.

ZigZag (Tran, Hua, & Do, 2003) creates a logical hierarchy of clusters of peers, with each member at a bounded distance from each other and one of them the cluster leader. The name of this technique emanates from the fact that the leader of each cluster forwards data only to peers in different clusters from its own. An example is shown in Figure 2, where there are 16 peers, organized in clusters of four at level 0. One peer from each cluster is the cluster leader or *head* (additionally depicted for clarity) at level 1. The main advantages of ZigZag are the small height of the multicast tree and the amount of data and control traffic at the server. However, leader failures can cause significant disruption, since both data and control traffic pass through a leader.

LEMP (Fouliras, Xanthos, Tsantalis., & Manitsaris, 2004) is a another variation which forms a simple overlay multicast tree with an upper bound on the number of peers receiving data from their parent. However, each level of the multicast tree forms a virtual cluster where one peer is the local representative (LR) and another peer is its backup, both initially selected by the server. Most of the control traffic remains at the same level between the LR and the rest of the peers. Should the LR fail, the backup takes its place, selecting a new backup. All new clients are assigned by the server to an additional level under the most recent or form a new level under the server with a separate broadcast. Furthermore, special care has been made for the case of frequent disconnections and re-connections, typical for mobile environments; peers require a single downlink channel at play rate and varying, but bounded uplink channels. This scheme has better response to failures and shorter trees than ZigZag, but for very populous levels there can be some bottleneck for the light control traffic at the LR.

Figure 2. ZigZag: Example multicast tree of peers (3 layers, 4 peers per cluster)



Other Proposals

Most of the existing proposals have been designed without taking into consideration the issues specific to mobile networks. Therefore, there has recently been considerable interest for research in this area. Most of the proposed solutions, however, are simple variations of the proposals presented already. This is natural, since the network infrastructure is typically static and only clients are mobile. The main exception to this rule comes from ad hoc networks.

Add hoc networks are more likely to show packet loss, due to the unpredictable behavior of all or most of the participant nodes. For this reason there has been considerable research effort to address this particular problem, mostly by resorting to multipath routing, since connectivity is less likely to be broken along multiple paths. For example, (Zhu, Han, & Girod, 2004) elaborate on this scheme, by proposing a suitable objective function which determines the appropriate rate allocation among multiple routes. In this way congestion is also avoided considerably, providing better results at the receiver. Also (Wei, & Zakhor, 2004) propose a multipath extension to an existing on-demand source routing protocol (DSR), where the packet carries the end-to-end information in its header and a route discovery process is initiated in case of problems and (Wu, & Huang, 2004) for the case of heterogeneous wireless networks.

All these schemes work reasonably well for small networks, but their scalability is questionable, since they have been tested for small size networks.

COMPARATIVE EVALUATION

We assume that the play out duration t_D of the item on demand is in general longer than at least an order of magnitude compared to t_w. Furthermore, we assume that the arrival of client requests is a Poisson distribution and that the popularity of items stored at the server follows the Zipf distribution. These assumptions are in line with those appearing in most of the proposals.

In order to evaluate the various proposals we need to define appropriate metrics. More specifically:

- Item access time: this should be smaller than t_w as detailed previously
- The bandwidth required at the server as a function of client requests
- The download and upload bandwidth required at a client expressed in units of the minimum bandwidth b_{min} for playing out a single item
- The minimum buffer size required at a client
- The maximum delay during redirection, if at all; obviously this should not exceed the remainder in the client's buffer
- The overall network bandwidth requirements
- Network infrastructure modification; obviously minimal modification is preferable
- Interactive capabilities

Examining the proposals for popular videos presented earlier, we note that they are unsuitable for mobile environments, either because they require a large client buffer, large bandwidth for downloads or very strict and complex synchronization. Furthermore, they were designed for popular videos with a static request pattern, where clients always request videos from their beginning.

On the other hand, patching, bandwidth skimming are better equipped to address these problems, but unless multicasting is supported, may overwhelm the server. Chaining was designed for multicasting, but uses the p2p computation model, lowering server load and bandwidth.

Nevertheless, unicast-based schemes are better in practice for both wired and mobile networks as

stated earlier. Although several proposals exist, Zigzag and LEMP are better suited for mobile environments, since they have the advantages of chaining, but are designed having taken into consideration the existence of a significant probability of peer failures, as well as the case of ad hoc networks and are scalable. Their main disadvantage is that they require a collaborative environment and considerable client upload bandwidth capability, which is not always the case for asymmetric mobile networks. Furthermore, they reduce server bandwidth load, but not the load of the overall network.

The remaining proposals either assume a radical reorganization of the network infrastructure (CDN) or are not proven to be scalable.

CONCLUSION AND FUTURE TRENDS

The research conducted by IETF for quality of service (QoS) in IP-based mobile networks and QoS policy control is of particular importance. Such research is directly applicable to the dissemination of multimedia data, since the temporal requirement may lead to an early decision for packet control, providing better network bandwidth utilization. The new requirements of policy control in mobile networks are set by the user's home network operator, depending upon a profile created for the user. Thus, certain sessions may not be allowed to be initiated under certain circumstances (Zheng, & Greis, 2004).

In this sense, most mobile networks will continue being hybrid in nature for the foreseeable future, since this scheme offers better control for administrative and charging reasons, as well as higher effective throughput and connectivity to the Internet. Therefore, proposals based on some form of CDN are better suited for commercial providers. Nevertheless, from a purely technical point of view, the p2p computation model is better suited for the mobile environment, with low server bandwidth requirements, providing failure tolerance and, most important, inherently supporting ad hoc networks and interactive multimedia.

KEY TERMS

CDN: Content distribution network is a network where the ISP has placed proxies in strategically selected points, so that the bandwidth used and response time to clients' requests is minimized.

Overlay Network: A virtual network built over a physical network, where the participants communicate with a special protocol, transparent to the non-participants.

QoS: A notion stating that transmission quality and service availability can be measured, improved, and, to some extent, guaranteed in advance. QoS is of particular concern for the continuous transmission of multimedia information and declares the ability of a network to deliver traffic with minimum delay and maximum availability.

Streaming: The scheme under which clients start playing out the multimedia immediately or shortly after they have received the first portion without waiting for the transmission to be completed.

Chapter 7.36
Data Broadcasting in a Mobile Environment

ABSTRACT

The advances in mobile devices and wireless communication techniques have enabled anywhere, anytime data access. Data being accessed can be categorized into three classes: private data, shared data, and public data. Private and shared data are usually accessed through on-demand-based approaches, while public data can be most effectively disseminated using broadcasting. In the mobile computing environment, the characteristics of mobile devices and limitations of wireless communication technology pose challenges on broadcasting strategy as well as data-retrieval method designs. Major research issues include indexing scheme, broadcasting over single and parallel channels, data distribution and replication strategy, conflict resolution, and data retrieval method. In this chapter, we investigate solutions proposed for these issues. High performance and low power consumption are the two main objectives of the proposed schemes. Comprehensive simulation results are used to demonstrate the effectiveness of each solution and compare different approaches.

INTRODUCTION

The increasing development and spread of wireless networks and the need for information sharing has created a considerable demand for cooperation among existing, distributed, heterogeneous, and autonomous information sources. The growing diversity in the range of information that is accessible to a user and rapidly expanding technology have changed the traditional notion of timely and reliable access to global information in a distributed system. Remote access to data refers to both mobile nodes and fixed nodes accessing data within a platform characterized by the following:

- low bandwidth,
- frequent disconnection,
- high error rates,
- limited processing resources, and
- limited power sources.

Regardless of the hardware device, connection medium, and type of data accessed, users require timely and reliable access to various types of data that are classified as follows:

- Private data, that is, personal daily schedules, phone numbers, and so forth. The reader of this type of data is the sole owner or user of the data.
- Public data, that is, news, weather information, traffic information, flight information, and so forth. This type of data is maintained by one source and shared by many—a user mainly queries the information source(s).
- Shared data, that is, traditional, replicated, or fragmented databases. Users usually send transactions as well as queries to the information source(s).

  Access requests to these data sources can be on-demand-based or broadcast-based.

On-Demand-Based Requests

In this case users normally obtain information through a dialogue (two-way communication) with the database server—the request is pushed to the system, data sources are accessed, operations are performed, partial results are collected and integrated, and the final result is communicated back to the user. This access scenario requires a solution that addresses the following issues.

- **Security and access control.** Methods that guarantee authorized access to the resources.
- **Isolation.** Means that support operations off-line if an intentional or unintentional disconnection has occurred.
- **Semantic heterogeneity.** Methods that can handle differences in data representation, format, structure, and meaning among information sources and hence establish interoperability.
- **Local autonomy.** Methods that allow different information sources to join and depart the global information-sharing environment at will.
- **Query processing and query optimization.** Methods that can efficiently partition global queries into subqueries and perform optimization techniques.
- **Transaction processing and concurrency control.** Methods that allow simultaneous execution of independent transactions and interleave interrelated transactions in the face of both global and local conflicts.
- **Data integration.** Methods that fuse partial results to draw a global result.
- **Browsing.** Methods that allow the user to search and view the available information without any information processing overhead.
- **Distribution transparency.** Methods to hide the network topology and the placement of the data while maximizing the performance for the overall system.
- **Location transparency.** Methods that allow heterogeneous remote access (HRA) to data sources. Higher degrees of mobility argue for higher degrees of heterogeneous data access.
- **Limited resources.** Methods that accommodate computing devices with limited capabilities.

The literature is abounded with solutions to these issues (Badrinath, 1996; Bright, Hurson, & Pakzad, 1992, 1994; Joseph, Tauber, & Kaashoek, 1997; Satyanarayanan, 1996). Moreover, there are existing mobile applications that address the limited bandwidth issues involved in mobility (Demers, Pertersen, Spreitzer, Terry, Theier,

& Welch, 1994; Fox, Gribble, Brewer, & Amir, 1996; Honeyman, Huston, Rees, & Bachmann, 1992; Joseph et al., 1997; Kaashoek, Pinckney, & Tauber, 1995; Lai, Zaslavsky, Martin, & Yeo, 1995; Le, Burghardt, Seshan, & Rabaey, 1995; Satyanarayanan, 1994, 1996).

Broadcast-Based Requests

Public information applications can be characterized by (a) massive numbers of users and (b) the similarity and simplicity in the requests solicited by the users. The reduced bandwidth attributed to the wireless environment places limitations on the rate of the requests. Broadcasting (one-way communication) has been suggested as a possible solution to this limitation. In broadcasting, information is provided to all users of the air channels. Mobile users are capable of searching the air channels and pulling the desired data. The main advantage of broadcasting is that it scales up as the number of users increases and, thus, eliminates the need to multiplex the bandwidth among users accessing the air channel. Furthermore, broadcasting can be considered as an additional storage available over the air for mobile clients. Within the scope of broadcasting one needs to address three issues:

- effective data organization on the broadcast channel,
- efficient data retrieval from the broadcast channel, and
- data selection.

The goal is to achieve high performance (response time) while minimizing energy consumption. Note that the response time is a major source of power consumption at the mobile unit (Imielinski & Badrinath, 1994; Imielinski & Korth, 1996; Imielinski, Viswanathan, & Badrinath, 1997; Weiser, 1993). As a result, the reduction in response time translates into reducing the amount of time a mobile unit spends accessing the channel(s) and thus has its main influence on conserving energy at the mobile unit.

Chapter Organization

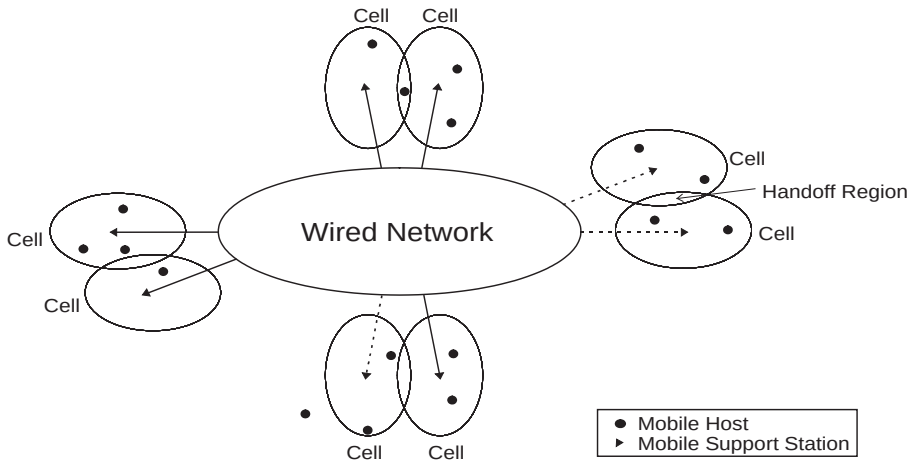
In this chapter, we first introduce the necessary background material. Technological limitations are outlined and their effects on the global information-sharing environment are discussed. Issues such as tree-based indexing, signature-based indexing, data replication, broadcasting over single and parallel channels, data distribution, conflict, and data access are enumerated and analyzed next. Then we present solutions to these issues with respect to the network latency, access latency, and power management. Finally, we conclude the chapter and point out some future research directions.

MOBILE COMPUTING

The mobile computing environment is composed of a number of network servers enhanced with wireless transceivers—mobile support stations (MSSs) and a varying number of mobile hosts (MHs) free to move at will (Figure 1).

The role of the MSS is to provide a link between the wireless network and the wired network. The link between an MSS and the wired network could be either wireless (shown as a dashed line) or wire based. The area covered by the individual transceiver is referred to as a cell. To satisfy a request, an MH accesses the MSS responsible for the cell where the MH is currently located. It is the duty of the MSS to resolve the request and deliver the result back to the client. Once an MH moves across the boundaries of two cells, a handoff process takes place between the MSSs of the corresponding cells. The MH is normally small, lightweight, and portable. It is designed to be compact with limited resources relying on temporary power supplies (such as batteries) as its main power source.

Figure 1. Architecture of the mobile-computing environment



Characteristics of the Mobile Environment

Wireless communication is accomplished via modulating radio waves or pulsing infrared light. Table 1 summarizes a variety of mobile network architectures. Mainly, three characteristics distinguish the mobile computing environment from traditional wired computing platforms, namely, wireless medium, mobility, and portability.

Wireless Medium

The common ground among all wireless systems is the fact that communication is done via the air (and not via cables). This fact changes a major underlying assumption behind the conventional distributed algorithms. The physical layer of the connection is no longer the reliable coaxial or optic cable. Communication over the air is identified by frequent disconnections, low data-rate, high cost, and lack of security (Alonso & Ganguly, 1992; Alonso & Korth, 1993; Chlamtac & Lin, 1997; Imielinski & Badrinath, 1994; Imielinski & Korth, 1996; Imielinski et al., 1997; Weiser, 1993).

Mobility

Mobility introduces new challenges beyond the scope of the traditional environment. Mobile devices can be used at multiple locations and in transition between these locations. Mobility results in several issues including disconnections due to handoff processes, motion management, location-dependent information, heterogeneous and fragmented networks, security, and privacy.

Portability

There are many variations of portable computer systems with different physical capabilities. However, they share many common characteristics such as limited memory, processing power, and power source. The ideal goal would be to develop a device that is compact, durable, lightweight, and that consumes a minimum amount of power.

Table 1. Mobile network architectures

Architecture	Description
Cellular Networks	• Provides voice and data services to users with handheld phones • Continuous coverage is restricted to metropolitan regions • Movement over a wide area may need user to inform the network of the new location • Low bandwidth for data-intensive applications • Could be based on either analog technology or digital technology
Wireless LANs	• A traditional LAN extended with a wireless interface • Serves small, low-powered, portable terminals capable of wireless access • Connected to a more extensive backbone network, such as a LAN or WAN
Wide Area Wireless Networks	• Special mobile radio networks provided by private service providers (RAM, ARDIS) • Provides nationwide wireless coverage for low-bandwidth data services, including e-mail or access to applications running on a fixed host
Paging Networks	• Receive-only network • No coverage problems • Low bandwidth • Unreliable

Satellite Networks	• Unlike the static, grounded MSSs, satellites are not fixed
	• Normally classified based on their altitudes (from earth) into three classes:
	  • Low Earth Orbit Satellites (LEOS)
	  • Medium Earth Orbit Satellites (MEOS)
	  • Geostationary Satellites (GEOS)

Table 2. Limitations of the mobile environment

Limitations	Concerns/Side Effects
Frequent Disconnections	• Handoff blank out in cellular networks • Long down time of the mobile unit due to limited battery power • Voluntary disconnection by the user • Disconnection due to hostile events (e.g., theft, destruction) • Roaming off outside the geographical coverage area of the window service
Limited Communication Bandwidth	• Quality of service (QoS) and performance guarantees • Throughput and response time and their variances • Efficient battery use during long communication delays
Heterogeneous and Fragmented Wireless Network Infrastructure	• Rapid and large fluctuations in network QoS • Mobility transparent applications perform poorly without mobility middleware or proxy • Poor end-to-end performance of different transport protocols across network of different parameters and transmission characteristics

Table 2 highlights some limitations of the mobile environment.

Broadcasting

The cost of communication is normally asymmetric: Sending information requires 2 to 10 times more energy than receiving the information (Imielinski, Viswanathan, & Badrinath, 1994). In the case of accessing public information, instead of the two-way, on-demand, traditional communication pattern, popular public information can be generated and disseminated over the air channel. The MH requiring the information can tune to the broadcast and access the desired information from the air channel.

In general, data can be broadcast either on one or several channels. Broadcasting has been used extensively in multiple disciplines, that is, management of communication systems (Comer, 1991) and distributed database environments (Bowen, 1992). In this chapter, the term *broadcast* is referred to as the set of all broadcast data elements (the stream of data across all channels). A broadcast is performed in a cyclic manner. The MH can only read from the broadcast, whereas the database server is the only entity that can write to the broadcast.

In the data-broadcasting application domain, power consumption and network latency are proven constraints that limit "timely and reliable" access to information. The necessity of minimizing power consumption and network latency lies in the limitation of current technology. The hardware of the mobile units have been designed to mitigate this limitation by operating in various operational modes such as active, doze, sleep, nap, and so forth to conserve energy. A mobile unit can be in active mode (maximum power consumption) while it is searching or accessing data; otherwise, it can be in doze mode (reduced power consumption) when the unit is not performing any computation. Along with the architectural and hardware enhancements, efficient power management and energy-aware algorithms can be devised to manage power resources more effectively. In addition, appropriate retrieval protocols can be developed to remedy network latency and hence to allow faster access to the information sources. In general, two issues need to be considered.

- The MH should not waste its energy in continuously monitoring the broadcast to search for information. As a result, the information on the broadcast should be organized based on a disciplined order. Techniques should be developed to (a) instruct the MH of the availability of the data element on the broadcast and (b) if the data element is available, instruct the MH of the location of the data element on the broadcast.
- An attempt should be made to minimize the response time. As will be seen later, this is achieved by shortening the broadcast length and/or reducing the number of passes over the air channel(s).

Data Organization on the Air Channel

Unlike the conventional wired environment, where a disk is assumed to be the underlying storage, data in the mobile environment are stored on air channel(s). A disk and an air channel have major structural and functional differences. The disk has a three-dimensional structure (disks can have a four-dimensional structure if multiple disks are used — redundant arrays of independent disks [RAID]). An air channel, on the other hand, is a one-dimensional structure. The disk has a random-access feature and the air channel is sequential in nature. Finally, the current raw data rate of a disk is generally much higher than that of the air channel.

Zdonik, Alonso, Franklin, and Acharya (1994) and Acharya, Alonso, Franklin, and Zdonik (1995) investigated the mapping of disk pages onto a

broadcast channel and the effects of that mapping on the management of cache at the MH. In order to place disk pages onto the data channel, the notion of multiple disks with different sizes spinning at multiple speeds was used. Pages available on faster spinning disks get mapped more frequently than those available on slower disks. In cache management, a nonconventional replacement strategy was suggested. Such a policy assumed that the page to be replaced might not be the least-recently used page in the cache. This is justifiable since the set of pages that are most frequently in demand are also the most frequently broadcast. This work was also extended to study the effect of prefetching from the air channel into the cache of the MH. These efforts assumed the same granularity for the data items on air channel and disk pages: if a data item is to be broadcast more frequently (replicated), the entire page has to be replicated. In addition, due to the plain structural nature of the page-based environment, the research looked at the pages as abstract entities and was not meant to consider the contents of the pages (data and its semantics) as a means to order the pages. In object-oriented systems, semantics among objects greatly influence the method in which objects are retrieved and, thus, have their direct impact on the ordering of these objects or pages. In addition, the replication should be performed at the data item granularity level.

An index is a mechanism that speeds up associative searching. An index can be formally defined as a function that takes a key value and provides an address referring to the location of the associated data. Its main advantage lies in the fact that it eliminates the need for an exhaustive search through the pages of data on the storage medium. Similarly, within the scope of broadcasting, an index points to the location or possible availability of a data item on the broadcast, hence, allowing the mobile unit to predict the arrival time of the data item requested. The prediction of the arrival time enables the mobile unit to switch its operational mode into an energy-saving mode. As a result, an indexing mechanism facilitates data retrieval from the air channel(s), minimizing response time while reducing power consumption. Table 3 summarizes the advantages and disadvantages of indexing schemes.

The literature has addressed several indexing techniques for a single broadcast channel as well as parallel broadcast channels with special attention to signature-based indexing and tree-based indexing (Boonsiriwattanakul, Hurson, Vijaykrishnan, & Chehadeh, 1999; Chehadeh, Hurson, & Miller, 2000; Chehadeh, Hurson, &

Table 3. Advantages and disadvantages of indexing schemes

Advantages	Disadvantages
Provides auxiliary information that allows mobile users to predict arrival time of objects	Longer broadcast
Enables utilization of different operational modes (active, nap, doze, etc.)	Longer response time
Reduces power consumption (less tune-in time)	Computational overhead due to complexity in retrieval, allocation, and maintenance of the indexes

Tavangarian, 2001; Hu & Lee, 2000, 2001; Imielinski et al., 1997; Juran, Hurson, & Vijaykrishnan, 2004; Lee, 1996).

Signature-Based Indexing

A signature is an abstraction of the information stored in a record or a file. The basic idea behind signatures on a broadcast channel is to add a control part to the contents of an information frame (Hu & Lee, 2000, 2001; Lee, 1996). This is done by applying a hash function to the contents of the information frame, generating a bit vector, and then superimposing it on the data frame. As a result, a signature partially reflects the data content of a frame. Different allocations of signatures on a broadcast channel have been studied; among them, three policies, namely, *single signature*, *integrated signature*, and *multilevel signature*, are studied in Hu and Lee (2000) and Lee (1996).

During the retrieval, a query is resolved by generating a signature based on the user's request. The query signature is then compared against the signatures of the data frames in the broadcast. A successful match indicates a possible hit. Consequently, the content of the corresponding information frame is checked against the query to verify that it corresponds to the user's demands. If the data of the frame corresponds to the user's request, the data is recovered; otherwise, the corresponding information frame is ignored. In general, this scheme reduces the access time and the tune-in time when pulling information from the air channel.

Tree-Based Indexing

Two kinds of frames are broadcast on the air channel: data frames and index frames. The index frame contains auxiliary information representing one or several data attributes pointing to the location of data collection (i.e., information frames) sharing the same common attribute value(s). This information is usually organized as a tree in which the lowest level of the tree points to the location of the information frames on the broadcast channel.

A broadcast channel is a sequential medium and, hence, to reduce the mobile unit's active and tune-in time, and consequently to reduce the power consumption, the index frames are usually replicated and interleaved with the data frames. Two index replication schemes (namely, *distributed indexing* and *(1, m) indexing*) have been studied in Imielinski et al. (1997). In distributed indexing, the index is partitioned and interleaved in the broadcast cycle (Hu & Lee, 2000, 2001; Lee, 1996). Each part of the index in the broadcast is followed by its corresponding data frame(s). In (1, *m*) indexing, the entire index is interleaved *m* times during the broadcast cycle (Imielinski et al., 1997; Lee 1996) — the whole index is broadcast before every 1/*m* fraction of the cycle.

Previous work has shown that the tree-based indexing schemes are more suitable for applications where information is accessed from the broadcast channel randomly, and the signature-based indexing schemes are more suitable in retrieving sequentially structured data elements (Hu & Lee, 2000, 2001). In addition, tree-based indexing schemes have shown superiority over the signature-based indexing schemes when the user request is directed towards interrelated objects clustered on the broadcast channel(s). Furthermore, tree-based indexing schemes relative to signature-based indexing schemes are more suitable in reducing the overall power consumption. This is due to the fact that a tree-based indexing provides global information regarding the physical location of the data frames on the broadcast channel. On the other hand, signature-based indexing schemes are more effective in retrieving data frames based on multiple attributes (Hu & Lee, 2000). Table 4 compares and contrasts the signature- and tree-based indexing.

Table 4. Signature-based versus tree-based indexing

Feature	Signature-Based Indexing	Tree-Based Indexing

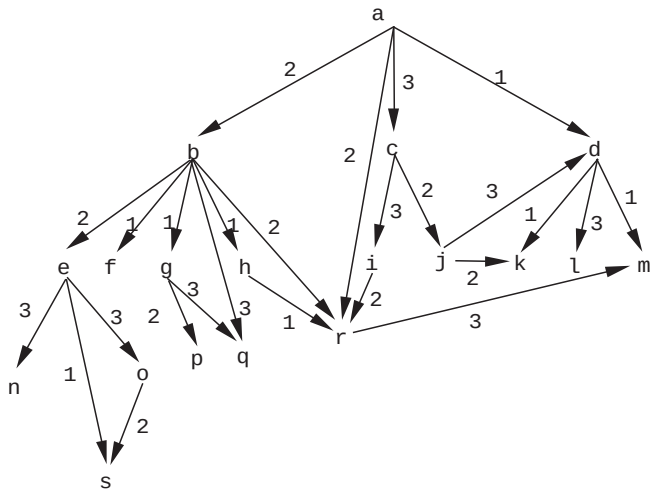
Data Organization on a Single Channel

An appropriate data placement algorithm should attempt to detect data locality and cluster related data close to one another. An object-clustering algorithm takes advantage of semantic links among objects and attempts to map a complex object into a linear sequence of objects along these semantic links. It has been shown that such clustering can improve the response time by an order of magnitude (Banerjee, Kim, Kim, & Garza, 1988; Chang & Katz, 1989; Chehadeh, Hurson, Miller, Pakzad, & Jamoussi, 1993; Cheng & Hurson, 1991a). In the conventional computing environment, where data items are stored on disk(s), the clustering algorithms are intended to place semantically connected objects physically along the sectors of the disk(s) close to one another (Cheng & Hurson, 1991a). The employment of broadcasting in the mobile computing environment motivates the need to study the proper data organization along the sequential air channel. Figure 2 depicts a weighted directed acyclic graph (DAG) and the resulting clustering sequences achieved when different clustering techniques are applied.

In order to reduce the response time, the organization of data items on an air channel has to meet the following three criteria.

- **Linear ordering.** The one-dimensional sequential access structure of the air channel requires that the object ordering be linear. In a DAG representation of a complex object, an edge between two nodes could signify an access pattern among the two nodes. The *linearity* property is defined as follows: If an edge exists between two objects, o_1 and o_2, and in the direction $o_1 \rightarrow o_2$, then o_1 should be placed prior to o_2.
- **Minimum linear distance between related objects.** In a query, multiple objects might be retrieved following their connection patterns. Intuitively, reducing the distance among these objects along the broadcast reduces the response time and power consumption.

Figure 2. Graph and various clustering methods



Clustering Method	Resulting Sequence
Depth First	abensofgpqhrmcijdkl
Breadth First	abrcdefgqhijklmnsop
Children-Depth First	abrcdefgqhmnsopijkl
Level Clustering	acibgqprmenosjdlkfh

- **More availability for popular objects.** In a database, not all objects are accessed with the same frequency. Generally, requests for data follow the 20/80 rule — a popular, small set of the data (20%) is accessed the majority of the time (80%). Considering the sequential access pattern of the broadcast channel, providing more availability for popular objects can be achieved by simply replicating such objects.

Figure 3 depicts a directed graph and multiple linear sequences that satisfy the linear ordering property. The middle columns represent the cost of delays between every two objects connected via an edge. For the sake of simplicity and without loss of generality, a data unit is used as a unit of measurement. Furthermore, it is assumed that all data items are of equal size. The cost associated with an edge between a pair of data items is calculated by counting the number of data items that separate these two in the linear sequence. For example, in the abfgchdeij sequence, data items a and d are separated by the sequence bfgch and thus have a cost of 6. The rightmost column represents the total cost associated with each individual linear sequence. An optimal sequence is the linear sequence with the minimum total sum. In a query where multiple related objects are retrieved, a reduced average linear distance

14	aedcijbhgf	6	3	2	1	3	2	1	4	2	3	1	28

translates into smaller average response time. In this example, the best linear sequence achieves a total sum of 26.

Data Organization on Parallel Channels

The broadcast length is a factor that affects the average response time in retrieving data items from the air channel — reducing the broadcast length could also reduce the response time. The broadcast length can be reduced if data items are broadcast along parallel air channels.

Formally, we attempt to assign the objects from a weighted DAG onto multiple channels, while (a) preserving dependency implied by the edges, (b) minimizing the overall broadcast time (load balancing), and (c) clustering related objects close

to one another (improving the response time). As one could conclude, there are trade-offs between the second and third requirements: Achieving load balancing does not necessarily reduce the response time in accessing a series of data items.

Assuming that all channels have the same data rate, one can draw many analogies between this problem and static task scheduling in a homogeneous multiprocessor environment — tasks are represented as a directed graph $D \equiv (N, A)$, with nodes (N) and directed edges (A) representing processes and dependence among the processes, respectively. Compared to our environment, channels can be perceived as processors (PEs), objects as tasks, and the size of a data item as the processing cost of a task. There is, however, a major distinction between the two environments. In the multiprocessor environment, information is normally communicated among the PEs, while in the multichannel environment there is no data communication among channels.

The minimum makespan problem, in static scheduling within a multiprocessor environment, attempts to find the minimum time in which n dependent tasks can be completed on m PEs. An optimal solution to such a problem is proven to be NP hard. Techniques such as graph reduction, max-flow min-cut, domain decomposition, and priority list scheduling have been used in search of suboptimal solutions. Similar techniques can be developed to assign interrelated objects closely over parallel channels.

Distribution of data items over the broadcast parallel air channels brings the issue of access conflicts between requested data items that are distributed among different channels. The access conflict is due to two factors:

- the receiver at the mobile host can only tune into one channel at any given time, and
- the time delay to switch from one channel to another.

Access conflicts require the receiver to wait until the next broadcast cycle(s) to retrieve the requested information. Naturally, multiple passes over the broadcast channels will have a significant adverse impact on the response time and power consumption.

Conflicts in Parallel Air Channels

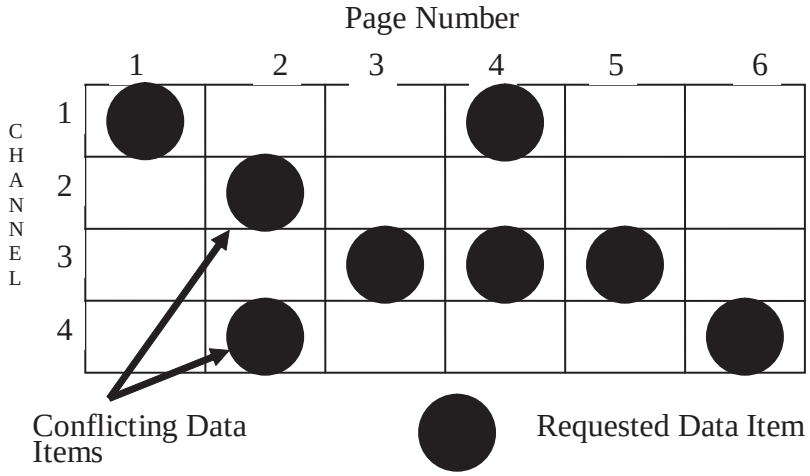
Definition 1. A K-data item request is an application request intended to retrieve K data items from a broadcast.

It is assumed that each channel has the same number of pages (frames) of equal length and, without loss of generality, each data item is residing on only a single page. A single broadcast can be modeled as an N x M grid, where N is the number of pages per broadcast and M is the number of channels. In this grid, K data items ($0 \leq K \leq MN$) are randomly distributed throughout the MN positions of the grid. Based on the common page size and the network speed, the time required to switch from one channel to another is equivalent to the time it takes for one page to pass in the broadcast. Thus, it is impossible for the mobile unit to retrieve both the ith page on Channel A and $(i + 1)$th page on Channel B (where $A \neq B$). Figure 4 is a grid model that illustrates this issue.

Definition 2. Two data items are defined to be in conflict if it is impossible to retrieve both on the same broadcast.

In response to a user request, the access latency is then directly dependent on the number of passes over the broadcast channels. One method of calculating the number of required passes over the broadcast channels is to analyze the conflicts between data items. For any particular data item, all data items in the same or succeeding page (column) and on a different row (channel) will be in conflict. Thus, for any specific page (data object) in the grid, there are $(2M - 2)$ conflicting pages (data items) in the broadcast (The last column has only $M - 1$ conflict positions, but it is assumed that N is sufficiently large to make this

Figure 4. Sample broadcast with M = 4, N = 6, and K = 8



difference insignificant.) These $(2M - 2)$ positions are known as the conflict region.

For any particular data item, it is possible to determine the probability of exactly i conflicts occurring, or $P(i)$. Because the number of conflicts for any particular data item is bounded by $(M - 1)$, the weighted average of these probabilities can be determined by summing a finite series. This weighted average is the number of broadcasts (passes) required to retrieve all K data items if all conflicts between data items are independent.

$$B = \sum_{i=0}^{M-1} (i + 1) * P(i) \qquad (1)$$

Access Patterns

In order to reduce the impact of conflicts on the access time and power consumption, retrieval procedures should be enhanced by a scheduling protocol that determines data retrieval sequence during each broadcast cycle. The scheduling protocol we proposed is based on the following three prioritized heuristics:

1) Eliminate the number of conflicts
2) Retrieve the maximum number of data items
3) Minimize the number of channel switches

The scheme determines the order of retrieval utilizing a forest - an *access forest.* An access forest is a collection of trees (*access trees*), where each access tree represents a collection of access patterns during a broadcast cycle. Naturally, the structure of the access forest, that is, the number of trees and the number of children that any parent can have, is a function of the number of broadcast channels.

Definition 3. An access tree is composed of two elements: nodes and arcs.

- **Node.** A node represents a requested data item. The nodes are labeled to indicate its

conflict status: mnemonically, C_1 represents when the data item is in conflict with another data item(s) in the broadcast and C_0 indicates the lack of conflict.

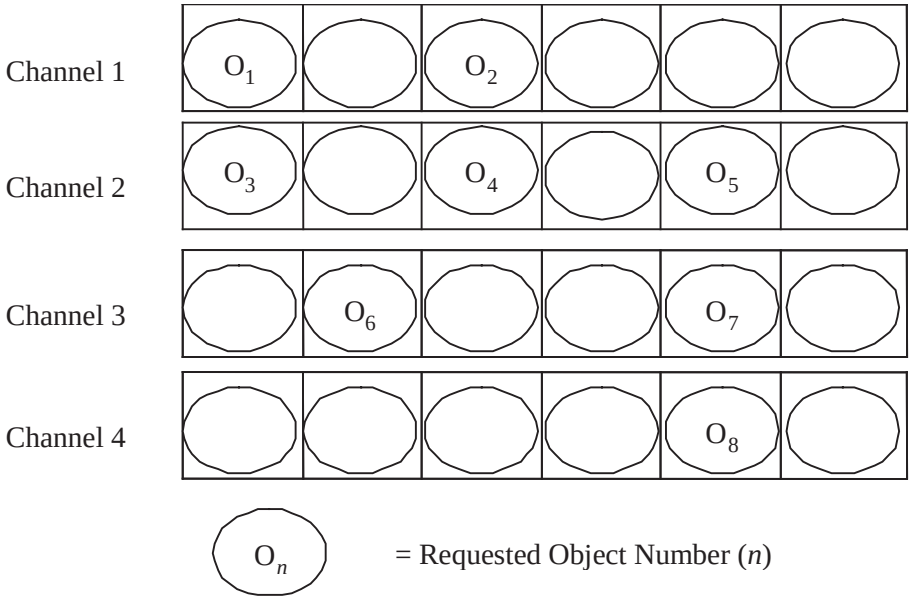
Each access tree in the access forest has a different node as a root-the root is the first accessible requested data item on a broadcast cycle. This simply implies that an access forest can have at most *n* trees where *n* is the number of broadcast channels.

- **Arcs.** The arcs of the trees are weighted arcs. A weight denotes whether or not channel switching is required in order to retrieve the next scheduled data item in the access pattern. A branch in a tree represents a possible access pattern of data items during a broadcast cycle with no conflicts. Starting from the root, the total number of branches in the tree represents all possible access patterns during a broadcast cycle.

This scheme allows one to generate all possible nonconflicting, weighted access patterns from all channels. The generated access patterns are ranked based on their weights-a weight is set based on the number of channel switches-and then the one(s) that allows the maximum number of data retrievals with minimum number of channel switches is selected. It should be noted that the time needed to build and traverse the access forest is a critical factor that must be taken into account to justify the validity of this approach. The following working example provides a detailed guide to illustrate the generation of the access patterns for each broadcast cycle.

1) **Search.** Based on the user's query, this step determines the offset and the chan-

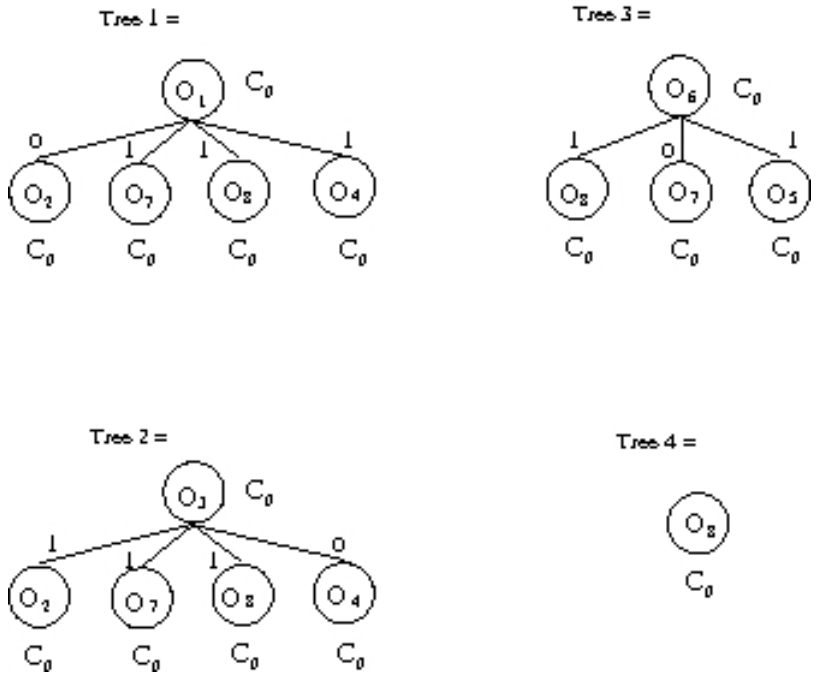
Figure 5. A parallel broadcast of four channels with eight requested data items



nel number(s) of the requested objects on the broadcast channels. Figure 5 depicts a request for eight data items from a parallel broadcast channel of four channels.

2) **Generation of the access forest.** For each broadcast channel, search for the requested data item with the smallest offset (these objects represent the roots of an access tree). For the example, the data items with the smallest offsets are O_1, O_3, O_6 and O_8. Note that the number of access trees is upper bounded by the number of broadcast channels.
3) **Root assignment.** For each channel with at least one data item requested, generate a tree with root node as determined in Step 2. The roots are temporarily tagged as C_0.
4) **Child assignment.** Once the roots are determined, it is necessary to select the child or children of each rooted access tree: For each root, and relative to its position on the air channel, the algorithm determines the closest nonconflicting data items on each channel. With respect to a data item $O_{i,x}$ at location X on air channel i ($1 \le i \le n$), the closest nonconflicting data item is either the data item $O_{i,x+1}$ or the data item $O_{j,x+2}$, $j \ne i$. If the child is in the same broadcast channel as the root, the arc is weighted as 0; otherwise it is weighted as 1. Each added node is temporarily tagged as C_0. Figure 6 shows a snapshot of the example after this step.
5) **Root label update.** Once the whole set of requested data items is analyzed and the access forest is generated, the conflict labels of the nodes of each tree are updated. This

Figure 6. Children of each root



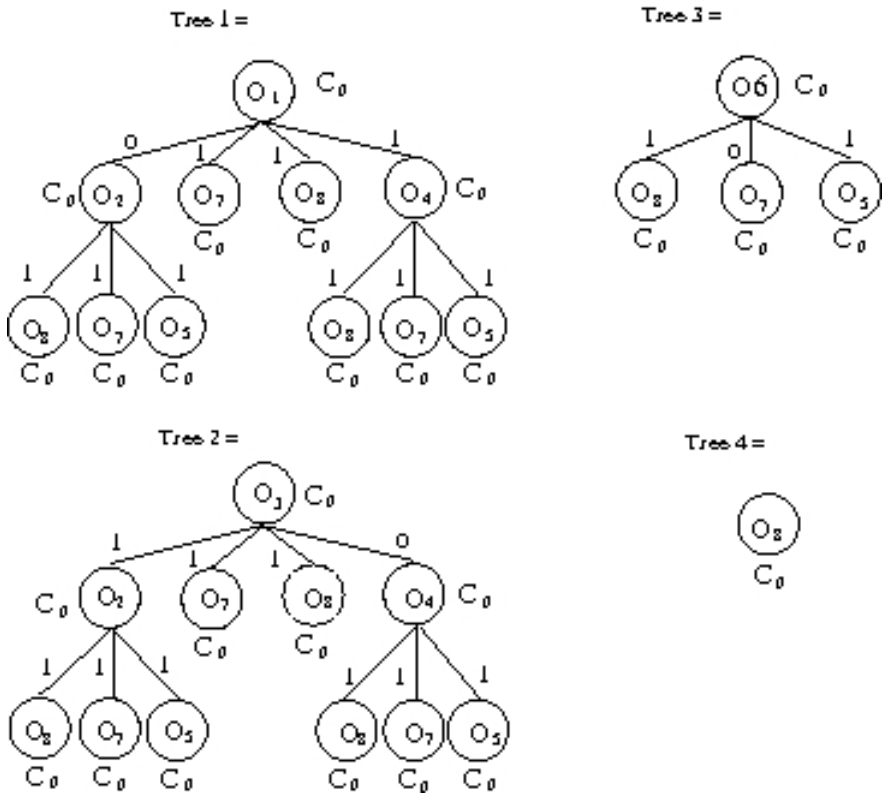
process starts with the root of each tree. If a root is in conflict with any other root(s), a label of C_1 is assigned to all the roots involved in the conflict, otherwise the preset value of C_0 is maintained.

6) **Node label update.** Step 5 will be applied to the nodes in the same level of each access tree in the access forest. As in Step 5, a value of C_1 is assigned to the nodes in conflict. Figure 7 shows the example with the updated labels.

7) **Sequence selection.** The generation of the access forest then allows the selection of the suitable access patterns in an attempt to reduce the network latency and power consumption. A suitable access pattern is equivalent to the selection of a tree branch that:
   - has the most conflicts with other branches,
   - allows more data items to be pulled off the air channels, and
   - requires the least number of channel switches.

The O_3, O_4, and O_5 sequence represents a suitable access pattern for our running example during the first broadcast cycle. Step 7 will be repeated to generate access patterns for different broadcast cycles. The algorithm terminates when all the requested data items are covered in different access patterns. The data item sequence

Figure 7. Final state of the access forest



O_1, O_2, and O_7 and data item sequence O_6 and O_8 represent the last two patterns for retrieving all of the data items requested in the example.

DATA ORGANIZATION ON A SINGLE CHANNEL

As noted in the literature, the object-oriented paradigm is a suitable methodology for modeling public data that are by their very nature in multimedia format (Atkinson, Bancilhon, DeWitt, Dittrich, Maier, & Zdonik, 1989; Fong, Kent, Moore, & Thompson, 1991; Hurson, Pakzad, & Cheng, 1993; Kim, 1990). In addition, object-oriented methodology provides a systematic mechanism to model a complex object in terms of its simpler components.

In this section, without loss of generality, we model information units as objects. Object clustering has proven to be an effective means of data allocation that can reduce response times (Banerjee et al., 1988; Chang & Katz 1989; Chehadeh et al., 1993; Cheng & Hurson, 1991b; Lim, Hurson, Miller, & Chehadeh, 1997). In our research, we investigated two heuristic allocation strategies. The first strategy assumes a strict linearity requirement and deals with nonweighted DAGs. The second approach relaxes such restriction in favor of clustering strongly related objects closer to one another and consequently deals with weighted DAGs.

Strict Linearity: ApproximateLinearOrder Algorithm

Definition 4. An independent node is a node that has either one or no parent. A graph containing only independent nodes makes up a forest.

Heuristic Rules

1) Order the children of a node based on their number of descendants in ascending order.
2) Once a node is selected, all of its descendants should be visited and placed on the sequence in a depth-first manner, without any interruptions from breadth siblings.
3) If a node has a nonindependent child, with all of its parents already visited, the nonindependent child should be inserted in the linear sequence before any independent child.

The ApproximateLinearOrder algorithm implements these heuristics and summarizes the sequence of operations required to obtain a linear sequence. The algorithm assumes a greedy strategy and starts by selecting a node with an in-degree of zero and out-degree of at least one.

ApproximateLinearOrder Algorithm

1) traverse DAG using DFS traversal and as each node is traversed
2) append the traversed node *N* to the sequence
3) remove *N* from {nodes to be traversed}
4) **if** {nonindependent children of *N* having all their parents in the sequence} $\neq \varnothing$
5) *Set* $\leftarrow$ {nonindependent children of *N* having all their parents in the sequence}
6) **else**
7) **if** {independent children of *N*} $\neq \varnothing$
8) *Set* $\leftarrow$ {independent children of *N*}
9) *NextNode* $\leftarrow$ node $\in$ *Set* | node has least # of descendants among the nodes in *Set*

Applying this algorithm to the graph of Figure 3 generates either the 5th or 11th sequence — dependent on whether c or d was chosen first as the child with the least number of independent children. As one can observe, neither of these sequences is the optimal sequence. However, they are reasonably better than other sequences and can practically be obtained in polynomial time. It should be noted that nodes not connected to any other nodes — nodes with in-degree and out-degree of zero — are considered harmful and thus

are not handled by the algorithm. Having them in the middle of the sequence introduces delays between objects along the sequence. Therefore, we exclude them from the set of nodes to be traversed and handle them by appending them to the end of the sequence. In addition, when multiple DAGs are to be mapped along the air channel, the mapping should be done with no interleaving between the nodes of the DAGs.

Varying Levels of Connectivity: PartiallyLinearOrder Algorithm

In a complex object, objects are connected through semantic links with different degrees of connectivity. The different access frequency of objects in an object-oriented database reveals that some patterns are more frequently traversed than others (Fong et al., 1991). This observation resulted in the so-called PartiallyLinearOrder algorithm that assumes a weighted DAG as its input and produces a linear sequence. It combines the nodes (single_node) of the graph into multi_nodes in descending order of their connectivity (semantic links). The insertion of single_nodes within a multi_node respects the linear order at the granularity level of the single_nodes. The multi_nodes are merged (with multi_nodes or single_nodes) at the multi_node granularity, without interfering with internal ordering sequences of a multi_node. Figure 8 shows the application of the PartiallyLinearOrder algorithm.

PartiallyLinearOrder Algorithm

1) **for** every weight w_s in descending order
2) **for** every two nodes N_1 & N_2 connected by w_s
3) merge N_i & N_j into one multi_node
4) **for** every multi_node *MN*
5) $w_m = w_s - 1$
6) **for** every weight w_m in descending order
7) **while** ∃ adjacent_node *AN* connected to *MN*
8) **if** ∃ an edge in both directions between *MN* & *AN*
9) compute $WeightedLinearDistance_{MN\_AN}$ & $WeightedLinearDistance_{AN\_MN}$
10) merge *MN* & *AN* into one multi_node, based on the appropriate direction

Performance Evaluation

Parameters

A simulator was developed to study the behavior of the proposed mapping algorithms based on a

Table 5. Description of parameters

Parameter	Description
Input Parameters	
Number of Nodes	Number of objects within the graph (excluding replication)
Object Size	Sizes of objects (small/medium/large)
Object-Size Distribution	Distribution of the sizes of objects within the database
Next-Node Ratio	Connectivity to next node (random or connection)
Out-Degree Distribution	Distribution of the type of nodes based on their out-degrees
Level Distribution	Semantic connectivity of two objects (weak/normal/strong)
Percentage of Popular Objects	Percentage of objects requested more often than others
Replication Frequency	The number of times a popular object is to be replicated
Output Parameter	
Average Access Delay	In a single query, the average delay between accessing two objects

set of rich statistical parameters. Our test bed was an object-oriented financial database. The OO7 benchmark was chosen to generate the access pattern graphs. We used the NASDAQ exchange (NASDAQ, 2002) as our base model, where data is in both textual and multimedia (graphics — i.e., graphs and tables) formats. Table 5 shows a brief description of the input and output parameters. The simulator is designed to measure the average access delay for the various input parameters. Table 6 provides a listing of the input parameters along with their default values and possible ranges.

Table 6. Input parameter values

Parameter	Default Value	Ranges
Number of Nodes	5,000	400-8,000
Object Size (in Bytes) • Small • Medium • Large	 $2 \le o < 20$ $20 \le o < 7K$ $7K \le o < 50K$	 2-20 20-7K 7K-50K
Object-Size Distribution [S:M:L]	1:1:1	0-6:0-6:0-6
Next-Node Ratio [C:R]	8:2	0-10:10-0
Out-Degree Distribution [0:1:2:3]	3:3:2:1	1-6:1-6:1-6:1-6
Level Distribution [W:N:S]	1:1:1	1-4:1-4:1-4
Percentage of Popular Objects	20%	10-50%
Replication Frequency	2	1-10

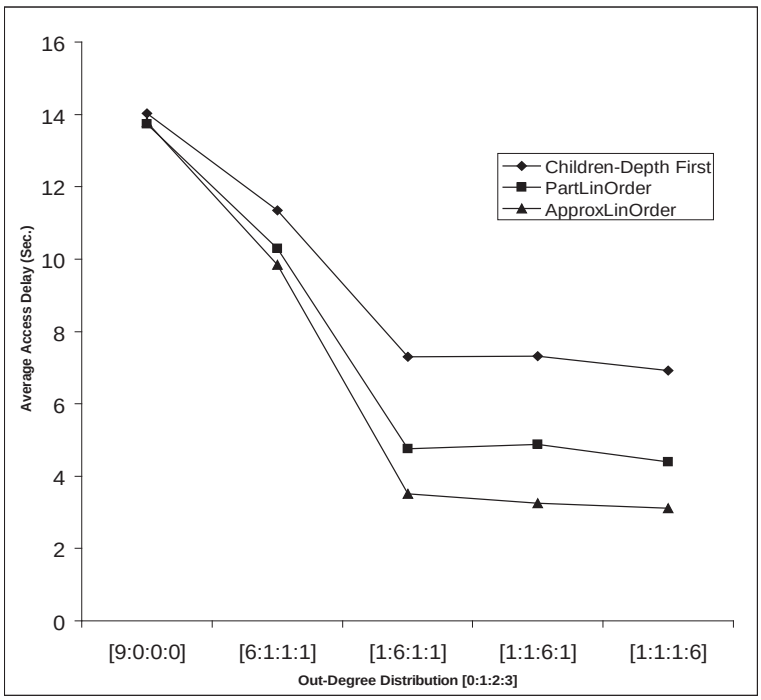
The default values are set as the value of the parameter when other parameters are varied during the course of the simulation. The ranges are used when the parameter itself is varied.

Results

The simulator operates in two stages.

- Structuring the access-pattern object graph, based on certain statistical parameters, and mapping it along the air channel using various mapping algorithms. To get a wide spectrum of possible graphs, parameters such as (a) the percentage of nonfree nodes, (b) the depths of the trees within the graph, and (c) the amount of sharing that exists between trees through nonfree nodes that were varied. Varying these statistical parameters, we generated 500 access graphs that were used as part of our test bed. In addition, we simulated three mapping algorithms: a nonlinear, children-depth-first clustering algorithm (Banerjee et al., 1988), and the PartiallyLinearOrder and ApproximateLinearOrder algorithms.
- Generating queries and accessing the requested objects from the air channel. During each run, each query on average accesses 20 objects either through their semantic links or randomly (following the [C:R] value of the next-node ratio). The simulator measured the average access delay. Each point in the curves (Figure 9) is the average result of running the simulator 100,000 times. Finally, we assumed a broadcast data rate of 1Mbit/sec and showed the results in terms of seconds.

Figure 9. Average access delay versus connectivity



Impact of Number of Objects. ApproximateLinearOrder and PartiallyLinearOrder schemes performed better than the conventional children-depth first by taking the linearity issue into consideration. As expected in all three cases, the average access delay increased as the total number of objects increased. The mapping of additional nodes on the broadcast introduced extra delays between the retrievals of two consecutive objects. Taking a closer look at this effect, we observed that this extra delay is mainly due to an increase in the distance for objects that are retrieved randomly (not based on their semantic links) since the goal of both algorithms is to cluster semantically related objects close to one another. The ApproximateLinearOrder algorithm outperformed the PartiallyLinearOrder algorithm since the latter attempts to cluster strongly connected objects closer to one another than loosely connected ones and, hence, compromises the linearity property for the loosely connected objects. This compromise overshadows the benefit and is amplified as the number of objects increased. To get a better insight on how our proposed schemes compare with the optimal case, two graphs with 10 nodes were constructed and the optimal sequences exhaustively generated. Using the same set of input values, the average access delay for both proposed schemes were simulated and compared against the average access delay for the optimal sequence. The results of ApproximateLinearOrder and PartiallyLinearOrder were 79% and 76%, respectively, of the access delay of the optimal case.

Size Distribution. In this experiment, we observed that the smallest average access delay took place when the air channel contained smaller data items. However, as the population of data items shifted toward the larger ones, the average access delay increased.

Next-Node Ratio. During the course of a query, objects are either accessed along the semantic links or in a random fashion. At one extreme, when all objects were accessed along the semantic links, the average access delay was minimal. The delay, however, increased for randomly accessed objects. Finally, where all the accesses are on a random basis, clustering (and linearity) does not improve the performance, and all mapping algorithms perform equally.

Out-Degree Distribution. This parameter indicates the number of children of a node within the graph — an out-degree of 0 indicates a sink node. Figure 9 shows the effect of varying the out-degree distribution within the graph structure. The point [9:0:0:0] indicates that all the nodes within the graph have an out-degree of 0, with no semantic link among the objects. This is similar to stating that any access to any object within the graph is done on a random basis. In general, the average access delay is reduced as more connectivity is injected in the access graph. It is interesting to note that it would be more desirable to deal with more, but simpler, objects than with few complex objects on the air channel.

In separate simulation runs, the simulator was also used to measure the effect of varying the percentage of popular objects and the replication frequency. These two parameters have the same effect on the total number of objects on the air channel, however, from the access pattern perspective, the semantic of the accesses are different. In both cases, the average access delay increased as either parameter increased. We also observed and measured the average access delay for different degrees of connectivity among objects. The average access delay for objects connected through strong connections is about 4.3 seconds, whereas it is 7.3 and 7.6 seconds for normally and weakly connected objects, respectively. As would be expected, these results show that the improvement is considerable for the objects connected by a strong connection, but for a normal connection, the performance was close to that of the weak-connection case since the algorithm performs its best optimization for strongly connected objects.

Section Conclusion

In this section, two heuristically based mapping algorithms were discussed, simulated, and analyzed. Performing the mapping in polynomial time was one of the major issues of concern while satisfying linearity, locality, and replication of popular objects. The ApproximateLinearOrder algorithm is a greedy-based approximation algorithm that guarantees the linearity property and provides a solution in polynomial time. The PartiallyLinearOrder algorithm guarantees the linearity property for the strongest related objects and relaxes the linearity requirement for objects connected through looser links. Finally, it was shown that the proposed algorithms offer higher performance than the traditional children-depth-first algorithm.

DATA ORGANIZATION ON PARALLEL CHANNELS

Reducing the broadcast length is one way to satisfy timely access to the information. This could be achieved by broadcasting data items along parallel air channels. This problem can be stated formally as follows: Assign the data items from a weighted DAG onto multiple channels while (a) preserving dependency implied by the edges, (b) minimizing the overall broadcast time (load balancing), and (c) clustering related data items close to one another (improving the response time). Realizing the similarities between these objectives and the task-scheduling problem in a multiprocessor environment, we proposed two heuristic–based, static scheduling algorithms, namely the largest object first (LOF) algorithm and the clustering critical-path (CCP) algorithm.

The Largest Object First Algorithm

This algorithm relies on a simple and localized heuristic by giving priority to larger data items. The algorithm follows the following procedure: For each collection of data items, recursively, a "proper" node with in-degree of 0 is chosen and assigned to a "proper" channel; a "proper" channel is the one with the smallest overall size and a "proper" node is the largest node with in-degree of 0. The assigned node along with all of its out-edges are eliminated from the object DAG. This results in a set of nodes with in-degree of 0. These nodes are added to the list of free nodes and then are selected based on their sizes. This process is repeated until all the nodes of the DAG are assigned.

Definition 5. A free node is a node that either has an in-degree of 0 (no parent) or has all of its parents allocated on a channel. A free node is a candidate node available for allocation.

Assuming that there are n nodes in the graph, the algorithm requires the traversal of all the nodes and thus requires n steps. At each step, the algorithm searches for the largest available node whose parents have been fully allocated. This would require at most $O(n^2)$. Therefore, the overall running time of the algorithm is $O(n^3)$. The LOF algorithm respects the dependency among the nodes, if any, and achieves a better load balancing by choosing the largest object first. This algorithm, however, does not allocate objects based on the degree of connectivity and/or the total size of the descendent objects that could play a significant role in balancing the loads on the channels. In addition, this algorithm does not necessarily cluster related object on the parallel air channels.

LOF Algorithm

1) **repeat (2-4)** until all nodes are assigned
2) assign a free node with the largest weight whose parents are fully allocated to the least-loaded channel
3) remove all out-edges of the assigned node from the DAG

4) insert resulting free nodes into the list of free nodes

The Clustering Critical-Path Algorithm

A critical path is defined as the longest sequence of dependent objects that are accessed serially. A critical path is determined based on the weights assigned to each node. A weight is defined based on several parameters such as the size of the data item, the maximum weight of the descendents, the total weight, and the number of descendents.

Definition 6. A critical node is a node that has a child with an in-degree greater than 1.

Load Balancing

Critical Node effect. Allocate a critical node with the highest number of children with in-degrees greater than 1 first.

Number of children with in-degrees of 1. Allocate nodes with the highest number of children with in-degrees of 1 first. This could free up more nodes to be allocated in parallel channels.

Clustering Related Objects

The weight of a node should be made a function of the weights of the incoming and outgoing edges. The weight of each node is calculated based on Equation 2. It should be noted that:

- There is a trade-off between load balancing and clustering related objects: The allocation strategy for the purpose of load balancing could upset the clustering of related objects and vice versa. Therefore, we propose a factor to balance the two requirements. This factor takes a constant value $\in [0,1]$ and can be assigned to favor either requirement over the other.
- The size of a data item is a multiple of a constant value.
- The weight of an edge is a multiple of a constant value.

$$W = MWC + F\left[S + NCID1 + \sum_{i=1}^{NCIDM} SPC_i - NCIDM(S)\right] + (1-F)\left[(NMIW)MIW + \frac{1}{(NMOW)MOW}\right] \quad (2)$$

where

W weight of a node
MWC maximum weight among the node's children
F factor of optimizing for load balancing versus clustering related objects
S size of a node (object)
NCID1 number of children with in-degrees of 1
NCIDM number of children with in-degrees greater than 1
SPC size of all parent objects
MIW maximum weight of incoming edges
NMIW number of maximum-weighted incoming edges
MOW maximum weight of outgoing edges
NMOW number of maximum-weighted outgoing edges

The algorithm required to assign the weight of every node in the graph with time complexity of $O(n^2)$ (n is the number of nodes in the DAG) is as follows.

AssignWeights(DAG) Algorithm

1) for every node *i* (Starting at the leaf nodes and traversing the DAG in a breadth-first manner)
2) Calculate SPC_i
3) Calculate W_i

The CCP algorithm takes a DAG as its input and calls the AssignWeights Algorithm. The running time of the CCP algorithm is equal to the running time of AssignWeights plus the running time of the *repeat* loop. The loop has to be repeated n times and Line 4 can be done in $O(n)$.

Therefore, the overall running time of the CCP algorithm is $O(n^2)$.

CCP(DAG) Algorithm

1) AssignWeights(DAG)
2) **repeat** until all the nodes have been processed
3) Select the free node N with the largest weight
4) **if** all parents of N are fully allocated on the channels
5) place it on the currently least-loaded channel
6) **else**
7) Fill up the least-loaded channel(s) with nulls up to the end of the last allocated parent of *N* then place *N* on it.

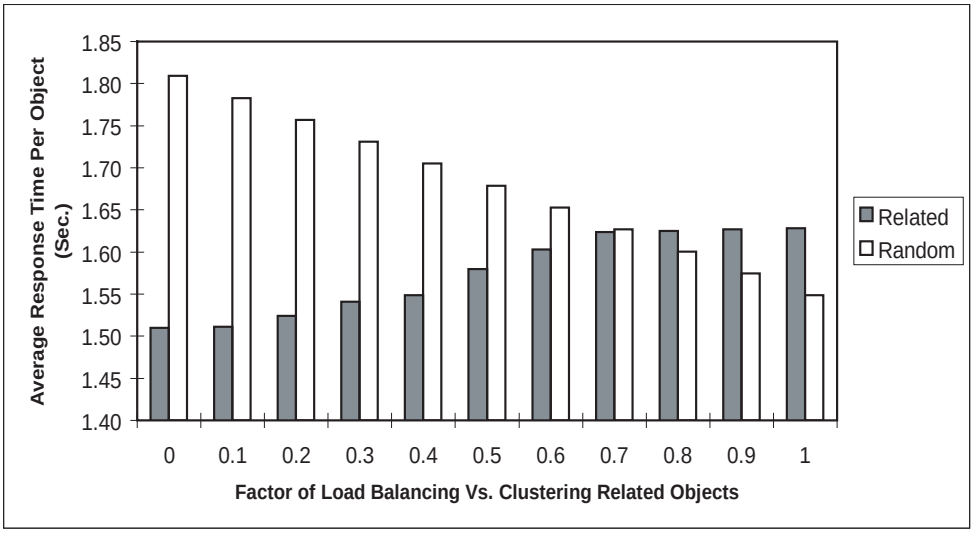
Performance Evaluation

To evaluate the performance of the proposed algorithms, our simulator was extended to measure the average response time per data item retrieval. To measure the effectiveness of the algorithms across a more unbiased test bed, the degree of connectivity among the data items in the DAG was randomly varied, and 100 different DAGs were generated. In every DAG, the out-degrees of the nodes were determined within the range of 0 and 3. To limit the experimentation running time, a decision was made to limit the number of nodes of each DAG to 60. The weights connecting the nodes, similar to the experiment reported in previously, were categorized as strong, normal, and weak, and were uniformly distributed along the edges of a DAG.

The simulation is accomplished in two steps: In the first step, every DAG is mapped onto the air channels using the LOF and CCP algorithms. In the second step, the simulator simulates the process of accessing the air channels in order to retrieve the data items requested in a query. Among the requested data items, 80% were selected based on their semantic relationship within the DAG and 20% were selected randomly. Finally, the average response time was calculated for 100,000 runs.

1) **Number of Air Channels.** As anticipated, increasing the number of channels resulted in a better response time for both the LOF and CCP. However, this improvement tapered off as the number of channels increased above a certain threshold value, since, additional parallelism provided by the number of channels did not match the number of free nodes available to be allocated, simultaneously. In addition, as expected, the CCP method outperformed the LOF method—the CCP heuristics attempt to smooth the distribution of the objects among the air channels while clustering the related objects.
2) **Out-Degree Distribution.** In general, the CCP method outperformed the LOF method. When the out-degree distribution is biased to include nodes with larger out-degrees (i.e., making the DAG denser), the LOF performance degrades at a much faster rate than the CCP method. This is due to the fact that such bias introduces more critical nodes and a larger number of children per node. The CCP method is implicitly capable of handling such cases.
3) **Factor of Load Balancing versus Clustering Related Objects.** To get a better insight on the operations of the CCP method, we analyzed its behavior by varying the load balancing and degree of clustering (F; Equation 2). In this experiment, 80% of the data items requested by each query were related through certain semantic links and the rest were selected randomly. As can be seen (Figure 10), biasing in favor of clustering degrades the average response time for randomly selected data items. Optimization based on clustering increases the overall length of the broadcast, thus, contributing to larger response time for randomly accessed objects. For semantically related data

Figure 10. Load balancing versus clustering



items, however, decreasing *F* influenced the broadcast to favor the allocation of related data items closer to one another, thus improving the average response time. Such rate of improvement, however, declined as *F* reached a certain threshold value (0.2 in this case). At this point the behavior of the system reaches a steady state (the objects cannot be brought closer to one another). In different simulation runs, the ratio of randomly selected and semantically related data items varied in the ranges between 30/70% and 70/30% and the same behavior was observed. This figure can be productive in tuning the performance of the CCP method. Assuming a feedback channel is to be used to collect the statistics of the users' access pattern, *F* can be adjusted adaptively to match the access pattern. As an example, if the frequency of accessing data items based on their connection is equivalent to that of accessing data items randomly, then a factor value of 0.7 would generate the best overall response time.

Section Conclusion

This section concentrated on the proper mapping of data items on multiple parallel air channels. The goal was to find the most appropriate allocation scheme that would (a) preserve the connectivity among the data items, (b) provide the minimum overall broadcast time (load balancing), and (c) cluster related data items close to one another (improving the response time). Applying the LOF heuristic showed an improvement in load balancing. However, it proved short in solving the third aforementioned requirement. The CCP algorithm was presented to compensate this shortcoming. Relying on the critical path paradigm, the algorithm assumed several heuristics and showed better performance.

ENERGY-EFFICIENT INDEXING

In this section, we investigate and analyze the usage of indexing and indexed-based retrieval techniques for data items along the single and parallel broadcast channel(s) from an energy-efficient point of view. In general, index-based channel access protocols involve the following steps.

1) **Initial probe.** The client tunes into the broadcast channel to determine when the next index is broadcast.
2) **Search.** The client accesses the index and determines the offset for the requested data items.
3) **Retrieve.** The client tunes into the channel and pulls all the required data items.

In the initial probe, the mobile unit must be in active, operational mode. As soon as the mobile unit retrieves the offset of the next index, its operational mode could change to doze mode. To perform the *Search* step, the mobile unit must be in active mode, and when the unit gets the offset of the required data items, it could switch to doze mode. Finally, when the requested data items are being broadcast (*Retrieve* step), the mobile unit changes its operational mode to active mode and tunes into the channel to download the requested data. When the data is retrieved, the unit changes to doze mode again.

Object-Oriented Indexing

Object-oriented indexing is normally implemented as a multilevel tree. We can classify the possible implementation techniques into two general schemes: single-class indexing and hierarchical indexing. In the single-class scheme, multiple multilevel trees are constructed, each representing one class. In this case, the leaf nodes of each tree point to data items belonging only to the class indexed by that tree. A query requesting all objects with a certain ID has to navigate all these trees. On the other hand, the hierarchical scheme constructs one multilevel tree representing an index for all classes. The same query has to only navigate the common tree.

Data Indexing on a Single Air Channel

We assume an *air-channel page* as the storage granule on the air channel. Due to the sequential nature of the air channel, the allocation of the nodes of a multilevel tree has to follow the navigational path used to traverse the tree, starting at the root. Therefore, an ordering scheme is used to sequentially map the nodes on the air channel. Similarly, data items are allocated onto air channel pages following their index.

Storage Requirement

The overall storage requirement is the sum of the storage required by the inner and leaf nodes. For both schemes, the structure of the inner node is the same (Figure 11). An inner node is a collection of records, where each record is composed of a [*Key*, *pointer*] pair. Assume the order of the tree is o and the fan-out of every node is f ($o \leq f \leq 2o$, except for the root where $2 \leq f \leq 2o$). The leaf node structures of both schemes are shown in Figure 12. As can be seen, the main difference between the two schemes is that the hierarchical scheme requires a list of classes that have data items indexed by the index.

For the sake of simplicity, and without loss of generality, we assume that there are no overflow pages, furthermore assuming the following notations.

- P size of air-channel page
- K average number of distinct keys for an attribute
- S average size of a leaf-node index record in a single-class index

Figure 11. Inner-node structure of single-class and hierarchical schemes

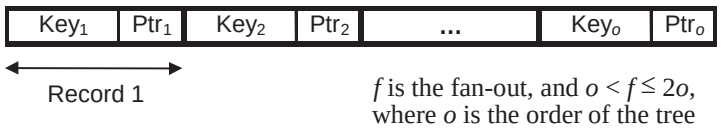


Figure 12. Leaf-node structure of single-class and hierarchical schemes

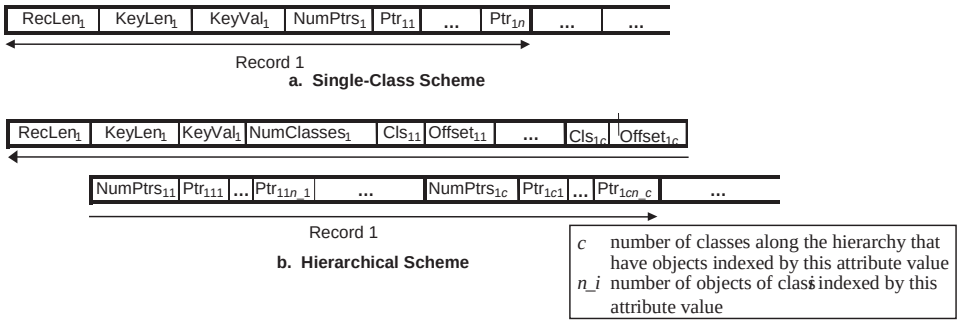

H average size of a leaf-node index record in a hierarchical index

L number of leaf-node pages

IN number of inner-node pages for either scheme

$$L_{Single-Class} = \lceil K / \lfloor P / S \rfloor \rceil \quad (3)$$

$$L_{Hierarchical} = \lceil K / \lfloor P / H \rfloor \rceil \quad (4)$$

$$IN = 1 + \lfloor L / f \rfloor + \lfloor \lfloor L / f \rfloor / f \rfloor + \ldots \quad (5)$$

It should be noted that in the case of a single-class scheme, Equations 3 and 5 should be calculated for all the classes.

Timing Analysis

To perform the timing analysis, one has to consider the domain of a query. The cardinality of the domain of a query is the number of classes to be accessed by the query along the hierarchy. Our timing analysis evaluates the *response* and *active* time as the performance metrics. The response time is defined as the time elapsed between the first user access to the air channel and when the required information is retrieved. The active time is defined as the time during which the mobile unit has to be active accessing the channel. In the timing analysis, we use the number of pages as our unit of measurement. Finally, to support our protocols, we assume that every air-channel

page contains control information indicating the location of the first page of the next index. This can simply be implemented as an offset (2 or 4 bytes).

a) **Hierarchical Method.** In this scheme, whether the domain of the query covers one class or all classes along the hierarchy, the same index structure has to be traversed. The protocol is shown below.

Hierarchical Protocol

1) Probe onto channel and get offset to the next index *active*
2) Reach the index *doze*
3) Retrieve the required index pages *active*
4) Reach the required data pages *doze*
5) Retrieve required data pages *active*

- **Response Time.** Assume I_H and D denote the size of the index and data, respectively. On average, it takes half the broadcast (the size of the broadcast is I + D) to locate the index from the initial probe. Once the index is reached, it has to be completely traversed before data pages appear on the broadcast. On average, it takes half the size of the data to locate and retrieve the required data items. Thus, the response time is proportional to:

$$\frac{I_H + D}{2} + I_H + \frac{D}{2} = \frac{3I_H}{2} + D = Broadcast + \frac{I_H}{2} \quad (6)$$

- **Active Time.** The mobile unit's modules have to be active to retrieve a page. Once the index is reached, a number of inner-node pages have to be accessed in order to get and retrieve a leaf-node page. The number of pages to be retrieved at the index is equal to the height of the index tree ($\log_f(D)$). Finally, the amount of the data pages to be read is equal to the number of data items to be retrieved that reside on distinct pages (NODP). Therefore, the active time is:

$$1 + \log_f(D) + NODP \quad (7)$$

b) **Single-Class Method.** In this scheme, we assume that the first page of every index contains information indicating the location of each index class. This structure can be implemented by including a vector of pairs [class_id, offset]. Assuming that the size of the offset and the class_id is 4 bytes each, the size of this structure would be 8c, where c is the number of class indexes on the broadcast.

Single-Class Protocol

1) Probe onto channel and get offset to the next index *active*
2) Reach the index *doze*
3) Retrieve offsets to the indexes of required classes *active*
4) for every required class
5) Reach the index *doze*
6) Retrieve the required index pages *active*
7) Reach the required data *doze*
8) Retrieve required data pages *active*

- **Response Time.** The size of a single index and its associated data are labeled as I_i and D_i, respectively. Since the total number of objects to be indexed is the same in single-class and hierarchical indexes, the sum of all D_i for all classes is equal to D. Assume a query references a set of classes where x and y stand for the first and last classes to be accessed. The average distance to be covered to get to x is half the distance covering the indexes and data between the beginning of y and the beginning of x. Once the index x is located, then all the indexes and data of all the classes between x and y (including

those of x) have to be traversed. Once y is reached, its index and half of its data (on average) have to be traversed. Thus, the response time is proportional to:

$$\frac{\sum_{i=y}^{x-1}(I_i + D_i)}{2} + \sum_{i=x}^{y}(I_i + D_i) - \frac{D_y}{2} \qquad (8)$$

Equation 8 provides a general means for calculating the average response time. However, the results are dependent on the location of the probe and the distance between x and y. It has been shown that the response time is lower bounded by half the size of the broadcast and upper bounded by slightly above the size of the broadcast. Further discussion on this issue is beyond the scope of this chapter and the interested reader is referred to Chehadeh, Hurson, and Kavehrad (1999).

- **Active Time.** Similar to the hierarchical case, the active time is dependent on the number of index pages and data pages to be retrieved. Therefore, the active time is the sum of the height of the trees for all the indexes of classes to be retrieved plus the number of the corresponding data pages. This is shown in the Equation 9. The 2 in the front accounts for the initial probe plus the additional page containing the index of classes (Line 3 in the protocol).

$$2 + \sum_{i=x}^{y}\left[\log_f(D_i) + NODP_i\right] \qquad (9)$$

Performance Evaluation

Our simulator was extended to study both the response time and energy consumption with respect to the two allocation schemes. The overall structure of the schema graph determines the navigational paths among the classes within the graph. The relationships of the navigational paths within the graph influence the number and structure of indexes to be used.

- **Inheritance Relationship.** Within an inheritance hierarchy, classes at the lower level of the hierarchy inherit attributes of the classes at the upper level. Therefore, data items belonging to the lower-level classes tend to be larger than those within the upper levels. The distribution of the number of data items is application dependent. In our analysis, and without loss of generality, we assumed the data items to be equally distributed among the classes of the hierarchy.
- **Aggregation Relationship.** In an aggregation hierarchy, data items belonging to lower classes are considered "part of" data items and those at the higher ends are the "collection" of such parts. Therefore, data items belonging to higher classes are generally larger than those belonging to the lower ones. In addition, the cardinality of a class at the upper end is smaller than a class at the lower end.

As a result, the organization of classes within the schema graph has its influence on the distribution of both the number and size of data items among the classes of the database. We assumed an average of eight classes for each hierarchy and categorize the sizes of data items as small, medium, large, and very large. Furthermore, 60% of the data items have distinct keys and the value of any attribute is uniformly distributed among the data items containing such attribute. Table 7 shows a list of all the input parameters assumed for this case.

The information along the broadcast channel is organized in four different fashions: the hierarchical and single-class methods for the inheritance and aggregation relationships. Table 8 shows the data and index page sizes for these organizations. Note that it is the number of data items (not data

Table 7. Input parameters

Parameter	Value (Default/Range)
Number of Data Items on Broadcast	5,120
Average Number of Classes Along Hierarchy	8
Percentage Distribution of Number of Data Items in Inheritance Hierarchy	25,25,25,25%
Percentage Distribution of Number of Data Items in Aggregation Hierarchy	40,30,20,10%
Distribution of Data Size [S,M,L,VL]	16,512,3K,6K bytes
Distribution of the Data Sizes in Inheritance Hierarchy	VL,L,M,S
Distribution of the Data Sizes in Aggregation Hierarchy	S,M,L,VL
Percentage of Classes to be Retrieved (Default/Range)	70% / [10-100%]
Average Number of Data Items to Retrieve per Class	2
Fan-Out in Index Tree	5
Average Number of Data Items with Distinct Key Attribute per Class	60% of data items per class
Size of Air-Channel Page	512 bytes
Broadcast Data Rate	1 M bits/sec
Power Consumption Active Mode	130 mW
Power Consumption Doze Mode	6.6 mW

Table 8. Number of index and data pages

	Aggregation/ Hierarchical	Aggregation/ Single [Eight Classes]	Inheritance/ Hierarchical	Inheritance/ Single [Eight Classes]
Index Pages	2,343	67,63,49,39,36,32,18,16	2,343	40,40,40,40,40,40,40,40
Data Pages	13,562	73,75,652,769,2504,28140,3206,3502	34,015	12517,11520,5253,4252,637,440,25,20

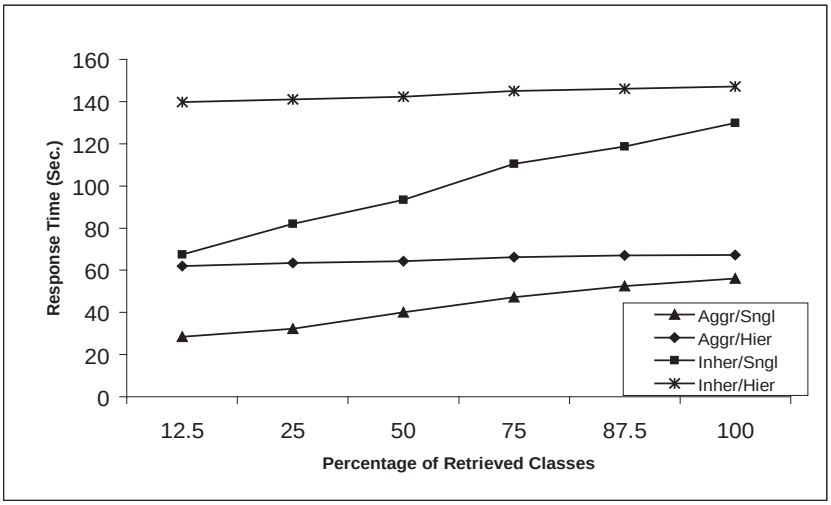
pages) that controls the number of index blocks. Within each indexing scheme, for each query, the simulator simulates the process of probing the air channel, getting the required index pages, and retrieving the required data pages. In each query, on average, two data items from each class are retrieved. The simulation measures the response time and amount of energy consumed.

a) **Response Time.** Placing an index along the air channel contributes to extra storage overhead and thus longer response time. Hence, the best response time is achieved when no index is placed, and the entire broadcast is searched. Table 9 shows the degradation factor in the average response time due to the inclusion of an index in the broadcast. The factor is proportional to the ratio of the size of the index blocks to that of the entire broadcast.

Figure 13 shows the response time for all four different broadcast organizations. From the figure, one could conclude that for both the inheritance and aggregation cases, the response time of the hierarchical organization remained almost constant (with a slight increase, as the number of classes to retrieve increases). This is due to the fact that regardless of the number of classes and the location of the initial probe, all accesses have to be directed to the beginning of the index (at the beginning of the broadcast). The slight increase is attributed to the increase in the total number of objects to be retrieved — assuming that the objects to be retrieved are distributed uniformly along the broadcast. It should be noted, however, that such an increase is only minor since the response time is mainly influenced by the initial procedure.

Two observations can be made: (a) the single-class method offers a better response time than the hierarchical case and (b) the response time for the single-class method increases as the number of retrieved classes increase. The first observation is due to the fact that in the single-class method, accesses do not have to be directed to the beginning

Figure 13. Response time versus number of retrieved classes



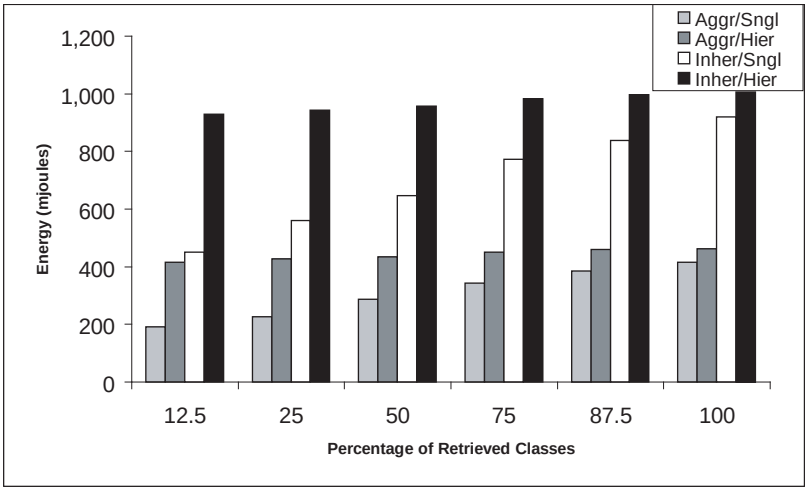
of the broadcast. The second observation is due to the fact that an increase in the number of classes to be retrieved directly increases the number of index and data pages to be accessed.

Indexing based on the aggregation relationship offers lower response time than indexing based on the inheritance relationship since the distribution of the number of objects in the inheritance relationship is more concentrated on the larger objects. Having larger objects results in a longer broadcast, and, hence, it takes longer to retrieve the objects.

b) **Energy.** For each query, the amount of energy consumed is the sum of the energy consumed while the unit is in both active and doze modes. In the case where no index is provided, the mobile unit is in active mode during the entire probe. However, in the case where an index is provided, the active time is proportional to the number of index and data pages to be retrieved. As expected, the active time increases as the number of retrieved classes increases. The hierarchical method searches only one large index tree, whereas the single-class method searches through multiple smaller index trees. The number of pages to retrieve per index tree is proportional to the height of the tree. For a query spanning a single class, the single-class method produces a better active time than the hierarchical method. As the number of classes to be retrieved increases, the hierarchical tree is still traversed only once. However, more single-class trees have to be traversed, and, hence, results in an increase in the active time.

In both the single-class and the hierarchical methods, the aggregation case requires lower active time than the inheritance case since the inheritance case has larger objects, thus requiring the retrieval of more pages. For the sake of practicality, we utilized the power consumption data of the Hitachi SH7032 processor: 130 mW when active and 6.6 mW when in doze. Since power is the amount of energy consumed per unit

Figure 14. Detailed energy consumption



of time, the total energy can be calculated directly using Equation 10:

$$Energy = (ResponseTime - ActiveTime)DozeModePower + (ActiveTime)ActiveModePower \quad (10)$$

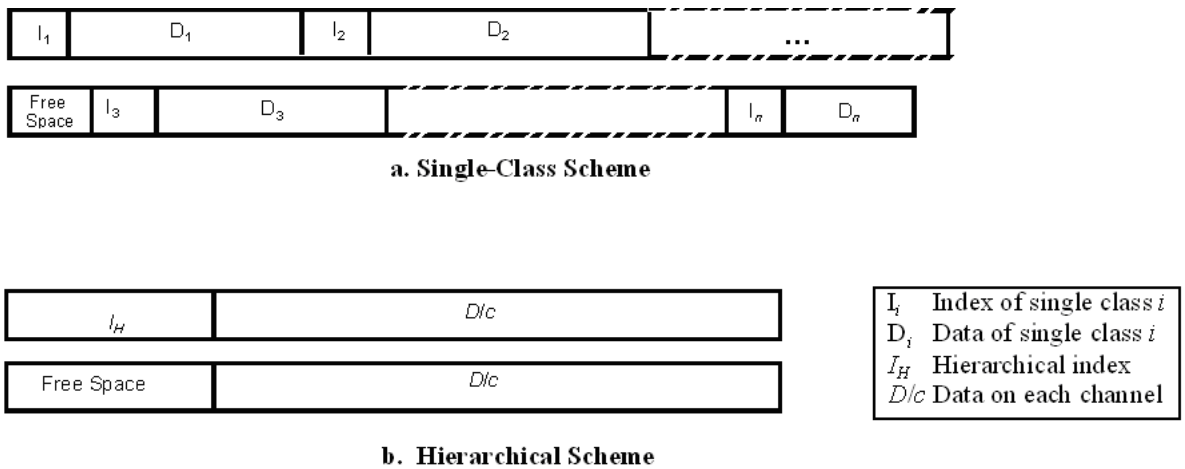
Figure 14 details the energy consumed during the entire query operation in mjoules. The power consumption of the mobile unit is much higher while the unit is in active mode, with a ratio of 19.7. However, our experiments showed that, in general, the duration of the active-mode operations was much smaller than doze-mode operations. As a result, the energy consumed during doze time was the dominating factor. As can be seen from Figure 14, the single-class method is superior to the hierarchical method. This is very similar to the results obtained for the response time, and similarly, the power consumption of the single-class method is lower than that of the hierarchical method.

Data Indexing on Parallel Air Channels

Allocation of Object-Oriented Indexing on Parallel Air Channels

Figure 15 shows the allocation of the single-class and hierarchical-based schemes on the two parallel air channels. For the single-class indexing scheme (Figure 15a), the index and data of each class are distributed and placed along the channels. The hierarchical indexing scheme (Figure 15b) places the index on one channel, and divides and distributes the data among the channels. The most popular data items can be put in the free space. Note that in both cases, similar to the single air channel, it is possible to interleave and distribute the index pages and associated data pages using a variety of methods.

Figure 15. Allocation of single-class and hierarchical indexes on two parallel air channels



Storage Requirement

In the case of broadcasting along parallel air channels, the storage requirement is the same as that for a single air channel.

Timing Analysis

In the case of parallel air channels, one has to account for switching between channels when analyzing access time and power consumption. During the switching time, the pages that are being broadcast on different channels cannot be accessed by the mobile unit. In addition, the mobile unit at each moment of time can tune into one channel—*overlapped page range*. By considering the average page size (512 bytes), communication bandwidth (1Mbit/sec), and switching time (the range of microseconds), we assume that the overlapped page range equals two pages. Finally, we assumed that the power consumption for switching between two channels is 10% of the power consumed in active mode. Equation 11 calculates the power consumption.

a) **Hierarchical Method.** The following protocol shows the sequence of operations.

Hierarchical Protocol

1) Probe onto channel and retrieve offset to the next index *active*
2) Do {Reach the next index *doze*
3) Retrieve the required index pages *active*
4) Do {Reach the next possible required data page *doze*
5) Retrieve the next possible required data page *active*
6) }while every possible required data page is retrieved from the current broadcast
7) } while there are unaccessed data items becuse of overlapped page range

$$EnergyConsumption = (ResponseTime - ActiveTime)* DozeModePower + (ActiveTime)* ActiveModePower + TheNumberOfSwitching *10% * ActiveModePower \quad (11)$$

- **Response Time.** I_H and D are used to denote the size of the hierarchy index and data, respectively. For the c-channel environment, the average size of data on each channel is D/c. To locate the index from the initial probe, it takes half the broadcast of one channel (the size of the broadcast is $I_H + D/c$). Once the index is reached, it has to be completely traversed before data pages appear on the broadcast and, on average, it takes half the size of the data to locate and retrieve the required data items. Thus, the response time from the initial probe to the first complete broadcast is proportional to

$$(I_H + D/c)/2 + I_H + (D/c)/2 = 3\,I_H/2 + D/c \quad (12)$$

Because of the overlapped page range, the mobile units may not be able to get all of the required data during one complete broadcast (e.g., because of conflicts). Therefore, it has to scan the next broadcast. Let P be the probability of the data that are in the same overlapped page range. The distance from the last location to the next index is also half the size of the data of one channel. Once the index is reached, the same process will occur. Thus, the response time from the last location of the previous broadcast until the mobile unit can acquire all of the required data is proportional to

$$P * (D/2c + I_H + D/2c) = P * (I_H + D/c) \quad (13)$$

As a result, on average, the response time is proportional to

$$(1.5 + P)\, I_H + (1 + P)\, D/c \qquad (14)$$

- **Active Time.** The mobile unit has to be active during the first probe (to retrieve a page). Once the index is reached, a number of nonleaf node pages have to be accessed in order to get and retrieve a leaf-node page. The number of pages to be retrieved at the index is equal to the height of the index tree ($\log_f(D)$). The amount of the data pages to be read is equal to the *NODP*. Again, because of the overlapped page range among parallel air channels, the probability of accessing the index of the next broadcast has to be included. Therefore, the active time is proportional to

$$1 + \log_f(D) + NODP + P * \log_f(D) \qquad (15)$$

b) **Single-Class Indexing Scheme**

Single-Class Protocol

1) Probe onto channel and retrieve offset to the next index *active*
2) Do {Reach the next index *doze*
3) Retrieve offsets to the indexes of required classes *active*
4) Reach the next possible index *doze*
5) Retrieve the next possible required index page *active*
6) Do {Reach the next possible index or data page *doze*
7) Retrieve the next possible index or data page *active*
8) } while not (all indexes and data of required classes are scanned)
9) } while there are some data pages which are not retrieved because of overlapped page range

- **Response Time.** As before, the size of a single index and its associated data are labeled as I_i and D_i, respectively. The response time is simply driven by dividing Equation 8 by the number of the air channels (Equation 16):

$$\frac{\sum_{i=y}^{x-1}(I_i + D_i)}{2c} + \frac{\sum_{i=x}^{y}(I_i + D_i)}{c} - \frac{Dy}{2c} \qquad (16)$$

Let P be the probability of the data that are in the same overlapped page range. Thus, the response time for getting the remaining required data items on the second broadast probe is proportional to

$$P*\left(\frac{\sum_{i=y}^{x-1}(I_i + D_i)}{2c} + \frac{\sum_{i=x}^{y}(I_i + D_i)}{c} - \frac{Dy}{2c}\right) \qquad (17)$$

As a result, the response time is proportional to

$$(1+P)*\left(\frac{\sum_{i=y}^{x-1}(I_i + D_i)}{2c} + \frac{\sum_{i=x}^{y}(I_i + D_i)}{c} - \frac{D_y}{2c}\right) \qquad (18)$$

- **Active Time.** Similar to the hierarchical case, the active time is the sum of the height of the trees for all the indexes of the classes to be retrieved plus the number of the corresponding data pages. This is shown in Equation 19. The *2* at the beginning of the equation accounts for the initial probe plus the additional page containing the index of classes. Because of the overlapped page range among parallel air channels, the probability of accessing the index of the next broadcast has to be included. Therefore, the active time is proportional to

$$2 + \sum_{i=x}^{y}\left[\log_f(D_i) + NODP_i\right] + \frac{P}{2}\sum_{i=x}^{y}\log_f(D_i) \qquad (19)$$

Performance Evaluation

Once again, our simulator was extended to study the response time and energy consumption of the single-class and hierarchical indexing schemes in parallel air channels based on the input parameters presented in Table 7.

a) **Response Time.** In the case of no indexing, the response time was constant and independent of the number of channels. This is due to the fact that without any indexing mechanism in place, the mobile unit has to scan every data page in sequence until all required data pages are acquired. Moreover, when indexing schemes are in force, the response time lessens as the number of channels increases.

For the inheritance and aggregation cases, the response time decreases as the number of channels increases. This is due to the fact that, as the number of channels increases, the length of the broadcast becomes shorter. However, the higher the number of channels, the higher the probability of conflicts in accessing data residing on different channels in the overlapped page range. As a result, doubling the number of channels will not decrease the response time by half.

For both the inheritance and aggregation indexing schemes, the single-class method offers a better response time than the hierarchical method. The single-class method accesses do not have to be started at the beginning of the broadcast. For the hierarchical method, on the other hand, any access has to be started from the beginning of the broadcast, which makes the response time of the hierarchical method longer. Indexing based on the aggregation relationship offers a lower response time than that of the inheritance relationship because the distribution of data items in the inheritance relationship is more concentrated on the larger data items.

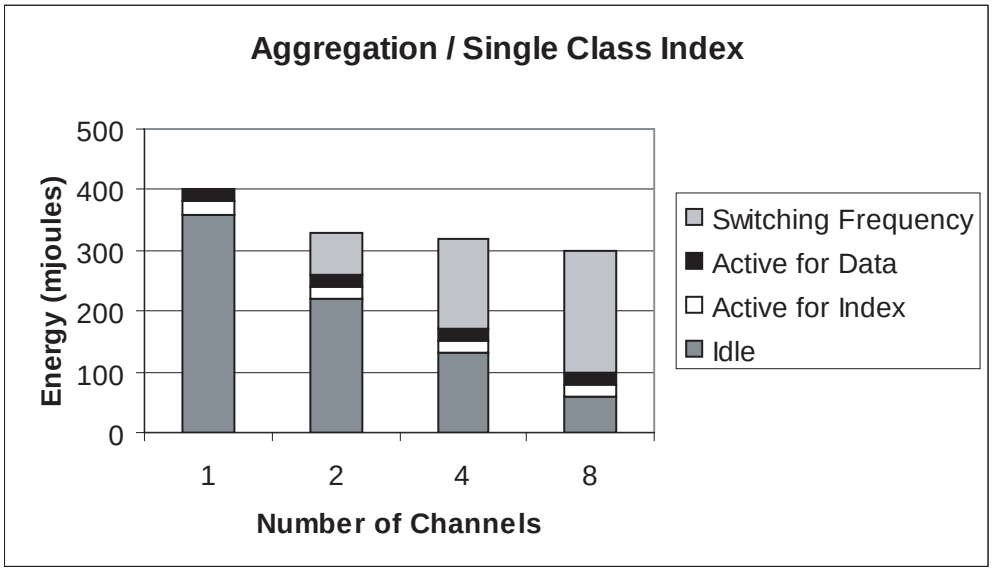
b) **Energy.** The active time is proportional to the number of index and data pages to be retrieved. For broadcast data without an index, the active time is the same as the response time. In addition, for all four indexing schemes, the active time remains almost constant and independent of the number of air channels. This is because the active time is proportional to the number of index and data pages to be retrieved.

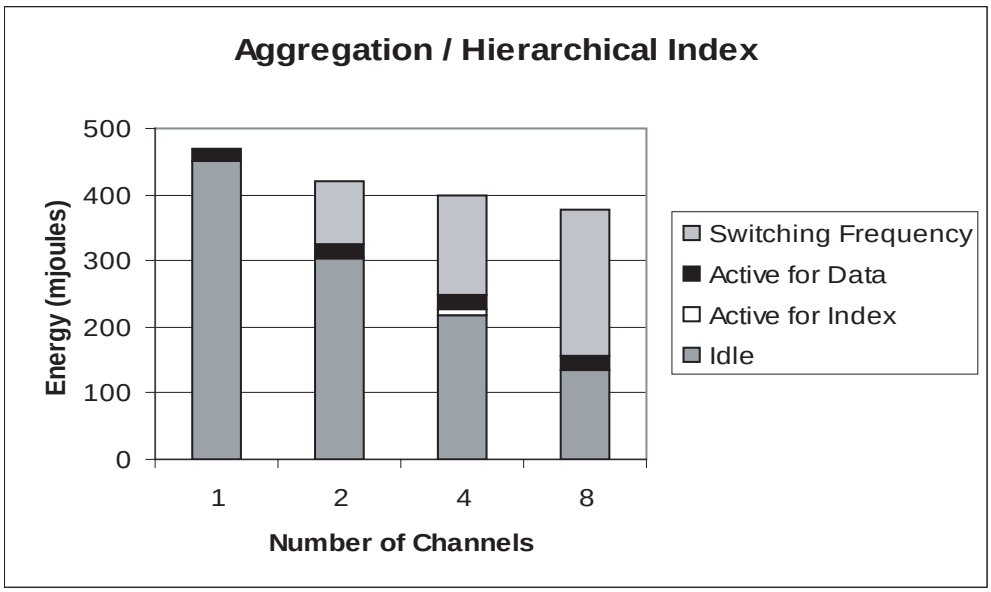
In general, the hierarchical method requires less active time than the single-class method. The hierarchical method searches only one large index tree, whereas the single-class method searches through multiple smaller index trees, and the number of pages to be retrieved per index tree is proportional to the height of the tree. In both the single-class and the hierarchical methods, the indexing based on an aggregation relationship requires lower active time than the inheritance method. This is simply due to the fact that the inheritance relationship resulted in larger data items, thus requiring the retrieval of more pages.

In a separate simulation run we observed the total energy consumption. It was concluded that the total energy consumption of broadcasting without any indexing schemes is much higher than that of broadcasting supported by indexing, and the energy consumption of the single-class method is lower than that of the hierarchical method. This is very similar to the results obtained for the response time. When indexing was supported, energy consumption, on average, decreased about 15 to 17 times in the case of the aggregation relationship and the inheritance relationship, respectively.

Figure 16 shows the detail of energy consumption for the aggregation relationship. As the number of channels increases, the energy

Figure 16. Detailed energy consumption





consumption during idle time decreases. The energy consumption for retrieving indexes increases because the probability of the data being in the same overlapped page range increases. The higher this probability, the more the mobile unit has to get the index from the next broadcast. Finally, the energy consumption for switching between two

different channels increases because the required data are distributed among the channels. The larger the number of channels, the more distributed is the data among the channels, and, consequently, the more frequent switching between channels.

Section Conclusion

This section investigated an energy-efficient solution by the means of applying indexing schemes to object-oriented data broadcast over single and parallel air channels. Two methods, namely, the hierarchical and single-class methods, were explored. Timing analysis and simulation were conducted to compare and contrast the performance of different indexing schemes against each other. It was shown that including an index degrades the response time moderately, however, such degradation is greatly offset by the improvement in energy consumption. For a single air channel, broadcasting with supported indexing schemes increased the response time when compared with broadcasting without indexing support. However, the response time is reduced by broadcasting data with an index along parallel air channels. Moreover, the response time decreased as the number of air channels is increased. Relative to nonindexed broadcasting, the mobile unit's energy consumption decreased rather sharply when indexing is supported. For a set of queries retrieving data items along the air channel(s), the single-class indexing method resulted in a faster response time and lower energy consumption than the hierarchical method.

CONFLICTS AND GENERATION OF ACCESS PATTERNS

One of the problems associated with broadcasting information on parallel air channels is the possibility for conflicts between accessing data items on different channels. Because the mobile unit can tune into only one channel at a time, some data items may have to be retrieved on subsequent broadcasts. In addition, during the channel switch time, the mobile unit is unable to retrieve any data from the broadcast. Conflicts will directly influence the access latency and, hence, the overall execution time. This section is intended to provide a mathematical foundation to calculate the expected number of passes required to retrieve a set of data items requested by an application from parallel air channels by formulating this problem as an *asymmetric traveling salesman problem* (TSP). In addition, in an attempt to reduce the access time and power consumption, we propose heuristic policies that can reduce the number of passes over parallel air channels. Analysis of the effectiveness of such policies is also the subject of this section.

Enumerating Conflicts

Equation 1 showed the number of broadcasts (passes) required to retrieve K data items from M parallel channels if conflicts between data items are independent. To calculate $P(i)$, it is necessary to count the number of ways the data items can be distributed while having exactly i conflicts, then divide it by the total number of ways the K data items can be distributed over the parallel channels. In order to enumerate possible conflicting cases, we classify the conflicts as single or double conflicts as defined below.

Definition 7. A single conflict is defined as a data item in the conflict region that does not have another data item in the conflict region in the same row. A double conflict is a data item that is in the conflict region and does have another data item in the conflict region in the same row.

The number of data items that cause a double conflict, d, can range from 0 (all single conflicts) up to the number of conflicts, i, or the number of remaining data items, $(K - i - 1)$. When counting combinations, each possible value of d must be considered separately. The number of possible

combinations for each value of d is summed to determine the total number of combinations for the specified value of i. When counting the number of ways to have i conflicts and d double conflicts, four factors must be considered.

- Whether each of the $(i - d)$ data items representing a single conflict is in the left or right column in the conflict region. Because each data item has two possible positions, the number of variations due to this factor is $2^{(i-d)}$.
- Which of the $(M - 1)$ rows in the conflict region are occupied by the $(i - d)$ single conflicts. The number of variations due to this factor is $\binom{M-1}{i-d}$.
- Which of the $(M-1)-(i-d)$ remaining rows in the conflict region are occupied by the d double conflicts; $(i-d)$ is subtracted because a double conflict cannot occupy the same row as a single conflict. The number of variations due to this factor is $\binom{(M-1)-(i-d)}{d}$
- Which of the $(MN - 2M + 1)$ positions not in the conflict region are occupied by the $(K - i - d - 1)$ remaining data items. The number of variations due to this factor is $\binom{MN-2M+1}{K-i-d-1}$.

Note that these sources of variation are independen from each other and, hence:

$$P(i) = \frac{\sum_{d=0}^{d \le MIN(i,K-i-1)} 2^{(i-d)} \binom{M-1}{i-d} \binom{(M-1)-(i-d)}{d} \binom{MN-2M+1}{K-i-d-1}}{\binom{MN-1}{K-1}} \quad (20)$$

If the conflicts produced by one data item are independent from the conflicts produced by all other data items, then Equation 20 will give the number of passes required to retrieve all K requested data items. However, if the conflicts produced by one data item are not independent of the conflicts produced by other data items, additional conflicts will occur which are not accounted for in our analysis. Equation 20 will thus underestimate the number of broadcasts required to retrieve all K data items.

Retrieving Data from Parallel Broadcast Air Channels in the Presence of Conflicts

The problem of determining the proper order to retrieve the requested data items from the parallel channels can be modeled as a TSP. Making the transformation from a broadcast to the TSP requires the creation of a complete directed graph G with K nodes, where each node represents a requested object. The weight w of each edge (i, j) indicates the number of broadcasts that must pass in order to retrieve data item j immediately after retrieving data item i. Since any particular data item can be retrieved in either the current broadcast or the next broadcast, the weight of each edge will be either 0 or 1. A weight of 0 indicates that the data item j is after data item i in the broadcast with no conflict. A weight of 1 indicates that data item j is either before or in conflict with data item i.

Simulation Model

The simulation models a mobile unit retrieving data items from a broadcast. A broadcast is represented as an N x M two-dimensional array, where N represents the number of data items in each channel of a broadcast and M represents the number of parallel channels. For each value of K, where K represents the number of requested data items $(1 \le K \le MN)$, the simulation randomly generates 1,000 patterns representing the uniform distribution of K data items among the broadcast channels. The K data items from each randomly generated pattern are retrieved using various retrieval algorithms. The number of passes is recorded and compared. To prevent the randomness of the broadcasts from affecting the

comparison of the algorithms, the same broadcast is used for each algorithm in a particular trial and the mean value is reported for each value of *K*. Finally, several algorithms for ordering the retrieval from the broadcast, both TSP related and non-TSP related, were analyzed.

Data Retrieval Algorithms

Both exact and approximate TSP solution finders and two heuristic based methods were used to retrieve the data items from the broadcast.

a) **TSP Methods.** An exact TSP solution algorithm was used to provide a basis for comparison with the other algorithms. These algorithms are simply too slow and too resource intensive. While a better implementation of the algorithm may somewhat reduce the cost, it cannot change the fact that finding the exact solution will require exponential time for some inputs. Knowing the exact solution to a given TSP does, however, allow us to evaluate the quality of a heuristic approach. A TSP heuristic based on the assignment problem relaxation requires far less CPU time and memory than the optimal tour finders, so it is suitable for use on a mobile unit. A publicly available TSP solving package named TspSolve (Hurwitz& Craig, 1996) was used for all TSP algorithm implementations.

b) **Next Data Item Access.** The strategy used by this heuristic is simply to always retrieve the next available data item in a broadcast. This can be considered as a greedy approach. It is also similar to the nearest neighbor approach to solving TSP problems.

c) **Row Scan.** A simple *row scan* heuristic was also used. This algorithm simply reads all the data items from one channel in each pass. If a channel does not have any requested data in it, it is skipped. This algorithm will always require as many passes as there are channels with requested data items in them. The benefit of this algorithm is that it does not require any time to decide on an ordering. It can thus begin retrieving data items from a broadcast immediately. This is especially important when a large percentage of the data items in a broadcast are requested.

Results

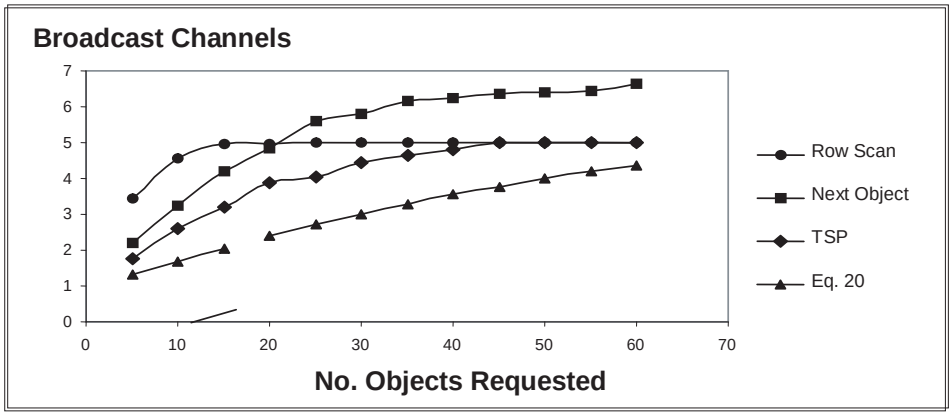
As expected, the TSP methods provide much better results than both the two heuristic-based algorithms. Our simulations showed that the TSP heuristic performed almost exactly as well as the optimal TSP algorithm. This is a very interesting observation because it means that one can use a fast heuristic to schedule retrievals of data items from the broadcast without any performance degradation.

In Figure 17, the TSP methods show that the number of broadcasts required to retrieve all *K* requested data items from a broadcast is much greater than the number of broadcasts predicted by Equation 20 — Equation 20 was based on the assumption that the conflicts among the requested data items are independent. Figure 17 used five parallel channels and 20 pages per channel. It is also interesting to note that the straightforward row scan nearly matches the performance of the TSP-based algorithms when more than about 45% of the total number of data items is requested. In this case, there are so many conflicts that it is virtually impossible to avoid having to make as many passes as there are parallel channels. When this occurs, it is better to do the straightforward row scan than to spend time and resources running a TSP heuristic.

Optimal Number of Broadcast Channels

More channels mean that a given amount of information can be made available in a shorter period of time at the expense of more conflicts.

Figure 17. Comparison of several algorithms for retrieving objects from parallel channels



The simulation results showed that it is always advantageous to use more broadcast channels. While there will be more conflicts between data items, this does not quite counteract the shorter broadcast length of the many-channel broadcasts. This was especially evident when only a few data items in a broadcast were being accessed.

Ordered Access List

The scope of the general access protocol for indexed parallel-channel configuration in the presence of conflicts was extended in order to use heuristics that can generate the ordered access list of requested data items that reduces

- the number of passes over the air channels and
- the number of channel switches.

During the *Search* step, the index is accessed to determine the offset and the channel of the requested data items. Then, a sequence of access patterns is generated. Finally, the *Retrieval* step is performed following the generated access patterns.

Extended Retrieval Protocol

1) Probe the channel and retrieve the offset to the next index
2) Access the next index
3) Do {Search the index for the requested object
4) Calculate the offset of the object
5) Get the channel on which the object will be broadcast
6) } while there is an unprocessed requested object
7) Generate access patterns for the requested objects (using retrieval scheme)
8) Do {Wait for the next broadcast cycle
9) Do {Reach the first object as indicated by the access pattern
10) Retrieve the object
11) } while there is an unretrieved object in the access pattern

12) } while there is an unprocessed access pattern

Performance Evaluation

We extended the simulator to emulate the process of accessing data from a hierarchical indexing scheme in parallel air channels. Moreover, the simulator also analyzes the effect of conflicts on the average access time and power consumption.

Our retrieval scheme, based on the user request, generates a retrieval forest representing all possible retrieval sequences. However, as expected, the generated retrieval forest grows exponentially with the number of requested data items. The key observation needed to reduce the size of the tree is to recognize that each requested data item has a unique list of children, and the number of children for a particular data item is limited to the number of channels. The simulator takes advantage of these observations to reduce the size of the retrieval tree and the calculation time without sacrificing accuracy.

The generation of the user requests was performed randomly, representing a distribution of K data items in the broadcast. In various simulations runs, the value of K was varied from one to $N \times M$—in a typical user query of public data, K is much less than $N \times M$. Finally, to take into account future technological advances, parameters such as transmission rate and power consumption in different modes of operation were fed to the simulator as variable entities.

The simulator calculates the average active time, the average idle time, the average query response time, the average number of broadcast passes, the number of channel switches, and the energy consumption of the retrieval process. As a final note, the size of the index was 13.52% of the size of the broadcast (not including the index) and the number of channels varied from 1 to 16 (2 to 17 when an independent channel was used for transmitting the index).

Simulation Model

For each simulation run, a set of input parameters, including the number of parallel air channels, the broadcast transmission rate, and the power consumption in different operational modes, was passed to the simulator. The simulator was run 1,000 times and the average of the designated performance metrics was calculated. The results of the simulations where an indexing scheme was employed were compared against a broadcast without any indexing mechanism. Two indexing scenarios were simulated.

- **Case 1.** The index was transmitted with the data in the first channel (index with data broadcast).
- **Case 2.** The index was transmitted over a dedicated channel in a cyclic manner.

Results

A comparison between the extended retrieval protocol against the row scan algorithm was performed. The index transmission was performed in a cyclic manner on an independent channel, and the number of requested data items was varied between 5 and 50 out of 5,464 securities within the NASDAQ exchange database. The simulation results showed that, regardless of the number of parallel air channels, the proposed algorithm reduces both the number of passes and the response time compared to the row scan algorithm. Moreover, the energy consumption was also reduced, but only when the number of data items retrieved was approximately 15 or less (Table 10).

Relative to the row scan algorithm, one should also consider the expected overhead of the proposed algorithm. The simulation results showed that in the worst case, the overhead of the proposed algorithm was slightly less than the time required to transmit one data page.

Table 10. Improvement of proposed algorithm versus row scan (10 data items requested)

# of Channels	# of Passes	Response Time	Energy
2	48.0%	28.0%	2.7%
4	68.0%	43.6%	3.1%
8	72.3%	46.5%	3.3%
16	71.8%	40.8%	3.4%

a) **Response Time.** Figures 18 to 20 show the response times in terms of the number of data items requested and the number of broadcast channels. Three cases were examined.

- **Case 1. Data and index are intermixed on broadcast channel(s).** Figure 18 shows the response times for different numbers of broadcast channels when retrieving the full range of existing data items from the broadcast. It can be concluded that when a few data items are requested, the response time decreases as the number of channels increases. After a certain threshold point, the response time increases as the number of channels increases. This is due to an increase in the number of conflicts and hence an increase in the number of passes over the broadcast channels to retrieve the requested data.
- **Case 2. Index is broadcast over a dedicated channel in cyclic fashion.** Similar to Case 1, Figure 19 depicts the simulation results when retrieving the full range of existing data from the broadcast. Again, as expected, the

Figure 18. Response time (Case 1)

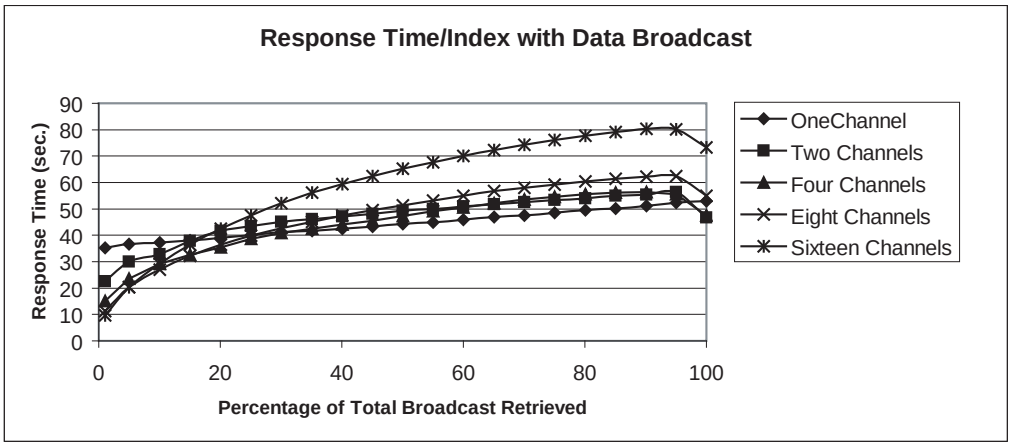


Figure 19. Response time (Case 2)

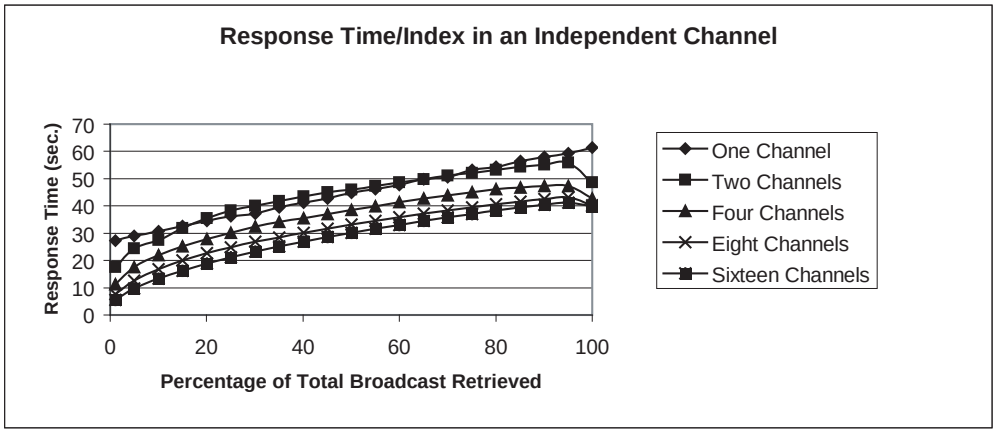

Figure 20. Response time (Case 3)

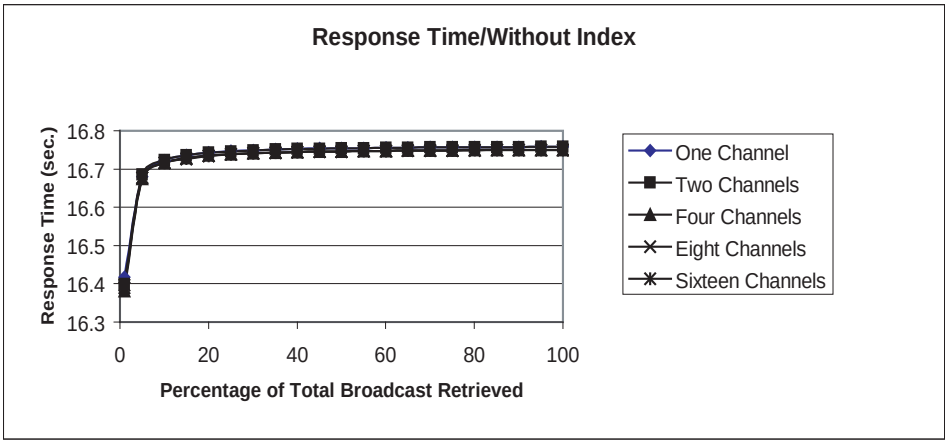


response time decreases as the number of channels increases. Comparing the results for one-channel and two-channel configuration, we can conclude that in some instances the two-channel configuration is not as effective — there is the possibility of conflicts, many of which unavoidably cause an increase in the number of passes and hence longer response time.

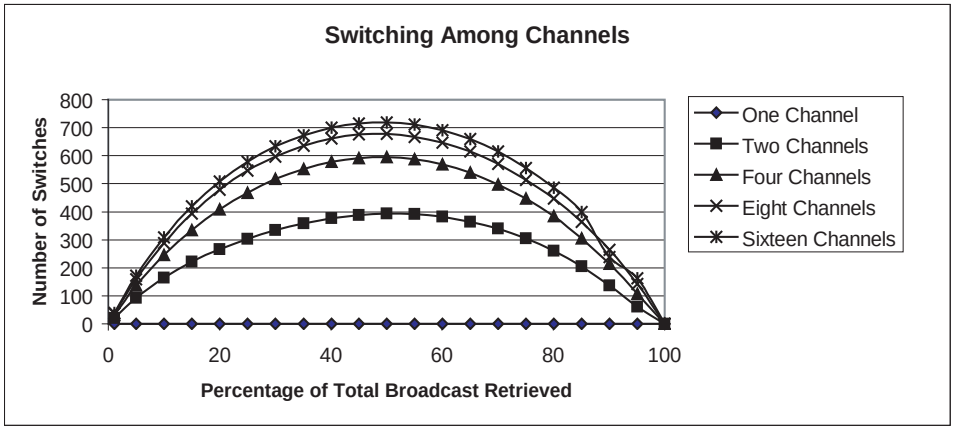
- **Case 3. No indexing is employed.** From Figure 20 one can conclude that the response time remains relatively constant regardless of the number of channels used. In this organization, the user must scan the same amount of data regardless of the user query and number of parallel channels.

In general, employment of an indexing scheme reduces the response time when retrieving a relatively small number of data items. As the percentage of data items requested increases, the number of conflicts increases as well. The proposed retrieval protocol tries primarily to reduce the conflicts in each pass of the broadcast; however, when the number of potential conflicts increases considerably, some conflicts become unavoidable, causing an increase in the number of passes and hence an increase in the response time. When the percentage of requested data approaches 100%, the response time reduces. This proves the validity of the proposed scheduling algorithm since it generates the same retrieval sequence as the row scan method.

b) **Switching Frequency.** Again, three cases were examined.

- **Case 1 & Case 2. Employment of indexing schemes.** Figure 21 shows the switching frequency for Case 1 and Case 2—the switching pattern is not affected by the indexing policy employed. From this figure one can conclude that the switching frequency increases as the number of channels and number of data items retrieved increase. This can be explained by an increase in the number of conflicts; as the proposed method tries to reduce the number of conflicts, the switching frequency will increase. Also, as stated previously, an increase in the number of channels increases the number of conflicts as well. One can notice that when the percentage of data items requested exceeds 50%, the switching frequency begins to decrease. This is due to the fact that the proposed method does not attempt to switch channels as often to avoid the conflicts as the number of conflicts increases substantially.

Figure 21. Switching frequency (Case 1 and Case 2)



- **Case 3. No indexing is employed.** When no indexing technique is utilized, the row scan method is employed, producing a constant switching frequency independent of the number of data items requested. The switching frequency is, at the most, equal to the number of total channels employed in the simulation.

c) **Energy Consumption.** Figures 22 and 23 depict detailed energy consumption when 1% of data items on the broadcast are requested. It can be observed that the energy consumption is almost the same; however, Case 1 consumes more energy than Case 2 in doze mode.

Figure 22. Energy consumption (Case 1)

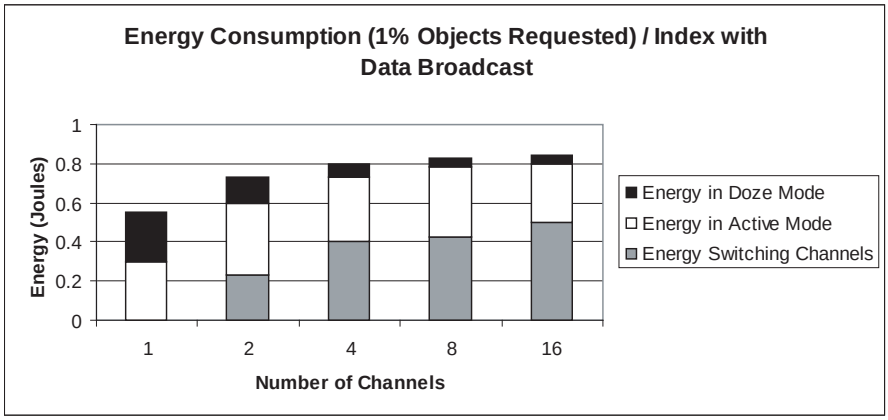


Figure 23. Energy consumption (Case 2)

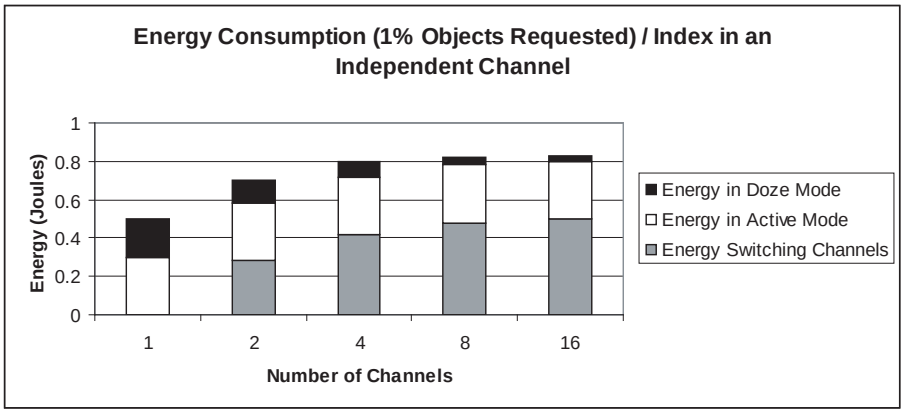

- **Case 1 & Case 2. Employment of indexing schemes.** In general, due to the increase in the number of channel-switching frequency, the energy consumption increases as the number of channels increases. In addition, we noted that the energy consumption increases when up to 50% of the broadcast data items are requested, then it decreases as the number of requested data items increases. This is directly related to the channel-switching frequency. In Case 1, in many instances, the mobile unit must wait in doze mode while the index is retransmitted.
- **Case 3. No indexing is employed.** When no indexing technique is used (Figure 24), the energy consumption varies only minimally due to the nature of the row scan algorithm employed.

From these figures we can observe that both Case 1 and Case 2 consume less power than Case 3 when a small percentage of data items is retrieved (around 1%). When the percentage of data items requested increases, the number of conflicts, the switching frequency, and, consequently, the energy consumption increase.

d) **Number of Passes.** As a note, the number of passes is independent of the index allocation scheme. Therefore, the number of passes for Cases 1 and 2 is the same.

- **Case 1 & Case 2. Employment of indexing schemes.** The increase in the number of passes is directly related to the increase in the number of channels and increase in the number of data items requested (Figure 25). An increase in the number of channels implies an increase in the number of conflicts, and, hence, the higher possibility of unavoidable conflicts, resulting in an increase in the number of passes. It can be noticed that when the number of data items requested is large, the number of passes exceeds the number of channels available. This is due to the priority order of the heuristics used in the proposed retrieval algorithm. In general, it is improbable that a query for public data requests a lot of data

Figure 24. Energy consumption (Case 3)

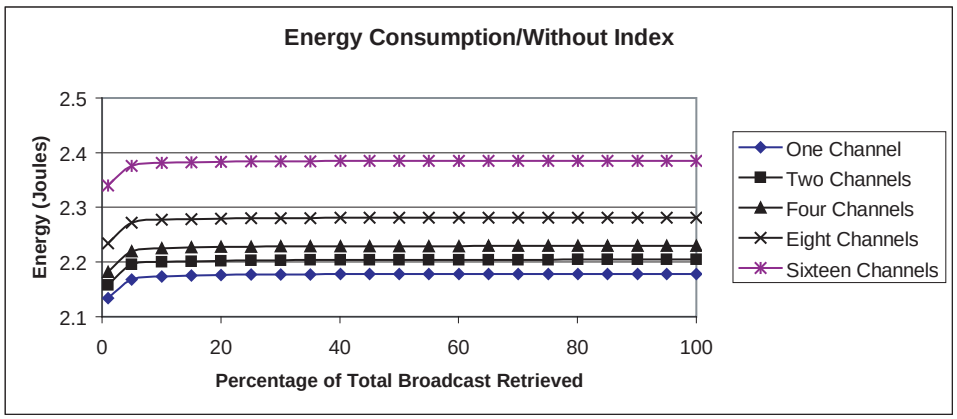

Figure 25. Number of passes over the parallel channels

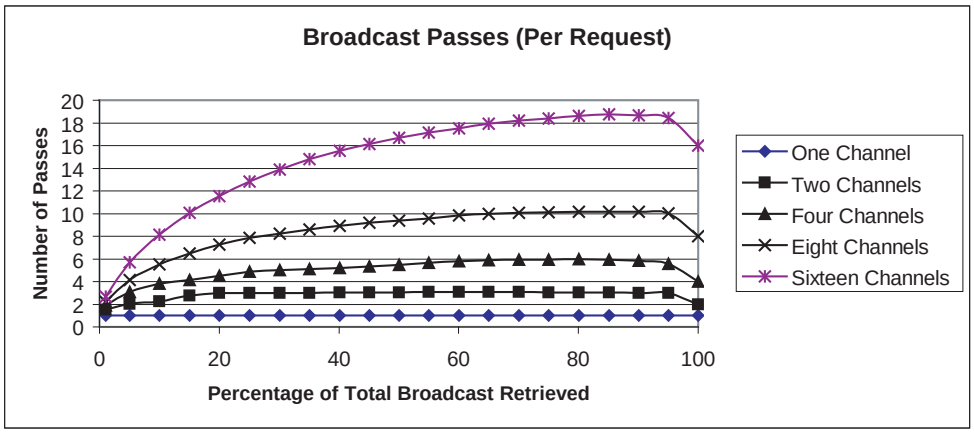

items from the broadcast channels. Our experience showed that for a query requesting up to 50 data items, the proposed method reduces the number of passes compared to Case 3.

- **Case 3. No indexing is employed.** In contrast, when no indexing technique is employed, the number of passes required is a function of the number of air channels. In the worst case we need *N* passes where *N* is the number of broadcast channels.

Section Conclusion

Conflicts directly influence the access latency and, hence, the overall execution time. This section provided a mathematical foundation to calculate the expected number of passes required to retrieve a set of data items requested by an application from parallel air channels. In addition, in an attempt to reduce the access time and power consumption, heuristics were used to develop access policies that reduce the number of passes over the parallel air channels. Analysis of the effectiveness of such policies was also the subject of this section.

CONCLUSION AND FUTURE RESEARCH DIRECTIONS

This chapter aims to address the applicability and effectiveness of data broadcasting from two viewpoints: energy and response time. Within the scope of data broadcasting, we discussed different data allocation schemes, indexing approaches, and data retrieval methods for both single and parallel air channels. Comparisons of different algorithms were demonstrated through simulation results.

The scope of this research can be extended in many directions. For instance, we assumed that the resolution of queries happens on an individual basis at the mobile unit. It may be possible to reduce computation by utilizing a buffer and bundling several queries together, processing them as a whole. Our proposed scheduling scheme

was based on three prioritized heuristics. It is interesting to investigate a new set of heuristics that can reduce the switching frequency while retrieving a large percentage of data items from the broadcast.

ACKNOWLEDGMENT

This work would have not been possible without the sincere effort of many students who participated in the development of conceptual issues as well as simulation results. We would like to thank them. In addition, this work in part has been supported by the Office of Naval Research and the National Science Foundation under the contracts N00014-02-1-0282 and IIS-0324835, respectively.

Chapter 7.37
Multimedia over Wireless Mobile Data Networks

Surendra Kumar Sivagurunathan
University of Oklahoma, USA

Mohammed Atiquzzaman
University of Oklahoma, USA

ABSTRACT

With the proliferation of wireless data networks, there is an increasing interest in carrying multimedia over wireless networks using portable devices such as laptops and personal digital assistants. Mobility gives rise to the need for handoff schemes between wireless access points. In this chapter, we demonstrate the effectiveness of transport layer handoff schemes for multimedia transmission, and compare with Mobile IP, the network layer-based industry standard handoff scheme.

I. INTRODUCTION

Mobile computers such as personal digital assistants (PDA) and laptop computers with multiple network interfaces are becoming very common. Many of the applications that run on a mobile computer involve multimedia, such as video conferencing, audio conferencing, watching live movies, sports, and so forth. This chapter deals with multimedia communication in mobile wireless devices, and, in particular, concentrates on the effect of mobility on streaming multimedia in wireless networks.

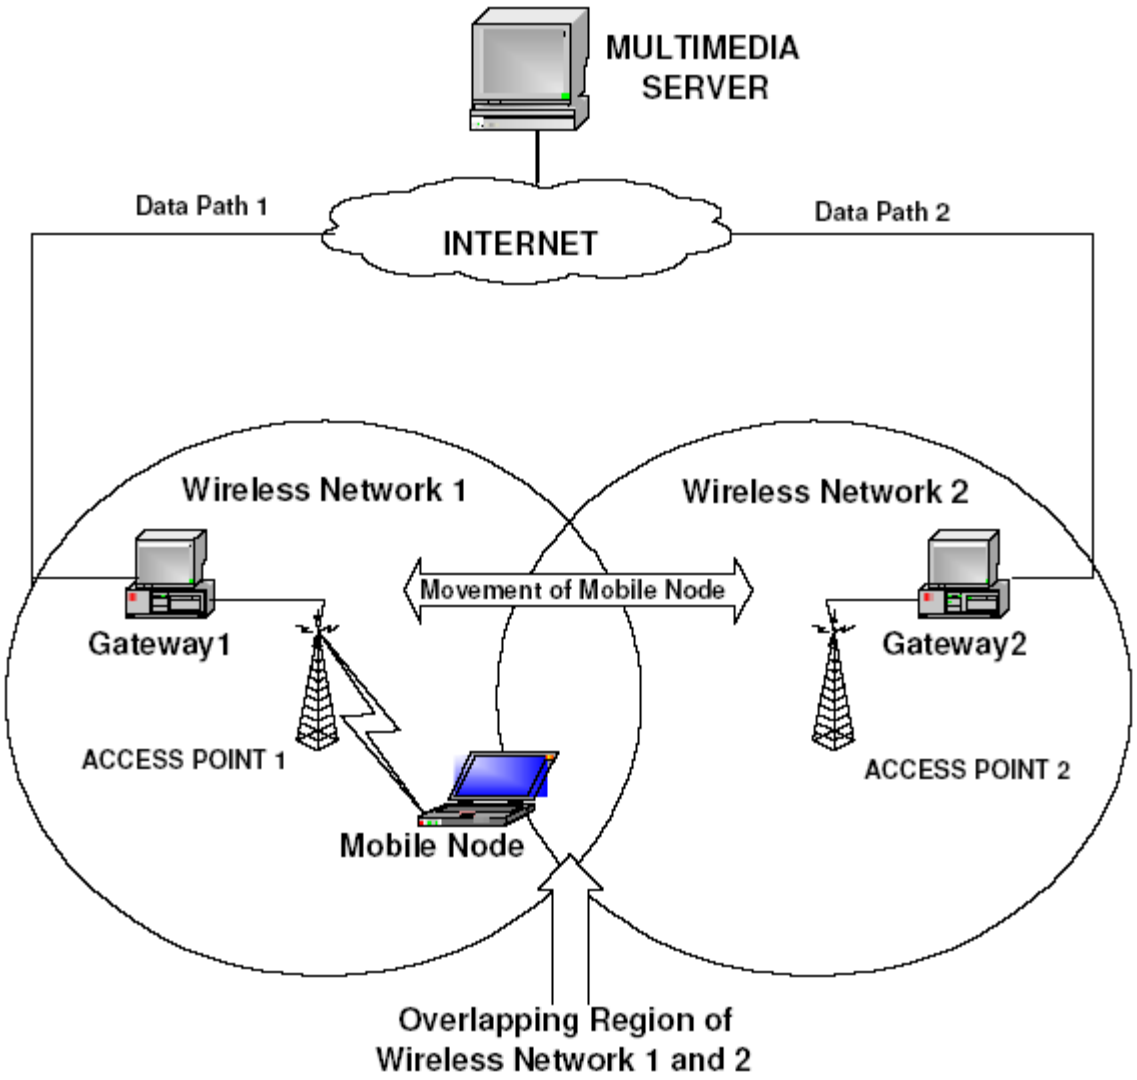
Streaming multimedia over wireless networks is a challenging task. Extensive research has been carried out to ensure a smooth and uninterrupted multimedia transmission to a mobile host (MH) over wireless media. The current research thrust is to ensure an uninterrupted multimedia transmission when the MH moves between networks or subnets. Ensuring uninterrupted multimedia transmission during handoff is challenging because the MH is already receiving multimedia from the network to which it is connected; when it moves into another network, it needs to break the connection with the old network and establish a connection with the new network. Figure 1 shows an MH connected to Wireless Network

1; when it moves, it has to make a connection with the new network, say Wireless Network 2. The re-establishment of a new connection takes a considerable amount of time, resulting in the possibility of interruption and resulting loss of multimedia.

The current TCP/IP network infrastructure was not designed for mobility. It does not support handoff between IP networks. For example, a device running a real-time application, such as video conference, cannot play smoothly when the user hands off from one wireless IP network to another, resulting in unsatisfactory performance to the user.

Mobile IP (MIP) (Perkins, 1996), from the Internet Engineering Task Force (IETF), addresses

Figure 1. Illustration of handoff with mobile node connected to Wireless Network 1



the mobility problem. MIP extends the existing IP protocol to support host mobility, including handoff, by introducing two network entities: home agent (HA) and foreign agent (FA). The HA and FA work together to achieve host mobility. The correspondent node (CN) always communicates with the mobile node (MN) via its home network address, even though MH may not dwell in the home network. For CN to have seamless access to MN, the MH has to be able to handoff in a timely manner between networks.

Handoff latency is one of the most important indicators of handoff performance. Large handoff latency degrades performance of real-time applications. For example, large handoff latency will introduce interruption in a video conference due to breaks in both audio and video data transmission. In addition to high handoff latency, MIP suffers from a number of other problems including triangle routing, high signaling traffic with the HA, and so forth. A number of approaches to reduce the MIP handoff latency are given next.

Mobile IP uses only one IP; a certain amount of latency in data transmission appears to be unavoidable when the MH performs a handoff. This is because of MN's inability to communicate with the CN through either the old path (because it has changed its wireless link to a new wireless network) or the new path (because HA has not yet granted its registration request). Thus, MH cannot send or receive data to or from the CN while the MH is performing registration, resulting in interruption of data communication during this time interval. This interruption is unacceptable in a real-world scenario, and may hinder the widespread deployment of real-time multimedia applications on wireless mobile networks. Seamless IP-diversity based generalized mobility architecture (SIGMA) overcomes the issue of discontinuity by exploiting multi-homing (Stewart, 2005) to keep the old data path alive until the new data path is ready to take over the data transfer, thus achieving lower latency and lower loss during handoff between adjacent subnets than Mobile IP.

The *objective* of this chapter is to demonstrate the effectiveness of SIGMA in reducing handoff latency, packet loss, and so forth, for multimedia transmission, and compare with that achieved by Mobile IP. The *contribution* of this chapter is to describe the implementation of a real-time streaming server and client in SIGMA to achieve seamless multimedia streaming during handoff. SIGMA *differs* from previous work in the sense that all previous attempts modified the hardware, infrastructure of the network, server, or client to achieve seamless multimedia transmission during handoff.

The rest of this chapter is organized as follows. Previous work on multimedia over wireless networks is described in the next section. The architecture of SIGMA is described in the third section, followed by the testbed on which video transmission has been tested for both MIP and SIGMA in the fourth section. Results of video over MIP and SIGMA and presented and compared in the fifth section, followed by conclusions in the last section.

BACKGROUND

A large amount of work has been carried out to improve the quality of multimedia over wireless networks. They can be categorized into two types:

- Studies related to improving multimedia (e.g., video or audio) over wireless networks. They do not consider the mobility of the MN, but attempt to provide a high quality multimedia transmission within the same wireless network for stationary servers and clients.
- Studies related to achieving seamless multimedia transmission during handoffs. They

consider mobility of the MH and try to provide a seamless and high quality multimedia transmission when the MH (client) moves from one network to another.

Although our interest in this chapter is seamless multimedia transmission during handoffs, we describe previous work on both categories in the following sections.

Multimedia over Wireless Networks

Ahmed, Mehaoua, and Buridant (2001) worked on improving the quality of MPEG-4 transmission on wireless using differentiated services (Diffserv). They investigated QoS provisioning between MPEG-4 video application and Diffserv networks. To achieve the best possible QoS, all the components involved in the transmission process must collaborate. For example, the server must use stream properties to describe the QoS requirement for each stream to the network. They propose a solution by distinguishing the video data into important video data and less important video data (such as complementary raw data). Packets which are marked as less important are dropped in the first case if there is any congestion, so that the receiver can regenerate the video with the received important information.

Budagavi and Gibson (2001) improved the performance of video over wireless channels by multiframe video coding. The multiframe coder uses the redundancy that exists across multiple frames in a typical video conferencing sequence so that additional compression can be achieved using their multiframe-block motion compensation (MF-BMC) approach. They modeled the error propagation using the Markov chain, and concluded that use of multiple frames in motion increases the robustness. Their proposed MF-BMC scheme has been shown to be more robust on wireless networks when compared to the base-level H.263 codec which uses single frame-block motion compensation (SF-BMC).

There are a number of studies, such as Stedman, Gharavi, Hanzo, and Steele (1993), Illgner and Lappe (1995), Khansari, Jalai, Dubois, and Mermelstein (1996), and Hanzo and Streit (1995), which concentrate on improving quality of multimedia over wireless networks. Since we are only interested in studies that focus on achieving seamless multimedia transmission during handoff, we do not go into details of studies related to multimedia over wireless networks. Interested readers can use the references given earlier in this paragraph.

Seamless Multimedia over Mobile Networks

Lee, Lee, and Kim (2004) achieved seamless MPEG-4 streaming over a wireless LAN using Mobile IP. They achieved this by implementing packet forwarding with buffering mechanisms in the foreign agent (FA) and performed pre-buffering adjustment in a streaming client. Insufficient pre-buffered data, which is not enough to overcome the discontinuity of data transmission during the handoff period, will result in disruption in playback. Moreover, too much of pre-buffered data wastes memory and delays the starting time of playback. Find the optimal pre-buffering time is, therefore, an important issue in this approach.

Patanapongpibul and Mapp (2003) enable the MH to select the best point of attachment by having all the reachable router advertisements (RA) in a RA cache. RA cache will have the entire router's link whose advertisements are heard by the mobile node. These RAs are arranged in the cache according to a certain priority. The priority is based on two criteria: (1) the link signal strength, that is, signal quality and SNR level, and (2) the

time since the RA entry was last updated. So the RAs with highest router priority are forwarded to the IP packet handler for processing. The disadvantage of this method includes extra memory for the RA cache.

Pan, Lee, Kim, and Suda (2004) insert four components in the transport layer of the video server and the client. These four components are: (1) a path management module, (2) a multipath distributor module at the sender, (3) a pair of rate control modules, and (4) a multipath collector module at the receiver. They achieve a seamless video by transferring the video over multiple paths to the destination during handoffs. The overhead of the proposed scheme is two-fold: reduction in transmission efficiency due to transmission of duplicated video packets and transmission of control packets associated with the proposed scheme, and processing of the proposed scheme at the sender and receiver.

Boukerche, Hong, and Jacob (2003) propose a two-phase handoff scheme to support synchronization of multimedia units (MMU) for wireless clients and distributed multimedia systems. This scheme is proposed for managing MMUs to deliver them to mobile hosts on time. The two-phase scheme consists of: setup handoff and end handoff. In the first phase, setup handoff procedure has two major tasks: updating new arrival BSs and maintaining the synchronization for newly arrived mobile hosts (MHs). If an MH can reach another BS, then MH reports "new BS arrived" to its primary BS. End handoff procedure deals with the ordering of MMUs and with the flow of MMUs for a new MH. Any base station can be a new primary base station. The algorithm notifies MHs, BSs, and servers, and then chooses the closest common node from the current primary base station and new base stations. This method suffers from the disadvantage of additional overhead of updating the base station (BS) with newly arrived BSs and ordering of MMUs.

SIGMA FOR SEAMLESS MULTIMEDIA IN MOBILE NETWORKS

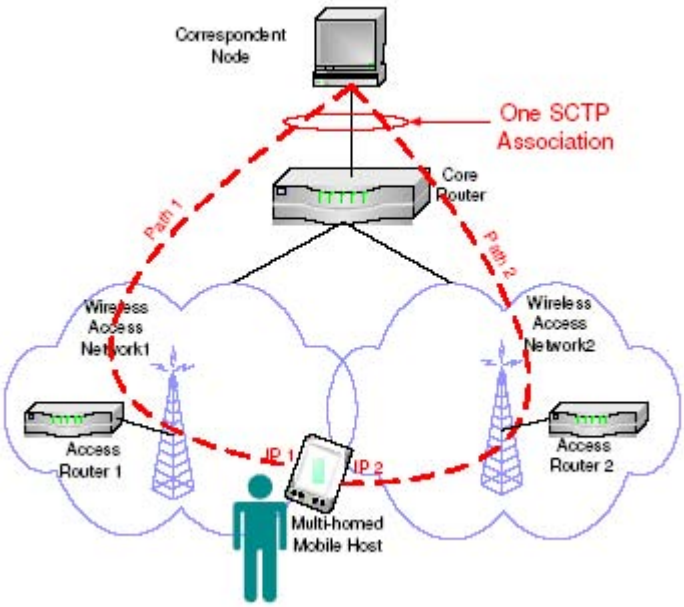
Limitations of previously proposed schemes in achieving seamless multimedia transmission during handoff in a wireless environment have been discussed in the previous section. In this section, we will discuss our proposed handoff scheme, called SIGMA, which has been designed for seamless multimedia transmission during handoffs, followed by its advantages over previous schemes.

Introduction to SIGMA

To aid the reader in getting a better understanding of SIGMA, in this section, we describe the various steps involved in a SIGMA handoff. A detailed description of SIGMA can be found in Fu, Ma, Atiquzzaman, and Lee (2005). We will use the stream control transmission protocol (Stewart, 2005), a new emerging transport layer protocol from IETF, to illustrate SIGMA.

Stream control transmission protocol's (SCTP) multi-homing (see Figure 2) allows an association between two endpoints to span across multiple IP addresses or network interface cards. One of the addresses is designated as the primary while the other can be used as a backup, in the case of failure of the primary address, or when the upper layer application explicitly requests the use of the backup. Retransmission of lost packets can also be done over the secondary address. The built-in support for multi-homed endpoints by SCTP is especially useful in environments that require high-availability of the applications, such as Signaling System 7 (SS7) transport. A multi-homed SCTP association can speedup recovery from link failure situations without interrupting any ongoing data transfer. Figure 2 presents an example of SCTP multi-homing where two nodes,

Figure 2. An SCTP association featuring multi-homing



CN and MH, are connected through two wireless networks, with MH being multi-homed. One of MN's IP addresses is assigned as the primary address for use by CN for transmitting data packets; the other IP address can be used as a backup in case of primary address failure.

STEP 1: Obtain New IP Address

Referring to Figure 2, the handoff preparation procedure begins when the MH moves into the overlapping radio coverage area of two adjacent subnets. Once the MH receives the router advertisement from the new access router (AR2), it should initiate the procedure of obtaining a new IP address (IP2 in Figure 2). This can be accomplished through several methods: DHCP, DHCPv6, or IPv6 Stateless Address Autoconfiguration (SAA) (Thomson & Narten, 1998). The main difference between these methods lies in whether the IP address is generated by a server (DHCP/DHCPv6) or by the MH itself (IPv6 SAA). For cases where the MH is not concerned about its IP address but only requires the address to be unique and routable, IPv6 SAA is a preferred method for SIGMA to obtain a new address since it significantly reduces the required signaling time.

STEP 2: Add IP Addresses to Association

When the SCTP association is initially setup, only the CN's IP address and the MH's first IP address (IP1) are exchanged between CN and

MH. After the MH obtains another IP address (IP2 in STEP 1), MH should bind IP2 into the association (in addition to IP1) and notify CN about the availability of the new IP address (Fu, Ma, Atiquzzaman, & Lee, 2005).

SCTP provides a graceful method to modify an existing association when the MH wishes to notify the CN that a new IP address will be added to the association and the old IP addresses will probably be taken out of the association. The IETF Transport Area Working Group (TSVWG) is working on the "SCTP Address Dynamic Reconfiguration" Internet draft (Stewart, 2005), which defines two new chunk types (ASCONF and ASCONF-ACK) and several parameter types (Add IP Address, Delete IP address, Set Primary Address, etc.). This option will be very useful in mobile environments for supporting service reconfiguration without interrupting on-going data transfers.

In SIGMA, MH notifies CN that IP2 is available for data transmission by sending an ASCONF chunk to CN. On receipt of this chunk, CN will add IP2 to its local control block for the association and reply to MH with an ASCONF-ACK chunk indicating the success of the IP addition. At this time, IP1 and IP2 are both ready for receiving data transmitted from CN to MH.

STEP 3: Redirect Data Packets to New IP Address

When MH moves further into the coverage area of wireless access network2, data path2 becomes increasingly more reliable than data path1. CN can then redirect data traffic to the new IP address (IP2) to increase the possibility of data being delivered successfully to the MH. This task can be accomplished by the MH sending an ASCONF chunk with the Set-Primary-Address parameter, which results in CN setting its primary destination address to MH as IP2.

STEP 4: Updating the Location Manager

SIGMA supports location management by employing a location manager that maintains a database which records the correspondence between MH's identity and current primary IP address (Reaz, Atiquzzaman, & Fu, 2005). MH can use any unique information as its identity, such as the home address (as in MIP), domain name, or a public key defined in the public key infrastructure (PKI).

Following our example, once the Set-Primary-Address action is completed successfully, MH should update the location manager's relevant entry with the new IP address (IP2). The purpose of this procedure is to ensure that after MH moves from the wireless access network1 into network2, further association setup requests can be routed to MH's new IP address IP2. This update has no impact on existing active associations.

We can observe an important difference between SIGMA and MIP: the location management and data traffic forwarding functions are coupled together in MIP, whereas they are *decoupled in SIGMA to speedup handoff and make the deployment more flexible*.

STEP 5: Delete or Deactivate Obsolete IP Address

When MH moves out of the coverage of wireless access network1, no *new* or *retransmitted* data packets should be directed to address IP1. In SIGMA, MH can notify CN that IP1 is out of service for data transmission by sending an ASCONF chunk to CN (Delete IP Address). Once received, CN will delete IP1 from its local association control block and reply to MH with an ASCONF-ACK chunk indicating the success of the IP deletion.

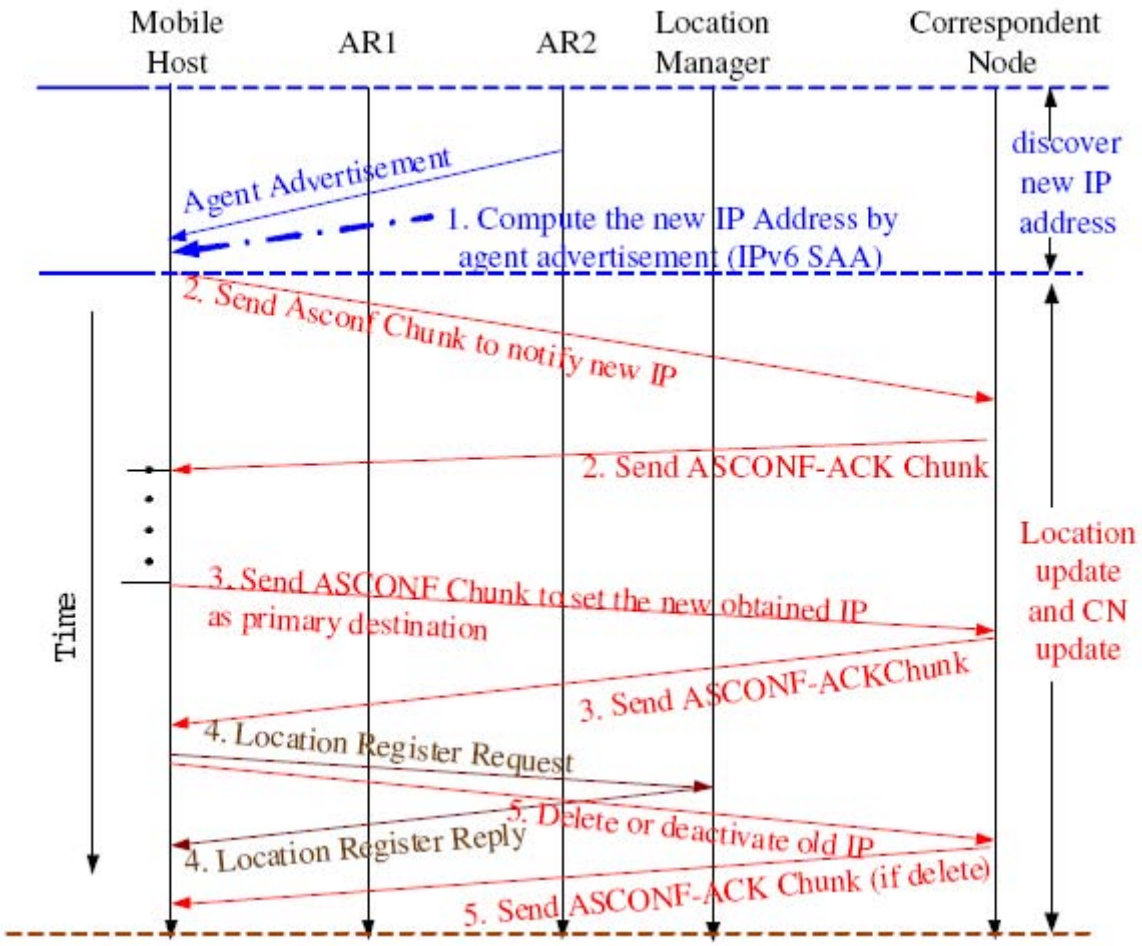
A less aggressive way to prevent CN from sending data to IP1 is for the MH to advertise a

zero receiver window (corresponding to IP1) to CN (Goff, Moronski, Phatak, & Gupta, 2000). This will give CN an impression that the interface (on which IP1 is bound) buffer is full and cannot receive any more data. By deactivating instead of deleting the IP address, SIGMA can adapt more gracefully to MH's zigzag (often referred to as ping pong) movement patterns and reuse the previously obtained IP address (IP1), as long as the lifetime of IP1 has not expired. This will reduce the latency and signaling traffic that would have otherwise been caused by obtaining a new IP address.

Timing Diagram of SIGMA

Figure 3 summarizes the signaling sequences involved in SIGMA. Here we assume IPv6 SAA and MH initiated Set-Primary-Address. Timing diagrams for other scenarios can be drawn similarly, but are not shown here because of space limitations. In this figure, the numbers before

Figure 3. Timeline of signaling in SIGMA



the events correspond to the step numbers in the previous sub-sections, respectively.

Advantages of SIGMA over the Previous Works

A number of previous work have considered seamless multimedia transmission during handoff, as mentioned in the second section, which have their own disadvantages. Here, we discuss the advantages of SIGMA over previous work. Lee et al. (2004) performed pre-buffering adjustment in client. Playback disruption may occur if the pre-buffered data is not enough to overcome the discontinuity of data transmission that occurs during handoff. Moreover, excessive pre-buffered data wastes memory usage and delays the starting time of playback. Find the optimal pre-buffering time is an important issue in this approach. Since SIGMA does not pre-buffer any data in the client, such optimization issues are not present in SIGMA.

Patanapongpibul et al. (2003) use the router advertisement (RA) cache. The disadvantage of this method is that it needs extra memory for RA cache; SIGMA does not involve any caching and hence does not suffer from such memory problems. Pan et al. (2004) use multipath (as discussed earlier), which suffers from (1) reduction in bandwidth efficiency due to transmission of duplicated video packets and transmission of control packets associated with the proposed scheme, and (2) processing overhead at the sender and receiver. Absence of multipaths or duplicate video packets in SIGMA results in higher link bandwidth efficiency.

Boukerche et al. (2003) proposed a two-phase handoff scheme which has additional overhead of updating the base station (BS) with newly arrived BSs, and also ordering of multimedia units (MMUs). In SIGMA, there is no feedback from MH to any of the base stations, and hence does not require ordering of multimedia units or packets.

EXPERIMENTAL TESTBED

Having reviewed the advantages of SIGMA over other schemes for multimedia transmission in the previous section, in this section, we present experimental results for SIGMA as obtained from an experimental setup we have developed at the University of Oklahoma. We compare the results of handoff performance during multimedia transmission over both SIGMA and Mobile IP. To make a fair comparison, we have used the same test bed for both MIP and SIGMA. Figure 4 (to be described later) shows the topology of our test bed, which has been used by a number of researchers—Seol, Kim, Yu, and Lee (2002), Wu, Banerjee, Basu, and Das (2003), Onoe, Atsumi, Sato, and Mizuno (2001)—for measurement of handoff performance. The difference in data communication between the CN and the MH for MIP and SIGMA lies in the lower layer sockets: the file sender for MIP is based on the regular TCP socket, while that for SIGMA is based on SCTP socket. We did not use the traditional *ftp* program for file transfer because it was not available for the SCTP protocol. To obtain access to the SCTP socket, we used Linux 2.6.2 kernel with Linux Kernel SCTP (LKSCTP) version 2.6.2-0.9.0 on both CN and MN. A number of MIP implementations, such as HUT Dynamics (HUT), Stanford Mosquito (MNET), and NUS Mobile IP (MIP), are publicly available. We chose HUT Dynamics for testing MIP in our test bed due to the following reasons: (1) Unlike Stanford Mosquito, which integrates the FA and MN, HUT Dynamics implements HA, FA, and MH daemons separately. This architecture is similar to SIGMA where the two access points and MH are separate entities. (2) HUT Dynamics implements hierarchical FAs, which will allow future comparison between SIGMA and hierarchical Mobile IP. Our MIP testbed consists four nodes: correspondent node (CN), foreign agent (FA), home agent (HA), and mobile node (MN). All the nodes run corresponding agents developed by HUT Dynamics.

The hardware and software configuration of the nodes are given in Table 1.

The CN and the machines running the HA and FA are connected to the Computer Science (CS) network of the University of Oklahoma, while the MH and access points are connected to two separate private networks. The various IP addresses are shown in Table 2. IEEE 802.11b is used to connect the MH to the access points.

The network topology of SIGMA is similar to the one of Mobile IP except that there is no HA or FA in SIGMA. As shown in Figure 4, the machines which run the HA and FA in the case of MIP act as gateways in the case of SIGMA. Table 1 shows the hardware and software configuration for the SIGMA experiment. The various IP addresses are shown in Table 2. The experimental procedure of Mobile IP and SIGMA is given next:

1. Start with the MH in Domain 1.
2. **For Mobile IP:** Run HUT Dynamics daemons for HA, FA, and MN. **For SIGMA:** Run the SIGMA handoff program, which has two functions: (1) monitoring the link

Table I. Mobile IP and SIGMA testbed configurations

layer signal strength to determine the time to handoff, and (2) carrying out the signaling shown in Figure 4.

3. Run file sender/video server and file receiver/video client (using TCP sockets for Mobile IP, using SCTP sockets for SIGMA) on CN and MN, respectively.
4. Run Ethereal (ETHEREAL) on the CN and MH to capture packets.
5. Move MH from Domain 1 to Domain 2 to perform handoff by Mobile IP and SIGMA. Capture all packets sent from CN and received at MN.

RESULTS

Various results were collected on the experimental setup and procedure described earlier. In this section, we present two kinds of results: file transfer and multimedia transmission. The reason for showing the results of file transfer is to prove that SIGMA achieves seamless handoff not only for multimedia but also for file transfers.

Results for File Transfer

In this section, we present and compare the results of handoffs using MIP and SIGMA for file

transfer. For comparison, we use throughput, RTT, and handoff latency as the performance measures. *Throughput* is measured by the rate at which packets are received at the MN. *RTT* is the time required for a data packet to travel from the source to the destination and back. We define *handoff latency* as the time interval between the MH receiving the last packet from Domain 1 (previous network) and the first packet from Domain 2 (the new network). The experimental results are described next.

Results from Mobile IP Handoff

Figure 5 shows the throughput during Mobile IP handoff between Domain 1 and Domain 2. The variations in throughput within HA (from 20 second to 30 second) and within FA (from 37 second to 60 second) are due to network congestion arising from cross traffic in the production CS network.

The average throughput before, during and after handoff are 2.436 Mbps, 0 Mbps and 2.390 Mbps, respectively. Figure 6 shows the packet trace during MIP handoff. The actual handoff latency for MIP can be clearly calculated by having a zoomed-in view of the packet trace graph. Figure 7 shows a zoomed-in view of the packet trace, where the calculated handoff latency is eight seconds for Mobile IP. Figure 8 shows the RTT for the MIP handoff. As we can see, the RTT is high for eight seconds (the handoff latency time), during the handoff.

The registration time (or registration latency) is also a part of the handoff latency. Registration latency, the time taken by the MH to register with the agent (HA or FA), is calculated as follows. Ethereal capture showed that the MH sent a

Figure 5. Throughput during MIP handoff

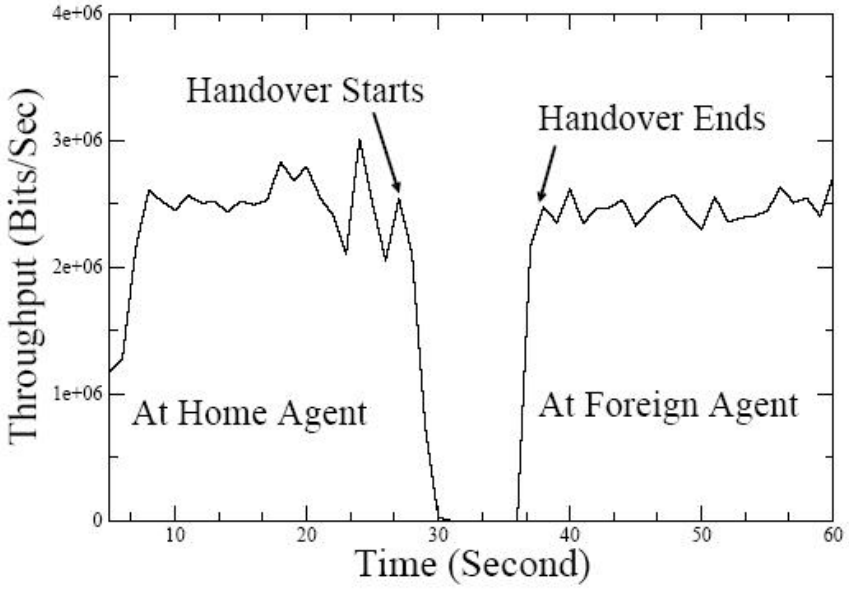

Figure 6. Packet trace during MIP handoff

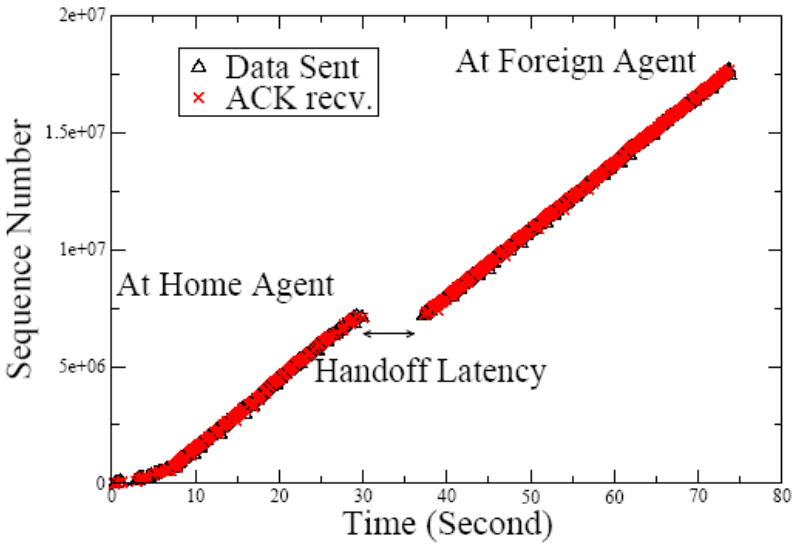

Figure 7. Zoomed in view during MIP handoff instant

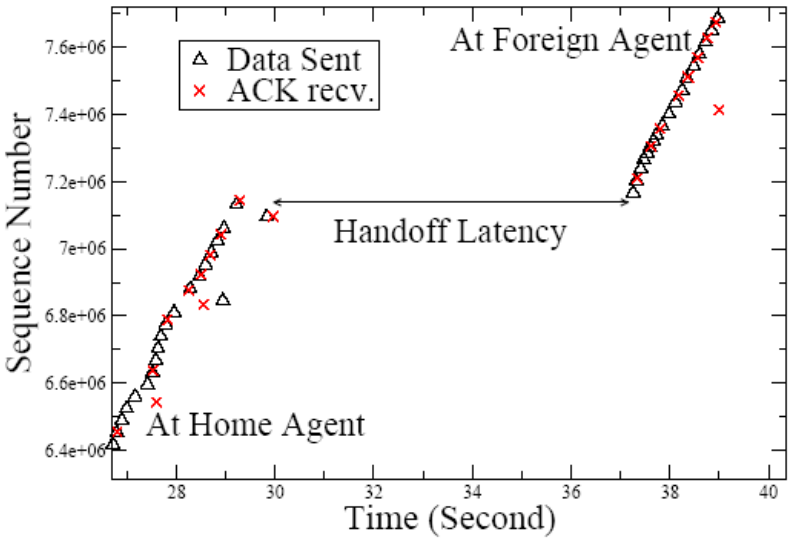

Figure 8. RTT during MIP handoff

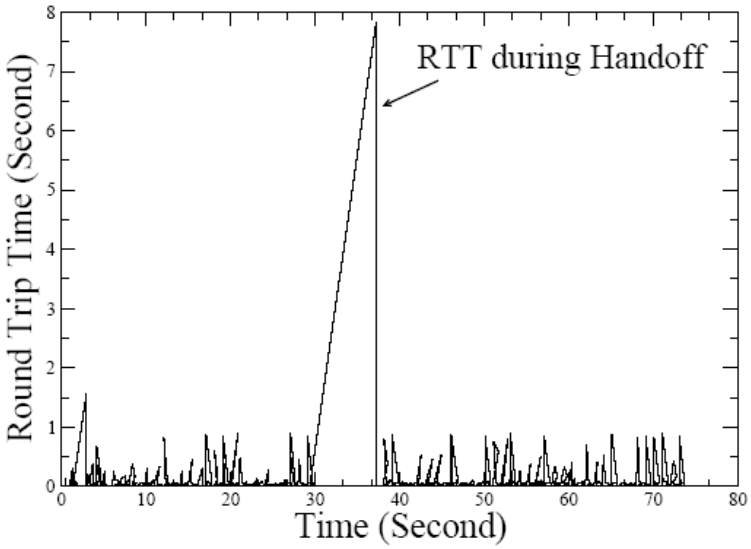

registration request to the HA at time t = 14.5123 second and received a reply from the HA at t = 14.5180 second. Hence, the calculated registration time for registering with HA is 5.7 milliseconds. Similarly, during MIP handoff, Ethereal capture showed that the MH sent a registration request to FA at time t =7.1190 second and received a reply from the FA at t =7.2374, resulting in a registration time of 38.3 milliseconds. This is due to the fact that after the MH registers with the HA, it can directly register with the HA. On the other hand, if it registers with the FA, the MH registers each new care-of-address with its HA possibly through FA. The registration latency is, therefore, higher when the MH is in the FA.

Results from SIGMA Handoff

Figure 9 shows the throughput during SIGMA handoff where it can observed that the throughput does not go to zero. The variation in throughput is due to network congestion arising from cross traffic in the production CS network. Although we cannot see the handoff due to it being very small, it should be emphasized that the ethereal capture showed the handoff starting and ending at t = 60.755 and t = 60.761 seconds, respectively, that is, a handoff latency of six milliseconds.

Figure 10 shows the packet trace during SIGMA handoff. It can be seen that packets arrive at the MH without any gap or disruption; this is also a powerful proof of SIGMA's smoother handoff as compared to handoff in Mobile IP. This experimentally demonstrates that *a seamless handoff can be realized with SIGMA.* Figure 11 shows a zoomed-in view of the packet trace during the SIGMA handoff period; a handoff latency of six milliseconds can be seen between the packets arriving at the old and new paths.

Figure 9. Throughput during SIGMA handoff

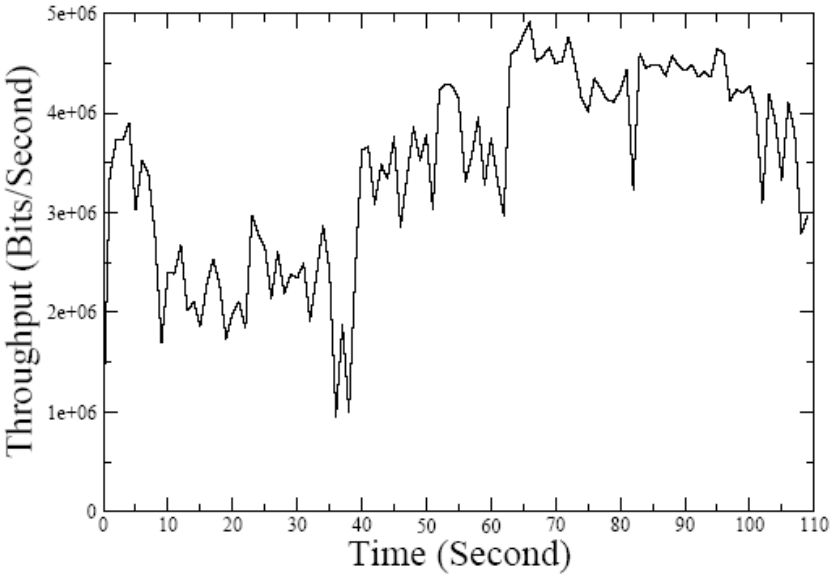

Figure 10. Packet trace during SIGMA handoff

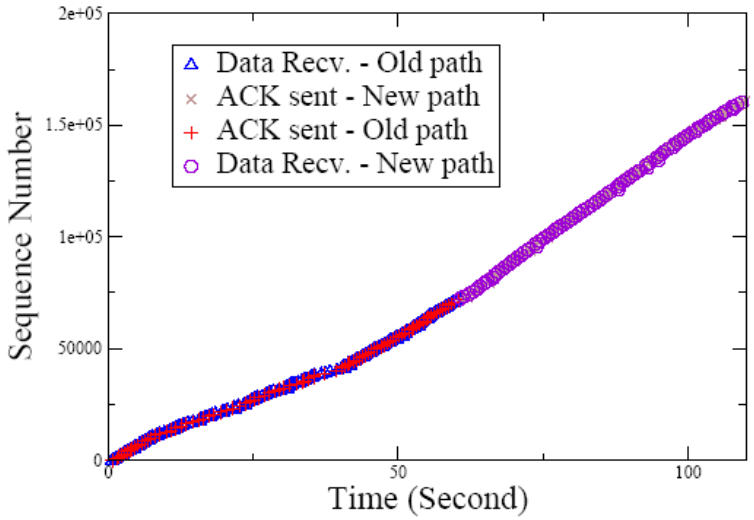

Figure 11. Zoomed in view during SIGMA handoff

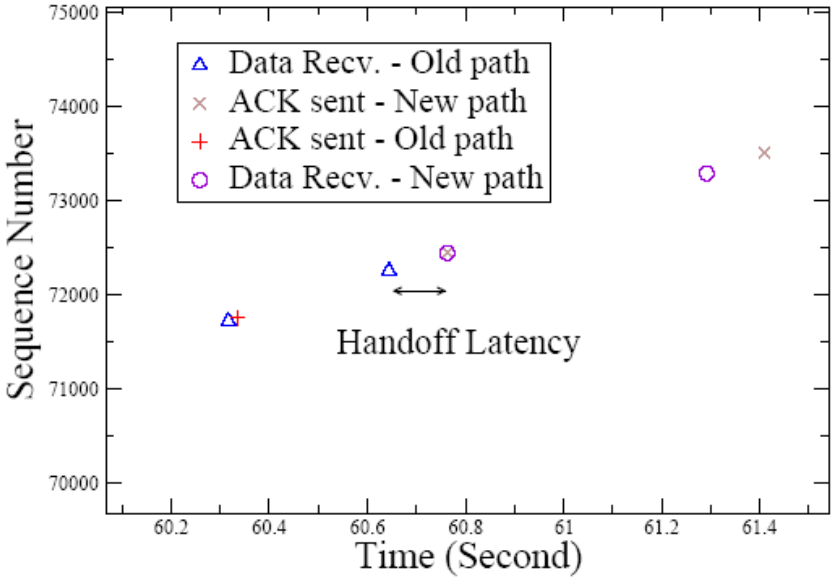

Figure 12. RTT during SIGMA handoff

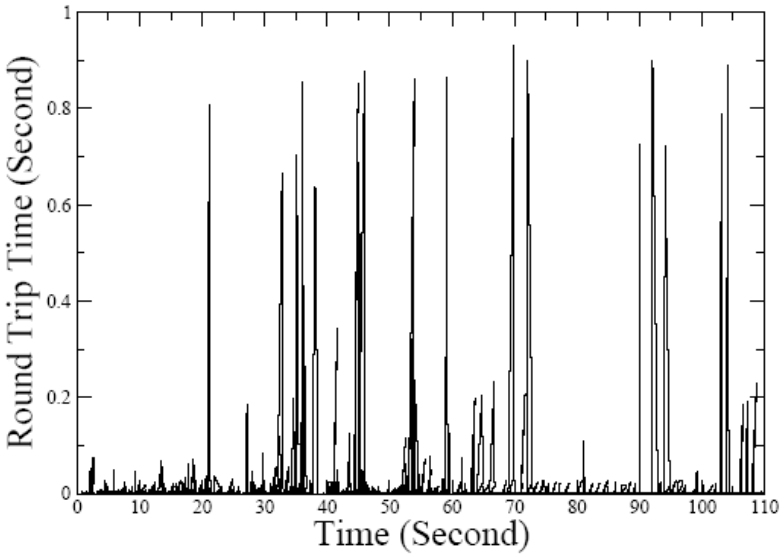

Figure 12 shows the RTT during SIGMA handoff. A seamless handoff is evident from the absence of any sudden RTT increase during handoff.

Result of Multimedia Data Transfer

To test the handoff performance for multimedia over SIGMA, we used a streaming video

Figure 13. Throughput of video during SIGMA handoff

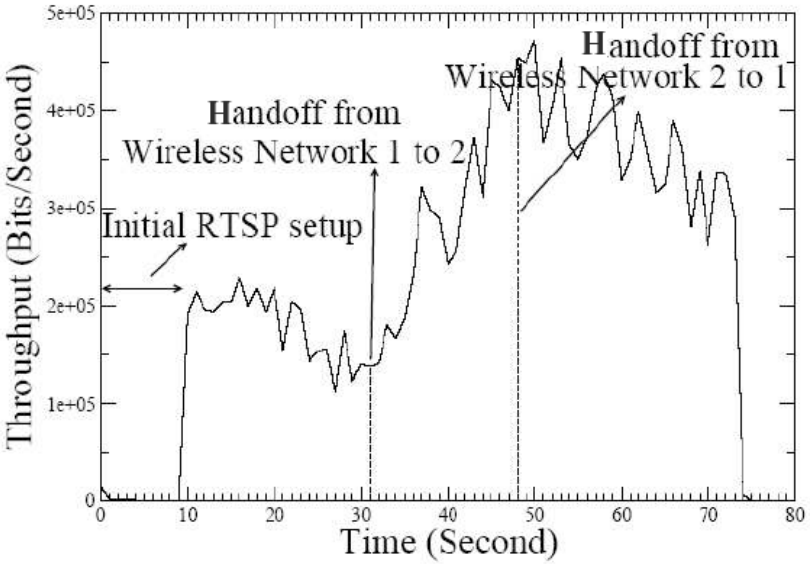

Figure 14. Screen shot of MPEG4-IP player

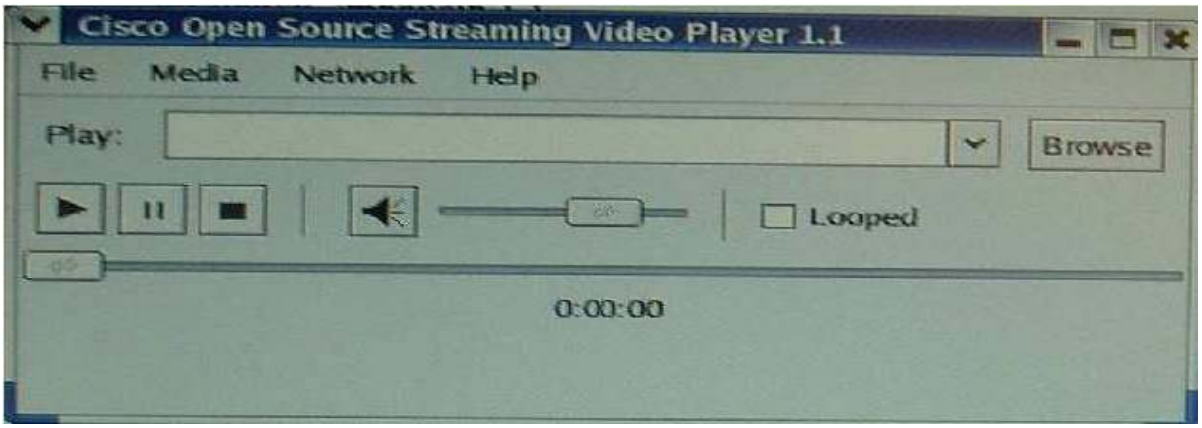

client and a streaming server at the MH and CN, respectively (details in the fourth section). Apple's Darwin Streaming Server (DARWIN) and CISCO's MPEG4IP player (MPEG) were modified to stream data over SCTP. A seamless handoff, with no interruption in the video stream, was achieved with SIGMA.

Figure 13 shows the throughput of multimedia (video) data, when the MH moves between subnets. The connection request and setup between the client and server is carried out during the first 10 seconds. It can be seen that the throughput does not drop during handoff at time = 31 second when MH moves from wireless network 1 to 2. A second handoff takes place when the MH moves from network 2 to network 1 at time = 48. It is seen that seamless handoff is achieved by SIGMA for both the handoffs.

Figure 14 shows a screen capture of the MPEG4IP player used in our experiment. Figure 15 shows the video playing in the player during handoff, where "rtsp://129.15.78.139/fta.sdp" represents the server's IP address and the streaming format (SDP).

Comparison of SIGMA and MIP Handoffs

We observed previously that the registration time of MIP was only 0.1 second, and the handoff latencies of MIP and SIGMA were eight seconds and six milliseconds, respectively. We describe the reasons for the MIP handoff latency being much longer than its registration time in the following:

Figure 15. Screen-shot of MPEG4-IP player playing streaming video

1. In HUT Dynamics, the MIP implementation used in this study, the MH obtains a registration lifetime after every successful registration. It originates another registration on expiry of this lifetime. So it is possible for the MH to postpone registration even after it has completed a link layer handoff and received FA advertisements. This may introduce some delay which can be up to the duration of a life time.
2. As mentioned in the previous section, the registration of MH also costs some time, measured as 38.3 milliseconds in our testbed.

The handoff latency in MIP comes from three factors: (1) remaining home registration lifetime after link layer handoff which can be from zero to a lifetime, (2) FA advertisement interval plus the time span of last time advertisement which is not listened by MN, and (3) registration latency. During these three times, the CN cannot communicate through either the previous path because it has completed link layer handoff, or the new path because MH has not yet completed the registration. As a result, the throughput was zero during this time. Obviously, such shortcoming has been eliminated in SIGMA through multi-homing and decoupling of registration and data transfer. Consequently, data continue to flow between the CN and MH during the handoff process.

CONCLUSION AND FUTURE TRENDS

We have shown that SIGMA achieves seamless multimedia transmission during handoff between wireless networks. As future work, video streaming can be tested over SIGMA during vertical handoffs, that is, between wireless LANs, cellular, and satellite networks.

Chapter 7.38
High Performance Scheduling Mechanism for Mobile Computing Based on Self-Ranking Algorithm

Hesham A. Ali
Mansoura University, Egypt

Tamer Ahmed Farrag
Mansoura University, Egypt

ABSTRACT

Due to the rapidly increasing number of mobile devices connected to the Internet, a lot of research is being conducted to maximize the benefit of such integration. The main objective of this article is to enhance the performance of the scheduling mechanism of the mobile computing environment by distributing some of the responsibilities of the access point among the available attached mobile devices. To this aim, we investigate a scheduling mechanism framework that comprises an algorithm that provides the mobile device with the authority to evaluate itself as a resource. The proposed mechanism is based on the "self ranking algorithm" (SRA), which provides a lifetime opportunity to reach a proper solution. This mechanism depends on an event-based programming approach to start its execution in a pervasive computing environment. Using such a mechanism will simplify the scheduling process by grouping mobile devices according to their self-ranking value and assigning tasks to these groups. Moreover, it will maximize the benefit of the mobile devices incorporated with the already existing Grid systems by using their computational power as a subordinate value to the overall power of the system. Furthermore, we evaluate the performance of the investigated algorithm extensively, to show how it overcomes the connection stability problem of the mobile devices. Experimental results emphasized that

the proposed SRA has a great impact in reducing the total error and link utilization compared with the traditional mechanism.

INTRODUCTION

Mobile computing and commerce are spreading rapidly, replacing or supplementing wired computing. Moreover, the wireless infrastructure upon which mobile computing is built may reshape the entire information technology (IT) field. Therefore, it is fair to say that nowadays, mobile devices have a remarkable high profile in the most common communication devices. Individuals and organizations around the world are deeply interested in using wireless communication, because of its flexibility and its unexpected and fast development. The first solution to the need for mobile computing was to make computers small enough so they could be easily carried. First, the laptop computer was invented; later, smaller and smaller computers, such as 3G, personal digital assistants (PDAs) and other handhelds, appeared. Portable computers, from laptops to PDAs and others, are called mobile devices. In recent years, a great development took place on the Internet and with mobile technologies. Consequently, the next step will be merging these two technologies, leading to the Wireless Internet. The Wireless Internet will be much more than just Internet access from mobile devices; the Wireless Internet will be almost invisible, as people will use mobile services and applications directly. On the other hand, these services and applications will be acting as our agents, conducting searches and communicating with other services and applications to satisfy our needs. Not only will the integration of mobile technology and the Internet paradigm reinforce the development of the new context-aware applications, but it also will sustain traditional features, such as user preferences, device characteristics, properties of connectivity and the state of service and usage history. Furthermore, the context includes features strictly related to user mobility, such as a user's current geospatial location (time and/or space). As direct use of existing Internet applications in a mobile environment is usually unsatisfactory, services and applications need to take into account the specific characteristics of mobile environments. The next section will provide an overview of mobile devices as well as the present relation model between mobile devices and the Grid.

Mobile Devices' Development

The number of individuals and organizations relying on wireless devices is continually increasing. Table 1 represents a statistical study of current and future increase in the sales of wireless equipment and the considerable growth in the sales of mobile phones.

Table 1 shows the rapid growth in sales rates of wireless equipment, and they serve the purpose of being a good metric of the flourishing future of mobile computing. From 2001 to 2005, investments on mobile devices are expected to increase by 41% and reach $31 billion. In 2004, the laptops on the market reached 39.7 million. On the other hand, not only did the number of mobile devices and wireless equipment increase, but also the computational power and memory storage. As a result, mobile computing and wireless Internet became a very important research area. This article will approach it from the computational Grid viewpoint.

Mobile Devices and the Computational Grid

The interaction between mobile devices and the computational Grid, such as depicted in Figure 1, can be classified into two models:

1. **Mobile as a user of Grid resources:** The development in the computational power of mobile devices, such as smart phones,

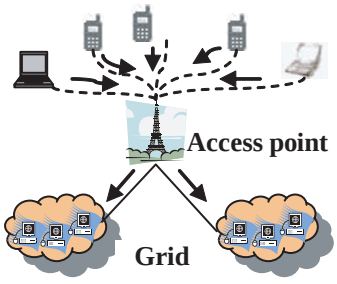
Table 1. Worldwide wireless LAN equipment shipments (1000s of units) (Navrati Saxena, 2005)

Product Segment	**2001**	**2002**	**2003**	**2004**	**2005**	**2006**
Adapters	6890	12599	21333	30764	41417	50415
Access Points	1437	1965	3157	3919	4851	5837
Broadband Gateways	552	850	1906	3365	5550	7941
Other WLAN Equipment	47	59	82	105	132	158
Total	8926	15473	26478	38153	51950	64351

PDAs, and so forth, will be limited due to its size, battery life, bandwidth and storage of data. However, when this integration occurs, all of the huge computational power and stored data of the Grid will be available to the mobile client. The mobile clients send their requests to the access point (AP), which can be considered as the Grid gateway; the scheduler is responsible for finding a suitable resource to perform the incoming request (Sanver, 2004).

2. **Mobile as a Grid resource:** When one mobile device is considered a resource, it will be a very inferior and low-ranking resource compared with a personal computer (PC). Meanwhile, because of the large number of mobile devices that can be used, it can be a worthwhile computational power. Also, because of its large geographical distribution, it can be considered a very excellent data collector, which can be used in many applications, such as geographical information systems, weather news, and so forth. Relatively, there are two approaches to integrate the mobile device into the existing Grid; *the first* is that all the information of every mobile device is recorded in the scheduler, so every device is considered to be one Grid resource. *The second approach* is one in which the information of the mobile devices is hidden from the scheduler; it considers all the devices connected to an access point as one Grid resource, and the access point responsible for scheduling tasks on the mobile devices is also connected to it.

Figure 1. An overview of integration of mobile devices with computational grid



This article introduces SRA, which will be used to build a mobile computing scheduling mechanism. Before introducing the proposed algorithm, an overview about related work in the scheduling mechanism in the Grid is given,

followed by a detailed description of the targeted problem at hand and a proposed framework. Moreover, the proposed SRA will be introduced, along with the simulation used to state the proposed algorithm and, finally, the results of that simulation will be analyzed.

RELATED WORK

Before elaborating on the problem, five of the most recent systems, especially on scheduling algorithms, are studied (He, 2003; Buyya, 2003; Somasundara, 2004; Berman & Casanova, 2005). Although the researchers have very different parameters and concepts, all of them have two main objectives. The first is to increase the utilization of the system, while the second is to find a suitable resource (as the economic cost, quality of services [QoS], deadline, etc.).

Table 2 shows a comparison between the most recent systems. Undoubtedly, one of the common problems that face any system when dealing with a large number of resources is "Load Balancing." Due to the fact that the ranking value of the resources is different, each of these systems

Table 2. Comparison between referenced systems

Project Features	Condor (Arun A. Somasundara, 2004)	Sphinx (Jang-uk In , 2004)	DBC (Rajkumar Buyya, 2003)	Disconnected operation service (Sang-Min Park, 2003)	QoS Guided Scheduling (Xiaoshan He ,2003)
Mobility	----	----	----	Job Proxy	----
Load Balancing	Backfilling	Resource usage Accounts and Users Quotas	Improved by considering Time deadline addition to Cost	----	QoS Guided improve but not direct solution
Long Beginning Time	Backfilling	Resource usage Accounts (Quotas)	Improved by considering Time deadline and Cost	----	----
Resource Ranking Parameters	By The User	Percent of resource usage account used	Cost	disconnection rate and the reconnection rate	Availability of required QoS
Multi Scheduler	supported	----	----	supported	----
Resource Reservation	Future work	supported	Future work	----	----
QoS support	----	supported	Future work	----	supported
Scheduling Constrains	FIFO, user priorities	user priorities	Budget, deadline	----	QoS (one dimensional)

endeavors to solve the problem, as illustrated in Table 2. Another problem is how the system will deal with the mobility of clients and resources. Noticeable is the limitation of research that takes into account the mobility of the resources (Nurmi, 2004; Park, 2003). The study of these five systems shows that they are based on different parameters to rank the resource, but the most popular are QoS and the economic cost (He, 2003; Buyya, 2003). The expressions used in Table 2 are explained here:

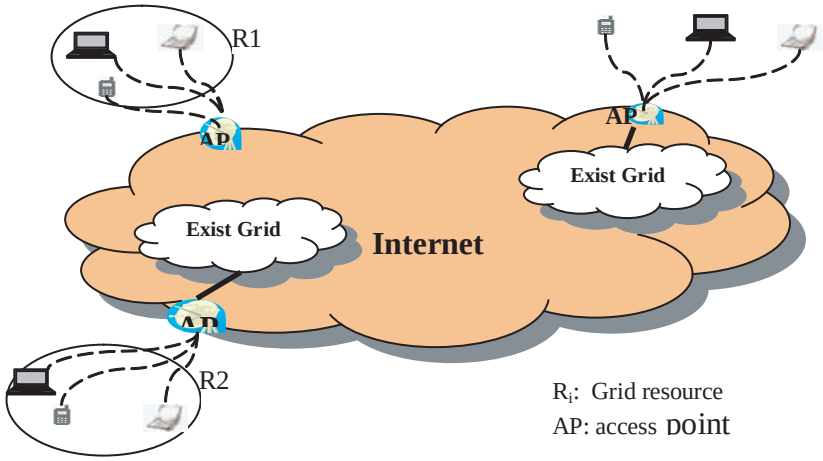
- **Backfilling:** A technique that tries to fill the gaps in the scheduling operation by executing the low-priority functions in the low-ranking resources that have not been used for a long time. This increases the system's overall utilization and makes a kind of load balancing between the resources (Somasundara, 2004).
- **Resource usage accounts (quotas):** Each resource must be assigned to certain functions according to its usage account. Preventing the resource from not being used can be caused by the presence of high QoS resources. This approach gives the scheduler force more functions to be assigned to a certain resource by maximizing its quota (In, 2004).
- **Job proxy:** Created when the mobile user submits a job, it is responsible for the interaction between the mobile device and the system. It can also simulate mobile action in case of mobile disconnecting. It does this until the mobile is connected again. If the mission is accomplished and the mobile is still disconnected, it stores the result for a certain time-out duration (Park, 2003).
- **QoS guided:** The QoS Guided scheduler has a kind of intelligence as not to consume the high QoS resource in performing the jobs that need low QoS. It does this to save its power to the other tasks that need this high QoS (He, 2003).

SCHEDULING AND THE CONNECTION STABILITY PROBLEM

The new approach in the computing area is *Internet computing.* It uses the already existing infrastructure of the Internet and builds its own Grid using devices interconnected to the Internet (Frontier, 2004). This is a very economical approach, because there is no need to build a special infrastructure. On the other hand, a lot of questions and issues raise, such as: "Do we need to build a new infrastructure of a grid to integrate the mobile devices as a grid user or as a grid resource?" and "What about the already existing grid projects?" (Gradwell, 2003; Dail, 2002; Frey, 2001; Berman, 2005). Figure 2 shows how the already existing infrastructure can be ordered and organized to create an infrastructure that helps to integrate the mobile devices with existing Grid systems like Condor, GriPhyN and Grid2003. This infrastructure aims at using huge computational power due to the large number of Internet users. It also aims at using the different services and resources available in the already existing Grid projects. Above all, the main objective is to use the Internet network to connect the mobile devices to the other parts of this infrastructure and to put all these services and computational power available to the mobile device. Finally, it aims at increasing the computational power and number of services of the system by integrating the large number of mobile devices distributed around the world (Saxena, 2005).

The most important problem that can face any Grid system is to develop a scheduling mechanism to manage such integration. The previous scheduling mechanisms depended on QoS (He, 2003), cost (Buyya, 2002; Barmouta, 2003) or a hybrid between other parameters (In, 2004; Takefusa, 2001) to select the best scheduling decision. Due to this integration and the mobility of the device, a new parameter appeared. This parameter represents the stability of the connection established between the devices and the access

Figure 2. The system infrastructure organization



point; in other words, the rate of disconnecting and the rate of reconnecting. All of the already existing systems make the scheduler monitor and evaluate the performance and availability of its attached resources. This was acceptable with PCs, but because of the huge number of mobile devices expected to attach to the scheduler, a very high overload on the scheduler can happen. So, the scheduler slows down more and more as the number of the attached resources increases.

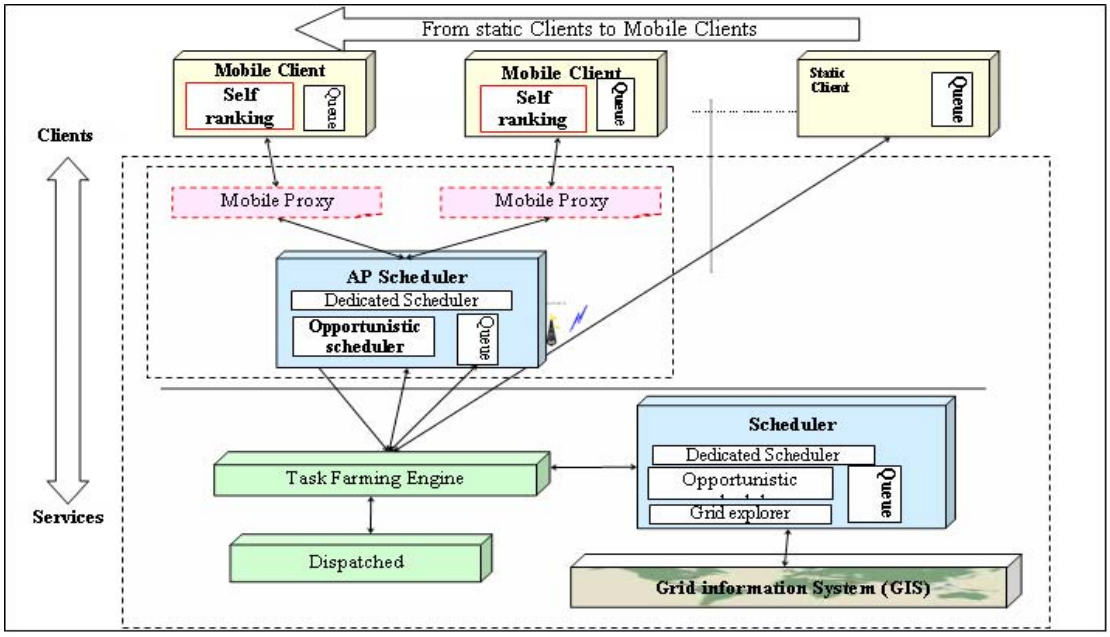
Plan of Solution

To overcome the overhead resulted from collecting the data at the access point scheduler and storing the historical ones of the mobile device performance, an SRA will be investigated. This algorithm has two key points: The *first* is to provide the mobile device with the authority to evaluate and rank itself and remove this task from the central point (scheduler). *Second* is considering the mobility of the resource as important metrics in such an environment. Therefore, the main aim of this algorithm is to calculate a ranking value for each attached mobile device that may be considered as a metric of the mobile performance. Moreover, it will be used to classify the mobile devices into groups to make the process of scheduling simpler and faster.

PROPOSED FRAMEWORK

Figure 3 depicts the framework and system components relationship for the given organization in Figure 2. The following design guidelines must be adhered to: (1) Use opportunistic schedulers introduced in the Condor (Somasundara, 2004), because it is an excellent idea to make a good load balance between high-ranking resources and low-ranking ones (e.g., mobile devices); (2) Use the mobile proxy introduced in Park (2003), but we changed its name from job proxy to our proposed name "mobile proxy" which will be the interface between the mobile client and the other components of the system; and (3) Use

Figure 3. Mobile device scheduling framework and components relationship



multi-schedulers because of the distribution of the considered infrastructure.

Proposed Framework Entities

In the following, the entities participating in the given framework are defined and their functions explained, as well as how they interact with each other.

- **The Task Farming Engine (TFE):** Responsible for partitioning the requested job into small tasks that will be assigned to resources to perform them using the scheduler and dispatcher.
- **The Scheduler**: Responsible for resource discovery, resource trading, resource selection and tasks assignment.
- **The Dispatcher:** Responsible for the actual assigning of tasks to the resources decided by the scheduler, monitoring execution of the tasks and controlling the process of collecting the different partitions of the job. Finally, it sends the overall result to the job requester.
- **Grid Information System (GIS):** Can be considered as the resources characteristics database used by the scheduler to find a suitable resource to perform the requested tasks using the resource QoS, cost, rank.
- **Dedicated Scheduler:** Each resource is assigned to one dedicated scheduler who has all rights to use the resource at any time except if the resource owner needs his resource. This monopoly may lead to non-functioning of some resources because

they are in the resources' list of certain Dedicated Schedulers, besides other high-ranked resources. So, these high-ranked resources will be preferred to the scheduler. This problem may be resolved by the temporary claiming of the resource to another type of scheduler named "opportunistic scheduler." This problem causes holes in the scheduling operation.

- **Opportunistic scheduler:** When the dedicated scheduler claims some of its resources because they were idle for a long time or they had a low-ranking value, which made them useless for a long time. The opportunistic scheduler tries to use this resource to execute some small tasks that may end before the dedicated scheduler needs the resource again. This operation is named "Backfilling." Note that this method will maximize utilization of the overall system.

If a mobile client is connected to an access point, the first step is to create a mobile proxy object, which will be considered as a simulation of the mobile device. So, it may store the hardware specification of the mobile and its current location, and it may also monitor the movement of the mobile from one access point to another. This mobile proxy information will be the base knowledge on which the scheduler builds its work.

Figure 4. Request processing flow

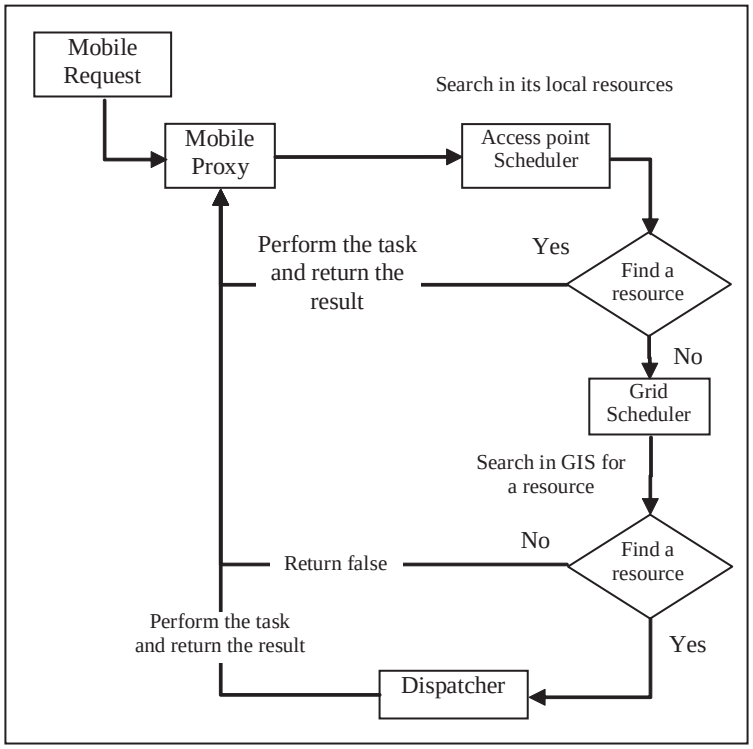


Figure 4 depicts a request-processing scenario. If the mobile client makes a request, this request will be stored in the mobile proxy. Then, it goes to a scheduler using the scheduling mechanism, trying to find a suitable resource to perform this request from its local connected resources. If the access point scheduler does not find a suitable resource, it forwards this request to a higher-level scheduler, which usually has static PCs with more computational power. This scheduler uses the GIS to find a suitable resource. When the resource is located, the dispatch assigns the requested task to this resource. When the task is performed, the outcome returns to the mobile proxy, which is responsible for sending the result to the mobile client in its current location.

PROPOSED SRA

The idea of the SRA is to reduce the dependability on the access point scheduler and distribute this overhead among the attached mobile devices. This can be done by making every mobile able to evaluate itself. Then, the access point can use this ranking value in the process of scheduling.

The trigger to start this algorithm execution depends on the event-based programming approach. The events that were taken into account are: (1) the event of disconnecting the mobile device and its scheduler, because this event means the end of the last connected period; (2) the event of reconnecting the mobile device to its scheduler, because this event means the end of the last disconnected period; and (3) the event of finishing a task, because this event changes the value of the mobile utilization. The self ranking value (R) has two parts: First is the Connectivity metric (M_{CD}), which can be considered as a metric of performance and connectivity of the mobile device, as well. The second part is the utilization metric (U), which can be considered as a metric of the success of the mobile device in performing the assigned task. When the mobile client has a new ranking value, this value must be sent to the mobile proxy to be entered as a parameter in the scheduling process.

Figure 5. Rank metric map

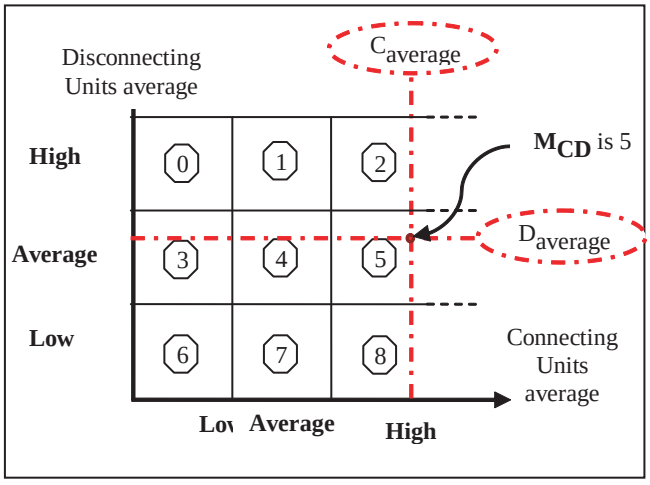

Figure 6. SRA for determining mobile device ranking value

0 Imports the prestored values :
t_s : the start of the last reconnection event. t_e: the end of the connection period .
T_u :Time unit defined by the scheduler N_c : number of reconnecting event occurring.
N_D: number of disconnecting event occurring.
$C_{average}$: The average number of time units to being connecting continually
$D_{average}$: the average number of time units being disconnecting continually
N_s : the number of successfully performed tasks N : total number of tasks assigned to the device.

1 Wait for incoming event and check it.

2 *if the event is Disconnecting Event at time (t) then :*

2.1 Replace the prestored value t_e with the new value t : $t_e = t$

2.2 Calculate the Connection Period P_c by using the stored value of t_s and t_e: $P_c = t_e - t_s$

2.3 Calculate number of time units X_c of the connection period P_c by using T_u provided by the Scheduler :

2.4 Calculate the new value of $C_{average}$ by using the prestored value of $C_{average}$ and the prestored N_c:

$$C_{average(new)} = C_{average\ (old)} * N_c + X_c / N_c + 1$$

2.5 $N_c = N_c + 1$.

2.6 Calculate the connectivity metric M_{CD} by using the new calculated $C_{average}$ and the prestored $D_{average}$ as coordinates of a point in the "rank metric map".

3 *if the event is reconnecting Event at time (t) then :*

3.1 Replace the prestored value t_s with the new value t : $t_s = t$

3.2 Calculate the disconnection Period P_D by using the stored value of t_s and t_e: $P_D = t_s - t_e$

3.3 Calculate number of time units X_D of the disconnection period P_D by using T_u provided by the Scheduler :

$$X_D = P_D / T_u$$

3.4 Calculate the new value of $D_{average}$ by using the prestored value of $D_{average}$ and the prestored N_D:

$$D_{average(new)} = D_{average\ (old)} * N_D + X_D / N_D + 1$$

3.5 $N_D = N_D + 1$.

3.6 Calculate the connectivity metric M_{CD} by using the new calculated $D_{average}$ and the prestored $C_{average}$ as coordinates of a point in the "rank metric map".

4 *if the event is Task finish notification Event at time (t) then :*

4.1 if this is a success notification then : $N_s = N_s + 1$.

4.2 N=N+1.

4.3 Calculate the Utilization metric U using the stored values of N_s and N : $U = (N_s / N) * 2$

5 Finally Using the M_{CD} and U values to calculate the Rank Value R as the following:

$$R = M_{CD} + U$$

The considered parameters to be used in the SRA are: the average number of time units being connected continually ($C_{average}$), the average number of time units being disconnected continually ($D_{average}$) and the previous utilization history metric (U). The calculated values of $C_{average}$ and $D_{average}$ will be used as a key to the proposed ranking map, which is used to calculate *the first* part of the rank value that measures the mobile performance and connectivity. The overall ranking value is assumed to be between 1 and 10. This part represents 80% of this value; this percentage can be changed according to the schedulers' administrators. Figure 5 shows the rank metric map, which is based on two roles, first as the $C_{average}$ value increases, the rank must increase also. Second, as $D_{average}$ value increases, the rank must decrease. The $C_{average}$ and $D_{average}$ is used to calculate values. It works as a coordinator of the connectivity metric (MCD) on the rank metric map. The second part of the ranking value is the metric of the utilization of the mobile devices. So, it is calculated by the ratio between the number of the successful tasks and the number of all tasks. Summation of the two parts will generate the overall ranking value of the mobile device. Figure 6 shows the proposed algorithm.

SIMULATION MODEL

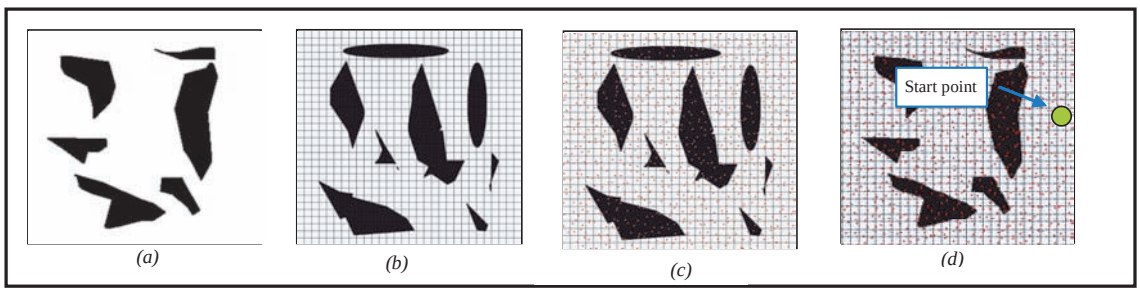
Validation of the proposed algorithm is done via simulation. The investigated simulation program is composed of three modules. The first is responsible for generating a random movement path for the mobile devices, while the second is responsible for tracking the generated path, and this will be done through the access point. Finally, the third is responsible for tuning critical parameters values and collecting outputs parameters, which are required to calculate $C_{average}$ and $D_{average}$.

Mobile Device Movement Mechanism

The mobile device movement path that will be generated is based on a mechanism that guarantees a random path as follows:

1. Generate random black-and-white areas as shown in Figure 7a. White areas imply that there is an available connection between the mobile device and the scheduler access point; black areas depict disconnection.
2. Divide the whole area into small rectangular areas, as shown in Figure 7b.
3. Generate a point within each rectangle at a random position, as shown in Figure 7c.

Figure 7. Steps of random movement path generation



4. Save the position of the generated points in an array.
5. Select one point from the previous array in random fashion to be the starting point of the movement path, as shown in Figure 7d.
6. Select one of the possible eight directions shown in Figure 8 for the next hop.
7. Continue the movement towards the previous selected direction for a random number of hops.
8. Repeat steps 6 and 7 until the required length of movement path is acquired.
9. Store all the selected points in steps 6, 7 and 8 to represent a path for mobile device movement.
10. Repeat steps 2-9 to generate another mobile movement path.

Figure 9 illustrates some examples of the generated random mobile movement paths based on the previous mechanism.

AP and Monitoring the Mobile Device

This module simulates the AP monitoring of the mobile device movement process. In such a process, the AP sends an "Are you alive?" message. If there is an available connection, the mobile device responses with an "I'm alive" message. The time between sending and receiving is called the response time T_r; this time can

Figure 8. Choose a random direction from eight possible

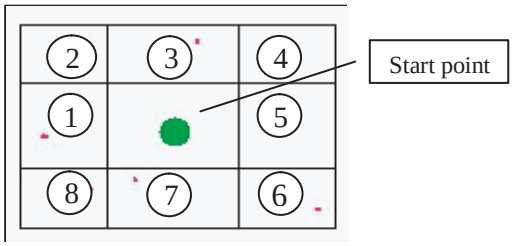


Figure 9. Examples of the random mobile movement paths

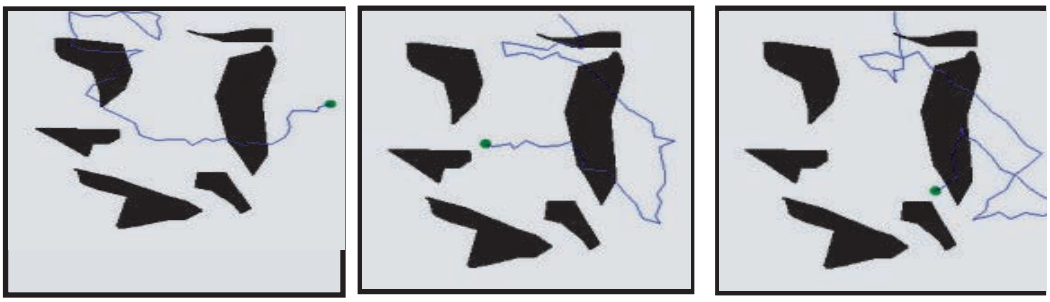

Figure 10. AP monitoring of the mobile device movement process

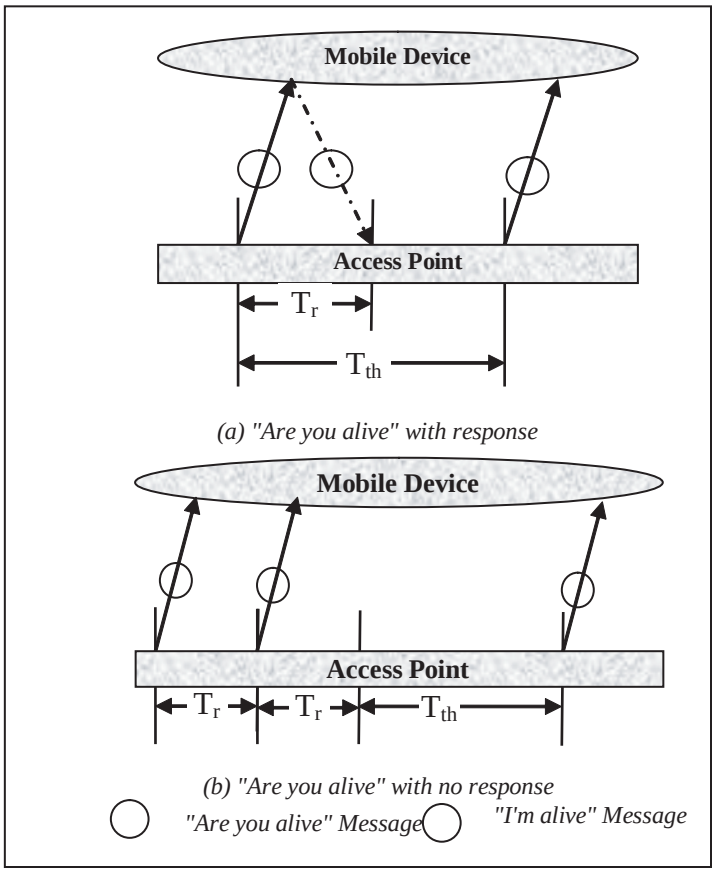


be determined experimentally. The AP waits for another threshold time T_{th} before sending the next monitoring message. On the other hand, if there is no response for T_r, the access point will send a message again. According to the response of the previous simulation, the AP reports the mobile device status. Figure 10 shows this process.

At this point, we have to notice that reducing T_{th} will lead to more accurate results, but on the other hand, the number of messages will increase. This means high-link usage, which is considered from the application point of view to be a bad usage.

Parameters Setting, Collecting, and Calculating

The different parameters, which are required for comparing the self-ranking against the traditional AP ranking from a network utilization and accuracy point of view, are calculated in this module.

First, the speed of the mobile device movement and T_{th} and T_r is tuned. Some parameters from the first and second modules are collected and stored, including: the length of the generated path, the number of connections and disconnections during the movement on the path, the total number of "Are you alive?" messages, and the number of messages with and without response. So, $C_{average}$ and $D_{average}$ can be calculated.

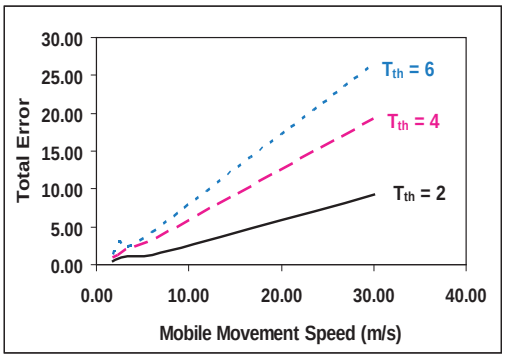
PERFORMANCE ANALYSIS AND DISCUSSION

Based on the previous discussion, on the change of the number of mobile devices used during the experiment (50, 75 and 100 mobiles) or on the change of the value of T_{th} (2, 4 and 6 seconds), various experiments are performed. Two factors were constant: the length of the movement path, which was selected to be relatively long (10000 hop); and T_r, which was selected to be relatively small (0.5 second). Each of these experiments will be repeated for different movement speeds, from low mobility (with average movement speed of 2 m/s) to high mobility (with average movement speed of 30 m/s).

The average error in calculating the $C_{average}$ and $D_{average}$ has been calculated for each experiment at each used speed, and their summation represents the total error in the experiment. Also, the number of network messages exchanged between AP and the mobile device, in both the AP monitoring and self monitoring, has been counted.

Figures 11, 12, and 13 show that the percentage of the total error increases rapidly as the movement speed of mobile device increases. This result is expected, because as movement speed increases, the ability of AP to sense the change in the mobile connectivity will be more and more limited. Also, the figures show that when the value of T_{th} increases, the percentage of the total error increases also, while the number of exchanged network messages decreases. This result is expected, because T_{th} represents the time between two monitoring messages; as this time increases, that means reduction in the ability of AP to sense the change in mobile connectivity. The figures show the comparison between the number of exchanged messages between AP and mobile devices in the case of self monitoring and case of AP monitoring. Note that, in the case of AP monitoring, the number approximately

Figure 11. Total error and link utilization at number of mobiles = 50



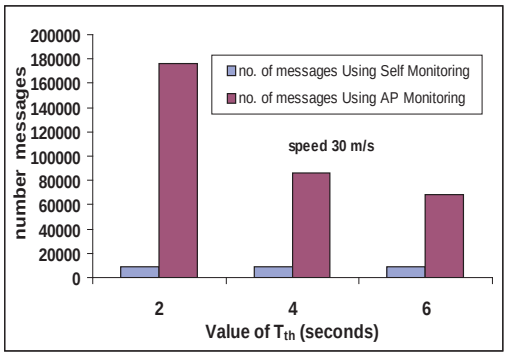


Figure 12. Total error and link utilization at number of mobiles = 75

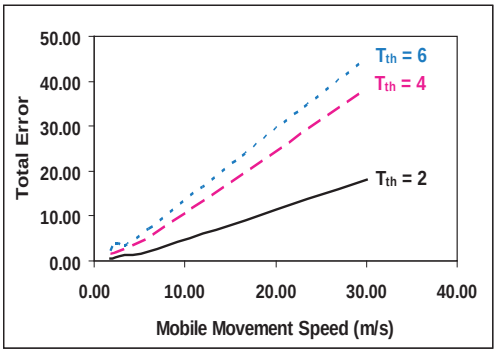

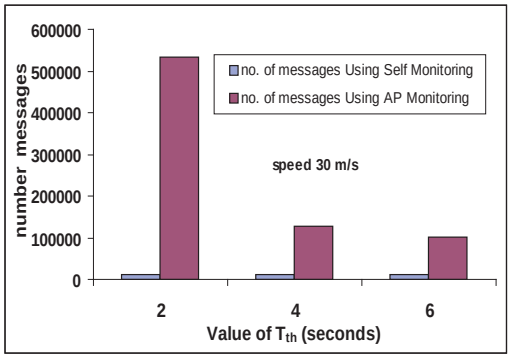

Figure 13. Total error and link utilization at no of mobiles = 100

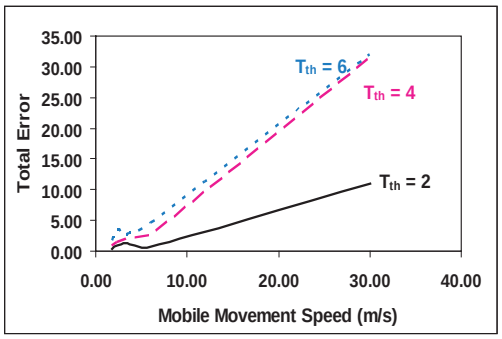

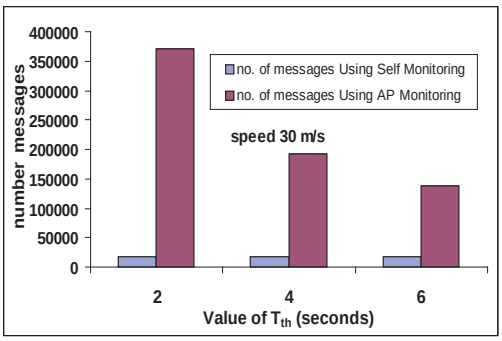

doubled more than 70 times compared to the case of self-monitoring.

CONCLUSION

This article points out an overview of the issues of mobile devices integration with the existing Grid. It shows that when some authorization is impeded within the mobile client, every mobile can evaluate its own performance. The traditional method makes an overhead on the scheduler to perform a historical evaluation to the mobile performance, which makes it busy in a secondary task and leaves its main task of scheduling. So, the SRA will be the base of a scheduling mechanism that will schedule the tasks on the mobile devices. The originality of the proposed mechanism concentrates on mobile cooperating with services at the AP. Using such a mechanism

will lead to *minimizing* the calculation time consumed in mobile ranking and evaluating before starting the scheduling process. Moreover, it will lead also to *minimizing* the amount of stored data at the scheduler and *simplifying* the scheduling process by grouping the mobile devices according to their self-ranking value and assigning tasks to these groups. Finally, it will result in *maximizing* the profit of the mobile devices integrated with the already existing Grid systems by using their computational power as an addition to the system's overall power. In brief, the outcome will be *maximizing* system utilization and making the system more flexible to integrate any new devices without any need to increase the system complexity.

In this article, we present the newly emerging technical issues for realizing this mobile Grid system, and particularly focus on the job scheduling algorithm to achieve more reliable performance. However, there are still challenging problems, such as limited energy, device heterogeneity, security and so on. We will tackle these issues in future works and develop a prototype of a mobile Grid system.

ABSTRACT

This chapter presents a method for the evaluation of user interfaces for mobile applications. The method is based upon an approach that combines user opinion, standard conformity assessment, and user performance measurement. It focuses on the evaluation settings and techniques employed in the evaluation process, while offering a comparison between the laboratory evaluation and field evaluation approaches. The method's presentation and the evaluation comparison will be supported by a discussion of the results obtained from the method's application to a case study involving a Personal Digital Assistant (PDA). This chapter argues that the experience gained from evaluating conventional user interfaces can be applied to the world of mobile technology.

INTRODUCTION

As proposals for new techniques and methods emerge for the evaluation of mobile device usability, it becomes more difficult for practitioners to choose among them. To be able to evaluate the efficacy of these techniques and methods, as well as to reproduce their steps, they have to be described in a level of detail not often found in the literature. Claims are often made without solid statistical results and are usually based on superficial descriptions. This makes it difficult, if not impossible, to compare alternative choices. Given the features of these new devices (such as mobility, restrictive resources for information input and output, and dynamic contexts of use), HCI specialists may question the efficacy of the methods, techniques, and settings already known

to them from previous experiences. Thus, the major question that is addressed is whether it is possible to adapt the methods, techniques, and settings from previous evaluation experiences to this new class of devices, given their distinctive features.

The most frequent question raised in the vast majority of studies presented in the literature is whether to adopt a field approach or a laboratory approach. However, little is discussed in terms of which techniques are best suited for the specific evaluation target and its context of use. While this polemic subject may represent to the HCI specialist an import concern, it is equally important to consider the efficacy of the method, which accompanies this choice of approach (efficacy meaning the quality of the answers to the questions formulated as the basis of the evaluation). This is because the efforts employed in the evaluation may not pay off if a method is not well chosen or well employed.

This chapter presents a method for evaluating mobile devices based upon a set of techniques already known to the HCI specialist community. Each technique evaluates the problem from different perspectives: the user perspective (expressed as views on the product obtained through a questionnaire), the specialist's perspective (expressed when analyzing the user performance during the usability evaluation), and the usability community perspective (expressed in the form of standards conformity assessment). Each of these perspectives identifies evaluation problems and, when overlaid, they lead to a more reliable and complete product appraisal.

The remainder of this chapter is structured as follows. The second section gives a brief overview of the evaluation approaches currently in use for mobile devices, according to the literature review. The third section outlines the multi-layered approach. The fourth section illustrates the application of the multi-layered approach by means of a case study involving a Personal Digital Assistant (PDA). The fifth section discusses the results of the case study and their implications for the questions posed in this chapter. Finally, the sixth section concludes with the discussion of future trends in evaluation methods and how to apply the existing experience to the evaluation of this new class of products.

USER INTERFACE EVALUATION FOR MOBILE DEVICES

In the context of user-centered design processes, a significant portion of usability work involves the coordinated acquisition of valid and reliable data by a team of professionals. These specialists have varied backgrounds and skills and employ a number of evaluation methods. The expected result is an improved system design. This is achieved by the successful identification of a system's usability problems that might impact the interaction quality for a range of users.

Usability data consists of any information that can be used to measure or identify factors affecting the usability of a system being evaluated (Hilbert & Redmiles, 2000). These data are crucial for designing successful systems intended for human use. Such data are gathered by usability evaluation methods and techniques that can assign values to usability dimensions (Rosson & Carroll, 2002) and/or indicate usability deficiencies in a system (Hartson, Andre, & Williges, 2003). According to the International Organization for Standardization (ISO, 1998), usability dimensions are commonly taken to include user efficiency, effectiveness, and subjective satisfaction with a system in performing a specified task in a specified context.

Usability data are gathered via either analytic or empirical methods (Nielsen, 1993; Mayhew, 1999; Rosson & Carroll, 2002). Analytic methods, in which a system is evaluated based on its interface design attributes, are usually conducted by HCI specialists and do not involve human participants performing tasks. This means that these

methods often rely on the specialists' judgment. Empirical methods, in which the system is evaluated based on observed performance in actual use, involve data collection of human usage.

Other classifications include direct methods (recording actual usage) and indirect methods (recording accounts of usage) (Holzinger, 2005). There are also formative and summative methods (Wixon & Wilson, 1997). The direct methods are used to generate new ideas and gather data during the development of a system in order to guide iterative design (Hix & Hartson, 1993). The indirect methods are used to evaluate existing systems and gather data to evaluate a completed system in use (Scriven, 1967). Discovery methods (also called qualitative methods) are used to discover how users work, behave, and think, and what problems they have. Decision methods (also called quantitative methods) are used in selecting a design among several alternatives or in picking elements of interface designs (Wixon & Wilson, 1997).

In essence, usability data have been classed in a number of other models and frameworks, often focusing on (1) the approach employed for gathering the data (including the resources expended and the degree of formality) (Danielson, 2006); (2) the context of use (including lighting, noise level, network connectivity, communication costs, communication bandwidth, and the social situation) (ISO, 1998; ISO, 1999; Jones & Marsden, 2006); (3) the nature and fidelity of the artifact being evaluated (EATMP, 2000); and (iv) the goal of the acquisition process (Kan, 2002).

It is a fact that usability evaluation for stationary computer systems has grown in the last two decades. In spite of debates still taking place within the HCI area, they are often based on a tacit understanding of basic concepts. One example of this understanding is in relation to the distinction between field and laboratory evaluation approaches and their importance to the area. Classical extensive guidelines were written that describe how usability evaluation in controlled environments should be conducted (e.g., Dumas & Reddish, 1999; Mayhew, 1999; Nielsen, 1993). Additionally, experimental evaluations of the relative strengths and weaknesses of different techniques are available that can be applied in a usability evaluation (e.g., Molich et al., 1998).

In the last decade, methodologies and approaches in HCI have been challenged by the increasing focus on systems for wearable, handheld, and mobile computing devices. One such move beyond office, home, and other stationary-use settings has pointed to the need for new approaches in designing and evaluating these systems (Kjeldskov, 2003). While the primarily task-centered evaluation approaches may be applicable to the desktop computing paradigm (often structured with relatively predictable tasks), they may not be directly applicable to the often-unpredictable continuous interaction possibilities and relatively unstable mobile settings. Additionally, it is not easy for evaluation methods to integrate completely or even adequately in real world or simulated settings contexts during the evaluation process. Authors argue that mobile computing demands not only real users but also a real or simulated context with device interaction tasks. It also demands real tasks or realistic task simulations.

There are a number of studies that discuss the question of whether the evaluation should be carried out in a laboratory or field context (e.g., Goodman et al., 2004; Kjeldskov & Stage, 2004; Kjeldskov et al., 2005; Po et al., 2004). All of these papers have a common theme, in that they apply a multi-method approach to performance measurement and discuss solutions for efficient data analysis. Nonetheless, it is important to note that the approach to usability evaluation depends on the relevance of the results presented as well as on the quality of the data analysis process. In general, the reports only present the results of the data analysis, omitting the details of the analysis process itself. While the data gathering method is critical for data quality, a more rigorous analysis

on user comments and problem reports could help specialists better assess their choices.

There is a lot of current human-computer interaction research on alternatives for data collection methods and techniques. However, adequate data analysis and validation are only presented in few cases (e.g., Nielsen, 1994; Dumas & Redish, 1999; Po et al., 2004). In general, this aspect of the HCI research is poorly described in the literature, there being only vague conclusions and little guidance for attempts at successfully replicating the findings in other evaluation contexts. Many methods and techniques have been employed in the analysis of empirical data gathered during usability evaluations. Examples are for field testing analysis, video data analysis (Sanderson & Fisher, 1994), expert analysis (Molich et al., 1998), and head-mounted video and cued recall (Omodei et al., 2002). Its time-consuming character and its poor applicability for industrial purposes can explain the absence of an in-depth usage data analysis when under resource constraints (Baillie & Schatz, 2005). Nonetheless, it is strongly recommended for research purposes as a means to support new findings. For the same reason, it is equally important to provide sufficient detail to allow for replication and a substantiated choice of methods with similar levels of description.

THE MULTILAYERED EVALUATION APPROACH

The method described here was originally proposed for evaluating desktop interfaces. It was then adapted to evaluate the usability of mobile devices. It is based upon a multi-layered approach that combines standard conformity assessment, user performance measurement, and user satisfaction measurement. Each one of these evaluation techniques detects problems from a specific point of view. The multilayered approach is based on the premise that the combination of techniques (triangulation) will produce complementary and more robust results.

Standard Conformity Assessment

According to the International Organization for Standardization (ISO), conformity assessment means checking whether products, services, materials, processes, systems, and personnel measure up to the requirements of standards (ISO, 2006).

In its original version, this evaluation method adopts the standard ISO 9241 (*Ergonomic Requirements for Office Work with Visual Display Terminals*).

In the PDA case study it was found that only some parts of this standard can be applied to this mobile device: Parts 11 (ISO 9241-11, 1998), 14 (ISO 9241-14, 1997), 16 (ISO 9241-16, 1999), and 17 (ISO 9241-17, 1998). There are also some other standards that apply to this kind of device such as the ISO/IEC 14754 (*Pen-based Interfaces—Common gestures for text editing with pen-based systems*) (ISO/IEC 14754, 1999) and others that, although applicable to mobile devices, do not apply in this specific case. Examples are the ISO/IEC 18021 (*User interfaces for mobile tools for management of database communications in a client-server model*), since it is for devices capable of performing data interchange with servers (ISO/IEC 18021, 2002); and ITU-T E.161 (*Arrangement of digits, letters, and symbols on telephones and other devices that can be used for gaining access to a telephone network*, also known as ANSI T1.703-1995/1999, and ISO/IEC 9995-8:1994) (ITU, 2001).

User Satisfaction Measurement

User satisfaction has received considerable attention from researchers since the 1980s as an important surrogate measure of information systems success (Aladwani & Palvia, 2002; Goodhue &

Thompson, 1995; Bailey & Pearson, 1983). While most user satisfaction measuring instruments were not Web-based at the time of development, others have been successfully validated in a Web-based environment (e.g., De Oliveira et al., 2005).

The user satisfaction diagnosis provides an insight into the level of user satisfaction with the product, highlighting the importance of the problems found and their impact on the product acceptance.

User Performance Measurement

The user performance measurement aims in general to provide data on the effectiveness and efficiency of a user's interaction with a product. It enables comparisons with similar products, or with previous versions of the same product along its development. Additionally, it can highlight areas where a product can be enhanced to improve usability. When used with the other methods, the evaluator can build a complete picture of the usability of a system.

The most significant user interface problems can be found by conducting experiments (usability tests) with representative users to observe how quickly, easily, and safely they can operate a product. The major change introduced in the original method concerns the introduction of field tests as a complement to the original laboratory tests.

The Experiment: Comparing Field and Laboratory Use of a PDA

The main objective of this study is to investigate the need for adapting the original evaluation method to the context of mobile devices, based on the analysis of the influence of the context (field versus laboratory and mobility versus stationary interaction) on the evaluation of mobile devices and applications.

The mobile device chosen as the target for this study was a PDA, the *Nokia 770 Internet Tablet* and some of its native applications. Tests were performed in a controlled environment (the usability laboratory) and also in the field. Twenty-four users took part in the experiment, divided into two groups of twelve.

Experiment Design

The study was designed to investigate the influence of the context (field and laboratory) and associated aspects such as mobility, settings, and so forth, and the user experience on the evaluation results. The independent variables are those that are not influenced by the context, by the test facilitator, or by external factors such as noise and lighting. An experiment plan was drawn from the study's objectives. The independent variables were chosen as follows:

- **Task context** comprises factors that may affect the users' behavior and their performance during the experiment (usability test). These factors may be internal or external to the user. The external factors originate in the field environment, examples being noise level and light intensity. The internal factors, on the other hand, are stress or other health conditions that may affect the user's mental and physical abilities.
- **User mobility** refers to the conditions under which the task is being performed. An example is if the user is required to work while being mobile, that is, moving between places or wandering while working.
- **User experience level** refers to the user's knowledge regarding mobile devices in particular and desktop computers systems in general.

The dependent variables are all dependant on the user's experience level:

- **Task time** represents the time taken by a device's user to perform a task.

- **Number of incorrect choices** measures how many times the user has made incorrect choices while selecting options in the interface through a menu dialogue.
- **Number of incorrect actions** measures how many times the same error (excluding the number of incorrect choices) was committed by the user while performing a task.
- **Number of accesses to the online help** and **number of accesses to the printed help** measure how many times the user accessed the online and printed help while performing a task.
- **Perceived usefulness** represents the user's opinion about the usefulness of the mobile application for the prescribed task.
- **Perceived ease of use** represents the user subjective satisfaction when using the mobile device.

Table 1 summarizes the experiment plan, which states the independent and dependent variables to be observed during the experiment and used as indicators to answer the research questions.

Test Environment

A software tool was used in the field environment to remotely capture the device's screen through a wireless connection to the lab. The user inputs (through keypad and stylus) were registered by a micro-camera coupled to the device and also

Table 1. Plan for the experiment with the device Nokia 770

Objective Indicators	1. Task execution time 2. Number of incorrect actions 3. Number of incorrect choices 4. Number of repeated errors 5. Number of accesses to the online help 6. Number of off-line help (printed manuals) accesses
Subjective Indicators	1. Product ease of use 2. Task completion easiness 3. Input mechanism ease of use 4. Text input modes ease of use 5. Understandability of terms and labels 6. Understandability of messages 7. Help mechanism efficiency

remotely connected to the laboratory through a wireless connection. The interaction was registered in the controlled environment using two video cameras installed in the laboratory. One was focused on the users´ facial expressions and the other registered the device screen. As in the field environment, software was used to remotely capture the device's screen. Since the field setting required a wireless network, the field experiment was performed in the area surrounding the university's computer department. In both cases, the test facilitator was a human interface specialist who remained within reach in case the user required any explanation on the test procedure.

Participants

Users participating in the PDA experiment were selected on the basis of having previous experience with mobile devices (such as mobile phones), computers, and the Internet. They were also required to have some familiarity with the English language, since this is the language adopted in the device's user interface and in its documentation. The user sample was then classed according to the users' experience level into the categories shown in Table 2.

The recruited users were divided into two groups of 12 to participate in the field and laboratory tests. Based on user experience level, both groups were then subdivided into three subgroups of four beginners, four intermediates and four experts.

Materials

Laboratory Test Materials

- **Hardware:** The Nokia 770 Internet Tablet; PC based Workstation (2); Video cameras (3); Microphones (2).
- **Software:** VNC (Virtual Network Computing) software to capture the screens during the interaction with the device; the WebQuest tool with the questionnaires pre-test (to gather the user profile) and post-test (to collect and process the user satisfaction level).
- **Miscellaneous:** The Nokia 770 Internet Tablet Manual; chronometer (1); CDs for video backup; participant registration form; test conditions acceptance forms on which the users declared their acceptance of the experiment conditions; task script that consists of a written task description to guide the user during the session (versions for the user and for the evaluator); Form for event log.

Table 2. User sample categorization

CATEGORY / CHARACTERISTIC	Beginner	Intermediate	Expert
Previous Computer Knowledge	Basic/ Intermediate	Intermediate/ Advanced	Intermediate/ Advanced
Previous Experience with *Nokia*	No	No	Yes

Field Test Materials

- **Hardware:** The Nokia 770 Internet Tablet; PC-based Portable (laptop) Workstation (1); wireless video micro-camera (1); apparatus to support the video micro-camera (1); television set (1); VCR equipment (1).
- **Software:** VNC (Virtual Network Computing) software to capture the screens during the interaction with the device; WebQuest tool with the questionnaires pre-test (to gather the user profile) and post-test (to collect and process the user satisfaction level).
- **Miscellaneous*:*** Chronometer (1); CDs and VHS tapes for video backup; participant registration form; test conditions acceptance forms on which the users declared to accept the experiment conditions; task script that consists of a written task description to guide the user during the session (versions for the user and for the evaluator); form for event log.

Camera Apparatus

The apparatus shown in Figure 1 was built to couple a video micro-camera to the mobile device. This allowed the recording of user interaction through a remote link with the laboratory computer.

The WebQuest Tool

A Web tool named *WebQuest* supports the method application (De Oliveira et al., 2005). This tool was developed to support the specialist during data collection, to provide automatic score computation, to perform statistical analysis, and to generate graphical results. *WebQuest* also enables the specialist to reach a more diverse and geographically widespread sample of users through the Internet. One of its features is a flexible questionnaire structure, which enables specific context adaptation and, by means of an estimation model, ensures a higher degree of confidence on the indicators of user satisfaction. Currently *WebQuest* supports two questionnaires: (i) a pre-test questionnaire, the *USer* (*User Sketcher*), conceived to raise the profile of the system users; and (ii) a post-test questionnaire, the *USE* (*User Satisfaction Enquirer*), conceived to raise the user degree of satisfaction with the system. The pre-test questionnaire incorporates a model to estimate the user's subjective satisfaction and can be answered directly on the Web. The questions are related to the users´ physical characteristics, knowledge, and skills. Both questions and answers are configurable.

As for the *USE* (*User Satisfaction Enquirer*), it allows gathering quantifiable variables on the user acceptance of the device. Three of its aspects are of special interest. Firstly, it incorporates a model to estimate user subjective satisfaction. Secondly, the questionnaires can be answered directly on the Web. Thirdly, the items are partially or totally configurable. The adoption of an estimation model by *USE* allowed us to establish

Figure 1. Apparatus to support video camera during experiment

a subjective satisfaction coefficient directly from the inspection of the respondents' samples. The *WebQuest* tool allows the specialist to easily edit the questionnaire's items. These items are organized into groups: (1) *fixed*, which are applicable to various evaluation contexts and thus are not allowed to be altered; (2) *semi configurable*, which allow for changes in the answer options; and (3) *configurable*, which can be fully configured (both the question and respective options of answers). *USE* supports the specialist from the data collection through to automatic score computation, performing statistical analysis, and generating graphics with the results.

Experiment Procedure

The techniques employed in the experiment procedure were the observation and subsequent video analysis for accumulating quantitative data (such as time spent and error rate). An automated video capturing tool recorded the interactions of the subjects during the field tests to ensure a non-intrusive observation method. During task execution, the users were asked for their consent before being filmed. The conditions of test-subject participation included a written commitment not to disclose any product information. The users were also asked to give consent so that their images and/or sound recordings made during the experiment could be used for research purposes or in a multimedia product evaluation report. On the other hand, the users were given assurances from the evaluation team that no personal information or individual performance results would be disclosed.

The first step in following the method consisted in defining the evaluation scope for the product as well as a scenario for the test. Table 3 illustrates the sequence of tasks performed during the experiment.

The decision was based on a heuristic evaluation performed by the evaluation team. This initial step also supports the definition of a general profile for the user sample and a classification into categories. Following, the method the evaluation objectives were defined. These became the basis for choosing the product evaluation scenario (product context of use and laboratory settings) and the corresponding tasks to be performed by the users during the experiment. Having planned the evaluation, a pilot test was conducted to verify the adequacy of the proposed experiment procedural, materials, and environment. Through this fine tuning procedure it was found, in the PDA case study, that the time to perform the tasks had been underestimated. This resulted in re-dimensioning the test scenario to six tasks, with a review of the tasks themselves to fit the established session time of sixty minutes to prevent user tiredness.

All subjects were submitted to the same procedure prescribed in the experiment protocol. The study was conducted first in a laboratory setting and then in the field environment. During the field tests the participants were taken outdoors, and the tasks were conducted in an environment that was as close to real-use conditions as possible.

The experiment conducted in the usability laboratory had the audio and video of each session recorded. In the field experiment, only the

Table 3. Test scenario and sequence of tasks to be performed during experiment

TASKS IN SCRIPT	
T01	**Initializing the device**

T03	**Visualizing a PDF file**
T04	**Entering textual information**
T05	**Using the electronic mail**
T06	**Using the audio player**

video of the sessions was recorded, supplemented by comments written by the specialist. As described in the experiment protocol, each session consisted of the following steps: (1) introducing the user to the test environment by explaining the test purpose, the procedure to be followed and the ethics involved in terms of the conditions of participation; (2) applying the pre-test questionnaire; (3) performing the task script; (4) applying the post-test questionnaire; and (5) performing a non-structured interview.

At the time of the experiment, the *Nokia 770 Internet Tablet* device was not yet widely known in the Brazilian market. The users who claimed to have had no previous contact with it were given a quick introduction. This introduction consisted of an instructional material given to the recruited users and also a quick explanation about the device's input and output modes and its main resources.

Results

The results obtained from the experiment in which the multi-layered method was applied support the original assumption that, in spite of the distinctive features of this class of devices, it is possible to adapt from the evaluation experience with conventional devices. This conclusion is supported by the evidence that the evaluation context did not significantly influence the user performance or the opinion about the device's usability, given through the analysis of the objective and subjective indicators associated with the experiment.

Standard Conformity Assessment Results

The results of the conformity assessment to the standards ISO 9241 Parts 14 and 16 and ISO 14754 are illustrated in Table 4. According to ISO, conformity assessment results can be summarized by computing an *adherence rate* (AR). This is the percentage of the applicable recommendations (Ar) that were successfully adhered to (Sar).

In spite of the device's characteristics that limit the number of applicable recommendations, these results corroborate the idea that the standards inspection is still applicable in the evaluation process. The efficacy of this technique can be considerably improved if it is based upon standards conceived specifically for mobile devices, which could evidence more usability problems.

Table 4. Nokia 770 conformity assessment with standards

Standard	#Sar	#Ar	AR (%)
ISO 9241 Part 14	**45,0**	**53,0**	**84,9**
ISO 9241 Part 16	**26,0**	**33,0**	**78,8**
ISO 14754	**4,0**	**11,0**	**36,4**

Sar—Successfully adhered recommendations
Ar—Applicable recommendations
AR—Adherence Rate

$$AR = \frac{Sar}{Ar} x100\%$$

User Satisfaction Measurement Results

For the PDA case study context, both questions and answers of the *USE* questionnaire were configured. The questionnaire was applied soon after the usability test and answered using the mobile device itself. As mentioned before, its purpose was to collect information on the user's degree of satisfaction with the device and on aspects such as interface navigation, documentation, and overall impressions.

The *USE* was composed of three sections. The first section is relative to "the product Use and Navigation." It is composed of 17 items and focuses on aspects such as menu items, navigation between functions, understandability of the messages, ease of use of the basic functionalities, and of the device's input and output mechanisms. The second section consists of six questions related to the online and off-line (printed manuals) documentation. The last section ("You and the product") consists of 15 items and aims to get the user's impressions and product acceptance level. The first 23 items use a 5-point semantic scale (1: *very easy*; 2: *easy*; 3: *not easy nor difficult*; 4: *difficult*; and 5: *very difficult*). The last 15 items use another 5-point semantic scale (1: completely agree; 2: agree; 3: do not agree nor disagree; 4: disagree; and 5: completely disagree). The users were asked to answer the questions and to assign an importance level to each one of them, on a scale from 0 to 10.

For the post-test questionnaire, *USE* adopts the model proposed by Bailey and Pearson (Bailey & Pearson, 1983) for measuring the overall user's sense of satisfaction. The following adaptations to the dimensions were considered: (1) the association of only one (1) semantic differential scale to the items, instead of the four (4) semantic differential scales, as proposed in the original model; (2) the adoption of a 5-point Likert scale, delimited by the ends -2 and 2 (instead of the 7-point scales delimited by the ends -3 and 3 as originally proposed); and (3) the incorporation of a 11-point importance scale (0 corresponding to *non applicable*), varying from 0.0 to 1.0 in intervals of 0.1 (instead of the original 7-point scales, which varied from 0.1 to 1.0 in intervals of 0.15).

The user's subjective satisfaction indicators for the PDA case study were 0.330 for the laboratory experiment and 0.237 for the field experiment. The normalized value ranges of the user satisfaction concerning a product are 0.67 to 1.00 (*Extremely Satisfied*), 0.33 to 0.66 (*Very satisfied*), 0.01 to 0.32 (*Fairly satisfied*), 0.00 (*Neither satisfied nor unsatisfied*), 0.01 to 0.32 (*Fairly dissatisfied*), 0.33 to 0.66 (*Very dissatisfied*), and 0.67 to 1.00 (*Extremely dissatisfied*). This is in accordance with the Bailey and Pearson model (Bailey & Pearson, 1983). The results obtained correspond respectively to *Very satisfied* and *Fairly satisfied*.

Performance Measurement Results

The User Sample Profile

The user sample profile was drawn with the support of the questionnaire *USer*. It was composed of 13 male and 11 female users, of which eight were *undergraduate students*, 12 *post-graduate students*, two *graduate level*, and two *post-graduate level*. The ages varied between *18* and *29* years. They were mainly *right handed* and mostly used some sort of reading aid (either *glasses* or *contact lenses).* All of them had at least one year of *previous experience of computer systems* and were currently using computers on a *daily* basis.

User Performance Data Analysis

After having analyzed the data gathered during the experiment on the user performance and having analyzed the list of problems found with this technique, it was possible to evaluate their impact and class them as: minor (50%), medium (50%), major (0%), consistency (35.7%), recurrent (64.3%), and general (0%).

The data analysis consisted of a statistical processing and had two main purposes: (1) to investigate the influence of the context on the results of the evaluation method (through the comparison of the results obtained from both environments); and (2) to investigate the influence of the user experience with the mobile device on the test results within each context. For the latter purpose, the three categories illustrated in Table 2 were used.

The statistic analysis performed consisted of: (1) building a report with univariance statistics; (2) generating the covariance matrices for the objective and subjective indicators that were previously defined; (3) applying the one-way F ANOVA test (Tabachnick & Fidell, 2006) to the data obtained from the previous step in order to investigate possible differences; and (4) applying the Tukey-Kramer process (Tabachnick & Fidell, 2006) to the one-way F ANOVA results aiming to investigate if the found differences were statistically significant to support inferences from the selected sample. The result of this technique was the identification of 13 problems, of which 92.3% were found in the laboratory and 61.5% in the field as: Laboratory (38.5%); Field (7.7%); and Laboratory & Field (53.8%).

Overlaying Results

Since the multi-layered evaluation is based upon a triangulation of results, Table 5 summarizes the usability problem categories identified by the three techniques.

The numbers correspond to the identification of each problem from a list of problems found through each technique. As can be seen from Table 5, some of the usability problem categories were more related to the performance measurement (e.g., hardware aspects, help mechanisms, processing capacity) whereas others (e.g., menu navigation, presentation of menu options) were identified by the conformity assessment. It was possible to identify 66.7% of the problems found by other methods when combining the results from the post-test questionnaire with the user comments made during the experiment and the informal interview at the end of the experiment. This confirms the importance of combining techniques to obtain a more complete result when performing usability evaluation. It must be pointed out that 29.62% of the problems based on the user opinion about the product were in disagreement with the results of the other two evaluation dimensions (specialist and the community points of view). This discrepancy can originate from the users' perception of product quality and the perception of their own skills to perform the task, accepting full responsibility over the difficulties that might arise during the interaction. When overlaying the problems in Table 5, in the category *Menu navigation*, the same problem was found by the techniques Standards Inspection and Performance Measurement.

DISCUSSION

From this study's data analysis it became evident that certain problem categories are better found by specific techniques, as shown in Table 5. For instance, problems associated to the device's physical characteristics are better found by means of conformity assessment, whereas the user performance located problems associated to the device's applications.

The analysis of the pre-test and post-test questionnaires and the informal interviews showed that domain knowledge and computer literacy have significant influence on user performance with mobile devices. This was true both under laboratory conditions and in the field, in relation to the incidence of errors. The univariate analyses of variance of the performance variables: *Time*, *Errors*, and *Accesses to help, are* presented in Table 6.

From this table, it can be seen that the user experience level had a more significant effect on

Table 5. Overlay of results obtained with the three evaluation techniques

PROBLEM CATEGORY	SI	PM	SM
Location and sequence of menu options	✓ **(05)**		× **(05)**
Menu navigation	✓ **(02)**	✓ **(01)**	
Presentation of menu options	✓ **(02)**

Table 6. Influence of the user experience on the performance indicators: Time, Number of errors, and accesses to help

Independent variable	Dependent variable	p-Value (Lab)	p-Value (Field)	Significance (α=0.05)
Experience	Task Time	0.081	0.081	Not significant
Experience	Errors	0.011	0.002	Significant
Experience	Help Accesses	0.427	-	Not significant

the number of errors in the field experiment than in laboratory experiment.

The studies in the literature fit basically into two categories: (1) user mobility, which means moving while using the device (inside of a laboratory or outdoors) and (2) user attention division. However, this study considers both aspects as part of the task context. In this experiment, the field test subjects were free to choose between moving or remaining still as they performed the task with the mobile device. During the informal interview the users stated that in a real context they would not perform the experiment tasks on the move**,** since they demanded too much attention. The specialist encouraged users to wander around the environment, although they could choose to enter a room in the building, sit down, or even lay the device on a table (which they did in most cases, under the argument that this setting was more comfortable). The movement registered was limited to situations in which the user waited for some device processing. (e.g., Web page downloads). There was a clear interference of the environment on the user attention during the field tests while moving.

The device's physical characteristics affected the user performance and the data gathering during the experiment**.** Outdoors, in ambient light, the device's legibility was reduced and aggravated by the reflections on the screen. According to the user's opinion stated during the informal interview, the camera apparatus did not interfere with the task execution, but the majority decided to lay the device down during task execution.

As for the entry of text information, the users showed a preference for the virtual keyboard instead of hand written character recognition. Based on their comments, as well as on the informal interview, it was concluded that writing long messages is very cumbersome both using the virtual keyboard and using the handwriting recognition application. Confirming previous findings, the experiment demonstrated that applications that require a lot of interaction and user attention are inappropriate for performing while walking due to attention division. This conclusion reinforces that, for the device targeted in this study, in spite of its mobility, the evaluation settings did not need to differ substantially from the one employed in the evaluation of stationary devices since the users tend not to wander while performing tasks that demand their attention or consisted of text input.

Until recently, studies have been published which deal with new paradigms and evaluation techniques for mobile devices. Few of the proposed new techniques are really innovative if compared to the ones traditionally employed. On the other hand, the main argument for proposing new techniques concerns the user and device mobility and the influence of this mobility on user performance. In contrast, this study evaluated the effect of mobility not only from the user performance perspective but also from user opinion point of view and the user level of satisfaction. From the application of the multi-layered approach, the data gathered and analyzed support the initial assumption that minor adaptations in the traditional evaluation techniques and respective settings are adequate to accommodate the evaluation of the category of mobile devices targeted by this study.

The conclusions corroborate with the views of the authors and that of Po (Po, 2003) that the laboratory and field evaluations do not diverge but are complimentary. As shown in this study, they both add to the evaluation process, producing data that is significant to the process and reinforcing the relevance of a multi-layered approach for the usability evaluation of mobile devices.

FUTURE TRENDS

Mobile devices impose challenges to the usability evaluation that are unique in respect to the observation strategies and the conception of test scenarios. With the continuous technological advances, a wider variety of new devices is being

released into the market, challenging users with the complexity of the interaction. In this scenario, the importance of the product usability is undisputable as is also the correct choice of evaluation methods, techniques, and tools.

One emerging trend in the mobile devices evaluation field is the possibility of gathering data in an unobtrusive way, using tools for remote, and automatic data capture that are transparent to the user. Developing those tools is a challenging activity given the inherent restrictions presented by the mobile devices (such as their limited processing power and limited storage capacity). But, in spite of the current limitations, it was shown in this study that the tools are becoming available to provide a great contribution to the evaluation setup and that these tools would benefit from further development.

KEY TERMS

Conformity Assessment: A collective term used for a number of techniques used to determine if a product, system, or process (including design) meets a defined specification.

Device Mobility during a Usability Evaluation: The ability to interact with the user and continue to perform its functions while being transported.

Efficacy of an Evaluation Method or Technique: Translated into the number of problems found, gravity of those problems versus the time, and cost of performing the experiments.

Likert Scale: An attitude scale in which respondents indicate their degree of agreement/disagreement with a given proposition concerning some object, aspect, person, or situation.

Multi-Layered Evaluation Approach: A product or prototype usability evaluation method that combines techniques for data gathering and analysis based on multiple perspectives (the user's, the specialist's, and the usability community). The results are overlaid in order to find discrepancies and offer more robust results.

User Mobility during the Usability Evaluation: The ability to move while performing a task with a product.

User Performance Measurement: The process of gathering actual data from users as they work with a system and its documentation. Usually, the user is given a set of tasks to complete and the evaluator measures the relevant parameters such as the percentage of tasks or subtasks successfully completed, time required to perform each task or subtask, frequency and type of errors, duration of pauses, indications of user frustration, and the ways in which the user seeks assistance.

User Satisfaction Measurement: The process of obtaining qualitative and quantitative information which indicates the extent to which user expectations concerning some object, process, product, or situation are being met. Such information can be obtained in a variety of ways, both formally and informally.

Virtual Network Computing (*VNC*): A desktop sharing system that uses the RFB (Remote Frame Buffer) protocol to remotely control another computer. It transmits the keyboard presses and mouse clicks from one computer to another over a network, relaying the screen updates back in the other direction.

ABSTRACT

As more and more servers appearing in the wireless environment provide accesses to mobile users, more and more demand and expectation is required by mobile users toward the available services. Mobile users are no longer satisfied with obtaining data only from one server, but require data from multiple servers either at the same or different locations. This eventually leads to the need for information gathering that spans across several non-collaborative servers. This article describes some of our researches in information gathering from multiple non-collaborative servers that may involve servers that not only accept direct queries from mobile users but also servers that broadcast data. We also look at how location dependent data plays an important role to mobile information gathering.

INTRODUCTION

The direction of the mobile technology industry is beginning to emerge and advance at a rapid pace as more mobile users have evolved (Myers & Beigl, 2003). Interests in mobile technology have grown exponentially over the last few years and are greatly influenced especially by the dramatic reduction in the cost of hardware and protocol standardization (Hurson & Jiao, 2005; Kapp, 2002). The increase in progression and advancement of

mobile technology has created a new paradigm of computing called mobile computing in which people are allowed to be connected wirelessly to access data anytime, anywhere without having to worry about the distance barrier (Lee, Zhu, & Hu, 2005; Lee et al., 2002; Madria, Bhargava, Pitoura, & Kumar, 2000). Users have also become more productive with the achievement of mobility since they are able to access a full range of resources regardless of where they are located and where they are able to get hold of real time information.

The emerging growth of the use of intelligent mobile devices (e.g., mobile phones and PDAs) opens up a whole new world of possibilities, which includes delivering information to mobile devices that are customized and tailored according to their current location (Gutting et al., 2000; Tsalgatidou, Veijalainen, Markkula, Katasonov, & Hadjiefthymiades, 2003; Xu et al., 2003). Mobile queries are requests for certain information that are initiated by mobile users to the appropriate servers from their mobile devices. Query processing in a mobile environment may involve join processing from either single or several different servers with the mobile devices (Liberatore, 2002; Lo, Mamoulis, Cheung, Ho, & Kalnis, 2003). In addition, mobile queries can be performed regardless of where the users are located and the results obtained are influenced by the location of the user. Data that are downloaded from different locations would be different and there is a need to bring together these data according to a user who may want to synchronize the data that are downloaded from different location to be consolidated into a single output. Thus, the intention is to take into account location dependent factors, which allow mobile users to query data without facing location problems (Song, Kang, & Park, 2005; Tse, Lam, Ng, & Chan, 2005; Xu, Tang, & Lee, 2003). This concept is associated with location dependent query.

One of the main objectives of this article is to demonstrate the importance of allowing mobile users who believe that obtaining data from a single server is not enough and may need further processing with data that are obtained from other servers. Furthermore, the user may get data from several servers that are from the same or different providers. In other words, there are times when the user has the desire to gather data from several non-collaborative servers into their mobile devices (Lo, et al, 2003; Malladi & Davis, 2002). Mobile devices have made it capable for mobile users to process and retrieve data from multiple remote databases by sending queries to the servers and then process the multiple data gathered from these sources locally on the mobile devices (Mamoulis, Kalnis, Bakiras, & Li, 2003; Ozakar, Morvan, & Hameurlain, 2005). By processing the data locally, mobile users would have more control over what they actually want as the final result of the query. They can therefore choose to query data from different servers and process them locally according to their requirements. Also, by being able to obtain specific data over several different sites, it would help bring optimum results to mobile user queries. Furthermore, by driving away the computation on the client device, the bandwidth computation may also be reduced.

Example 1: *A mobile user may want to know where the available vegetarian restaurants are in the city he or she is currently visiting. There are two major servers (e.g., tourist office and the vegetarian community) that may give information about the available vegetarian restaurants. First, using his or her wireless PDA, he or she would download information broadcast from the tourist office. Then, he or she would download the information provided by the vegetarian community. After obtaining the lists from the two information providers, he or she may perform an operation on his or her mobile device that joins the contents from the two relations obtained earlier from the two non-collaborative organizations. This illustrates the importance of assembling information obtained from multiple non-collaborative sources*

in a mobile device in order to obtain more comprehensive information.

This article investigates the need for information gathering spanning several non-collaborative servers that may bring to mobile users. Furthermore, due to the various nature of how a server may disseminate their data (e.g., through ad-hoc queries or data broadcasting), this article also evaluates the query processing methods involving the previously mentioned strategies.

In this article, we first present an insight of the background of mobile environment, non-collaborative servers, and prospective applications for information gathering from multiple sources. By formulating the taxonomy, it helps to give understanding of the possible database operations that can be performed on the mobile devices. We will also describe the process of information gathering that results from multiple servers that involves location dependent data, which are then followed by a system prototype. Finally, the last section concludes the article. Note that in this article we use the term mobile client, mobile user, and users interchangeably.

BACKGROUND AND PRELIMINARIES

Before discussing more details, the process of information gathering, and its rationale, this section would first introduce some background and preliminaries related to mobile query processing in a typical mobile environment, which involves multiple non-collaborative servers. Firstly, this section provides some introductory knowledge on the wireless environment covering what constitutes the architecture of a typical mobile computing environment, followed by the usefulness of obtaining information from multiple sources and lastly the prospective application of this study.

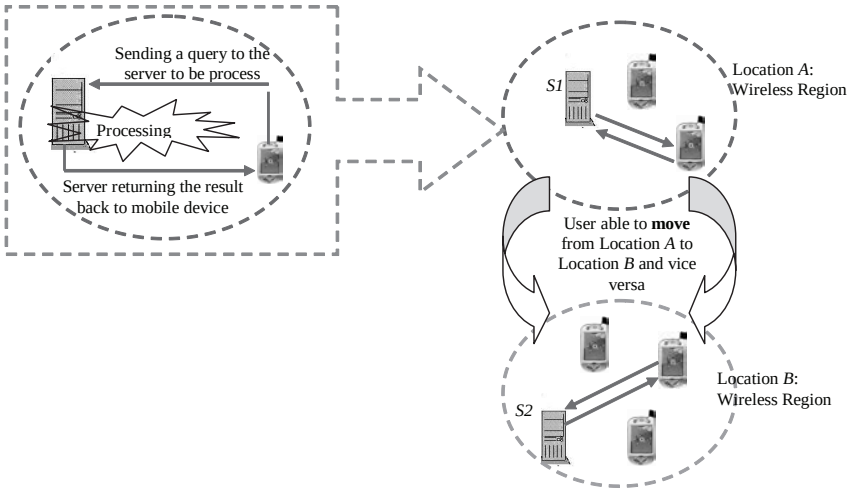
Mobile Computing Environment: A Background

Mobile computing has provided mobile users the ability to access information anytime, anywhere. It enables mobile users to query databases from their mobile devices over the wireless communication channels (Imielinski & Badrinath, 1994). In general, mobile users with their mobile devices and servers that store data are involved in a typical mobile environment (Lee et al., 2005; Madria et al., 2000; Wolfson, 2002). Each of these mobile users communicates with a single server or multiple servers that may or may not be collaborative with one another. This server is also known as mobile base station (MBS), which the mobile users communicate to in order to carry out any activities such as transaction and information retrieval. The servers supply its services to a wide range of users who are within the active region through a wireless interface. Thus, mobile users have to be within a specific region to be able to receive a signal in order to connect to the servers.

Figure 1 depicts a mobile environment architecture where two servers are involved, *S1* and *S2*, in location *A* and location *B* respectively. Mobile users move freely within the different region to obtain different data by accessing the different servers via sending a query and receiving the results back to the mobile device upon completion of processing.

Example 2: *A property investor, while driving his or her car, downloads a list of nearby apartments for sale from a real-estate agent. As he or she moves, he or she downloads the requested information again from the same real-estate agent. Because his or her position has changed since he or she first inquires, the two lists of apartments for sale would be different due to the relative location when this investor was inquiring the information. Based on these two lists, the investor would prob-*

Figure 1. Mobile environment architecture



ably like to perform an operation on his or her mobile device to show only those apartments that exist in the latest list, and not in the first list.

Hence, in a typical mobile environment, it is unacceptable to meet with situations where a mobile user is currently obtaining data from a current active region and is still not feeling satisfied with the result. This leads to the need of further processing with other data that can only be obtained from other servers that may or may not be collaborative to each other.

Overview of Non-Collaborative Servers

The term collaborative usually relates to the traditional distributed databases whereby the desire to integrate the data of a particular enterprise and to provide centralized and controlled access to that data (Bell & Grimson, 1992; Ceri & Pelagatti, 1984; Özsu & Valduriez, 1999). The technology of distributed database may not be appropriate for use in the mobile environment, which involves not only the nomadic clients, which move around, but also non-collaborative servers, which are basically servers that are maintained by different organizations (Lo et al., 2003).

Therefore, non-collaborative servers would refer to servers that do not know each other and do not have any relation between one another. There are basically just individual server providers, which disseminate data to the users and they do not communicate with one another. Since each server can just be an independent service provider, often these independent servers are specialized within the domain of the information they are providing.

An example of such a server that disseminates information on restaurants normally just focuses on the restaurants information and limited supporting information, which can sometimes be included (e.g., how to get there--the transportation is just supporting information since it does not exactly show the route on how to get there from a particular location the user is currently

at). Therefore, there is still a need to obtain full information from multiple servers, which in this case are the restaurant and transportation servers separately.

In addition, not all service providers are supported by the usage of a mediator (Lo et al., 2003). Therefore, information obtained from other independent non-related service providers needs to be processed individually. It is not a fair assumption that all service providers are linked through a mediator. Hence, in our research, we focus on independent service providers, which refers to non-collaborative servers. Thus, it is vital to consider gathering information from non-collaborative servers because it is often not enough to just get data from a single server.

Prospective Applications

Information gathering in the context of mobile environment is a source where collecting various data together regardless of whether it is related or not related as long as it is useful for the mobile users. There exists several significant influences of information gathering from multiple sources that lies on personal applications. Next, we show summarized lists of some promising applications that bring great impacts to mobile users.

- **Entertainment applications:** Shopping appears to be a popular trend and hobby. Often shoppers would prefer to go to shops that give the lowest price for the item they are interested in buying. Many shops in the same shopping complex may sell the same item, but they are different companies and they are not related with one another. Thus, with the ability of getting the information, especially the pricing for the desired item, separately from the various shops could aid users in deciding which shops to go to that offers a better price.

Example 3: *A mobile user who is currently in a shopping complex is interested in a buying a tennis racquet. There are two different sports shops in the complex, sports shop A and sports shop B, that sell the tennis racquet that the user wants to buy. So first, by sending a query to shop A, he or she obtains a list of the prices for the tennis racquet. Then he or she sends a query to shop B, which again he or she will get a list of prices for the tennis racquet. So with these two lists, the mobile user can do a local processing, which compares the matching racquets and displays the shop that gives a lower price for the respective racquets that are being matched.*

- **Tourism applications:** Tourism brings value added in terms of economical growth to not only the country, but also the physical relationship between the visitor and the producer of a good or service. Tourism is an important element to boost the country's reputation and economy. Thus, it is important to give both local and international travelers the best and most convenient. Giving the ability of information gathering from multiple sources tends to emerge as valuable services to the mobile travelers regardless of where their current geographical coordinates.

Example 4: *An international tourist, while traveling to a foreign country, does not know the where abouts of the tourist attraction spots. He or she looks for famous tourist spots recommended by both the transport office and tourism office. First, using his or her wireless PDA, he or she would download information broadcast from the tourism office to get a list of the famous tourist spots. Then, he or she would download the information provided by the transport office to get information on the available transportation. Once he or she obtains the lists from the two information providers, he or she may perform an operation on his*

or her mobile device that joins the contents to match the tourist spots together with transport information on how to get there.

- **Emergency responses applications:** There are times especially when someone on the highway is having trouble with their car and needs to find the nearest possible petrol station that offers car services as soon as possible. In this circumstance, the person on the highway can use his or her mobile device to make a query as he or she travels along the highway to look for a petrol station that offer car services. This comes into the category of emergency cases, as it is rare and is not needed all the time.

Example 5: *A traveler currently in location A wants to know where the nearest gas station is (petrol kiosk) and using the mobile device, they downloaded a list of available petrol kiosk nearby to his or her current surrounding location. As they travel further until they arrive in location B, he or she makes another query to get another list of petrol kiosk, but this time the list is somewhat different since he or she has been driving and the location has moved from A to B. Therefore, based on these two lists, the traveler wants to display only those petrol kiosks that provide car service regardless of whether it is in A or B.*

- **Double checking applications:** Data that are stored in the servers that are to be disseminate to the public can sometimes be outdated due to the company that manages the data being closed down or other undesired catastrophes. If the users are still able to query for the data, part of the data may not be accurate anymore since it has not been maintained and updated well. This will make the data worthless if the users download it. Therefore, a certain degree that allows the users to see the data that is downloaded are obtained from a reliable source or not may be useful if the ability of processing data that are obtained from one server together with another list of data obtained from another server as a double checking precaution.

Example 6: *This example requires an assumption of one property that can be handled by several estate agents. A user obtains a list of properties in the city that are ready for sale from real-estate agent A. Without knowing, real-estate agent A has just been declared bankrupt and the lists that are currently in the server have not been updated since. Thus, some of the properties that the user has downloaded have actually been sold. Without knowing all this, since the user is able to obtain another list of properties in the city from another agent, which is agent B, this list would have been able to be used as a reference list to the previous list that was obtained from agent A. Since one property can be handled by several agents, the properties for sale in the city between list A and list B should be the same. The only difference may be the price on whether the agent is selling it cheaper or more expensive than the other. Thus, by seeing the difference in the availability of the properties between the two lists, this information can appear to the mobile user that one or the other is not correct since we have to assume one property is to be handled by several agents.*

In summary, we can see from the previous sample application domain that obtaining from a single place is not sufficient enough to provide the desired results to the mobile users. The mobile users often require several data that are non-related with one another to be gathered and processed together so that a higher level and meaningful information can be obtained. By giving more flexibility to the mobile users to "mix-and-match" non-related data from several servers proves to return a more comprehensive result that is able to satisfy the needs of the users. Therefore, information gathering from multiple non-collaborative servers brings benefits and gives a good prospect

for users to achieve a higher quality and productive information.

MOBILE USER QUERIES

The context of mobile user queries in this article is that the mobile queries contain operations that are being carried out when multiple lists of data are obtained from multiple servers (Lim, Taniar, & Srinivasan, 2006). In this section, we will present a taxonomy of the mobile user queries in two elements namely (i) *non-location-based on-mobile queries* and (ii) *location-based on-mobile queries.*

- In non-location-based on-mobile queries, the need to obtain constructive information often requires mobile users to download lists from multiple sources to be integrated and processed together. In a mobile environment, joins are used to bring together information from two or more different information sources. It joins multiple data from different servers into a single output to be displayed on the mobile device. The idea of this is basically to ensure mobile users have the ability to reduce the query results with maximum return of satisfaction because with the additional post-processing, the output results can be greatly reduced based on the user's requirements and needs before the final display on the device.

Consider Example 1 presented earlier where it shows how a join operation is needed to be performed on a mobile device as the mobile user downloads information from two different sources, which are the tourist office and the vegetarian community. In this case, two pieces of information might be joined on the restaurant IDs from the two different lists. This therefore, illustrates a simple on-mobile join case, where it is basically a process of combining data from one relation to another.

- Location-based on-mobile queries have become a growing trend due to the constant behaviour of mobile users who move around. Location-dependent processing is of interest in a number of applications, especially those that involve geographical information systems (Cai & Hua, 2002; Cheverst, Davies, & Mitchell, 2000; Jung, You, Lee, & Kim, 2002; Tsalgatidou et al., 2003). An example query might be "to find the nearest petrol kiosk" or "find the three nearest vegetarian restaurants." As the mobile users move around, the query results may change and would therefore depend on the location of the issuer. This means that if a user sends a query and then changes his or her location, the answer of that query has to be based on the location of the user issuing the query (Seydim, Dunham, & Kumar, 2001; Waluyo, Srinivasan, & Taniar, 2005). Location dependent processing involves the circumstances when mobile users are in the situation where they download a list when in a certain location and then they move around and download another list in their new current location. Or another circumstance might be a mobile user might already have a list in his or mobile device but moves and needs to download the same list again but from a different location. In any case, there is a need to synchronize these lists that have been downloaded from a different location.

Consider Example 2 presented earlier. It shows an example of how location dependent queries processes are being carried out. With the two different lists on hand that the investor currently had based on the properties in the two different locations, the investor would probably like to perform some kind of database operation on his

or her mobile device. The difference in the list is due to the moving location from one point to another point by the investor.

MODELS OF INFORMATION PROCESSING

There are times when a user may need to query several non-collaborative servers in order to obtain a more comprehensive list of data. The user may need to perform some database operations locally on the mobile device based on the list of data that has been downloaded from the remote databases.

Figure 2 models the various strategies that the server can adopt. *Server strategy* involves mobile users sending queries to the server for processing (Seydim et al., 2001). It relates to processing to be taken by the server to process and return the results based on the mobile user queries. *On-air strategy* is similar to traditional broadcasting

Figure 2. Query processing strategies

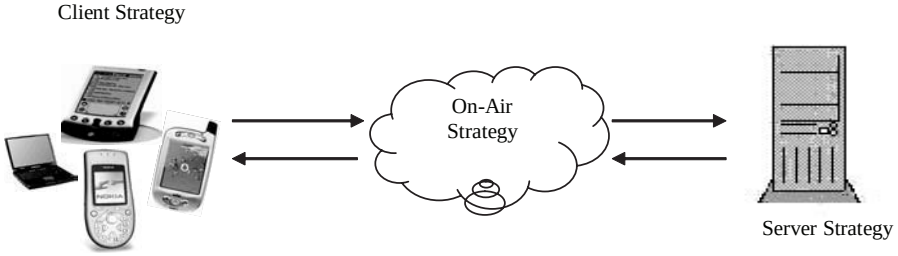


Figure 3. Example of assembling information from two different servers

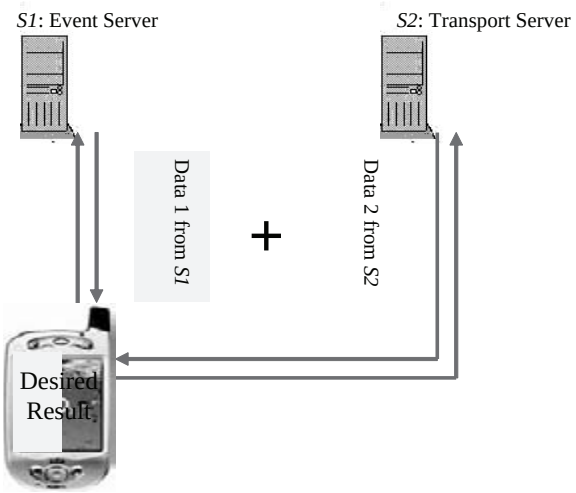


techniques whereby the sets of database items are broadcasted through the air to a large number of mobile users over a single channel or multiple channel (Tran, Hua, & Jiang, 2001; Triantafillou, Harpantidou, & Paterakis, 2001). With the set of data on the air, mobile users can tune into one or more channel to get the data. *Client strategy* relates to maintaining cached data in the local storage and being able to have the ability to do local processing if queries results are being sent back to the mobile device and stored in the cache memory. Thus, efficient cache management is critical in mobile query processing (Cao, 2003; Elmargamid, Jing, Helal, & Lee, 2003; Xu, Hu, Lee, & Lee, 2004; Zheng, Xu, & Lee, 2002).

Lists of information can be obtained from servers that distribute their respective data using various strategies such as server strategy, on-air strategy, and client strategy. Each of the available servers has their associated query processing strategies and they can be processed together regardless of whether part of the servers use a different strategy.

Example 7: *Suppose a mobile user wants to know the timetable for the transportation services to a particular event. Each of the transportation timetables, as well as the event, is stored in different servers and maintained by two different organizations. Transport servers would deal with transportation data while an event server would deal with current events that are happening. Therefore, in order to know the transportation timetable for a particular event, the user has to gather data from the two different servers, which is first sending a query to obtain the event list into the mobile device, and then sending another query to the transport server to obtain the list of transportations. Now these two lists are in the mobile device and are ready to be processed locally to match the transportation timetable onto the respective events. This exemplifies the importance of assembling information from multiple servers into a single information, which is the desired result as the outcome on the PDA.*

Assuming that both transport and event servers are individual servers that accept direct query from the users, Figure 3 models an illustration of how two different lists are obtained from two different sources to be processed locally. This achieves the object of processing information obtained from multiple non-collaborative servers.

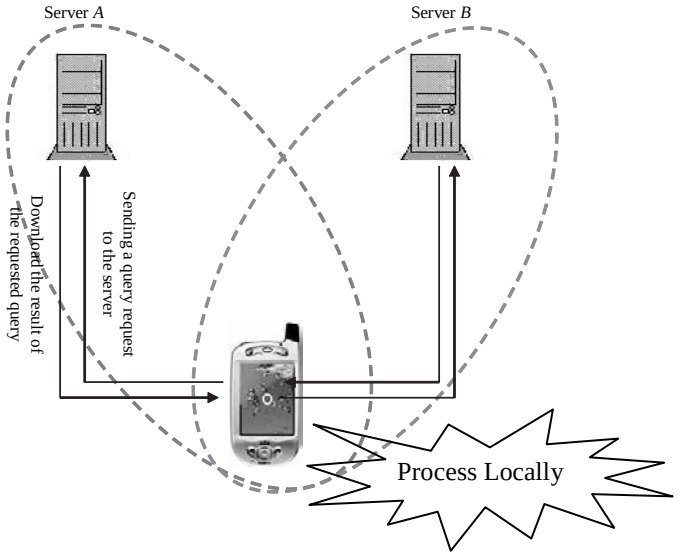
In the following sub section, we will uncover several case studies and explain how multiple non-collaborative servers that use the different strategies integrate its results into useful information for the mobile users. Just for illustration and simplicity purposes, we only illustrate situations where there are only two servers that are in use.

Case Study 1: Both Servers use Server Strategy

Without acknowledging the current standing location of the user, we would like to allow the user to be able to carry out simple database operations locally on the mobile device such as simple join between the different lists of data that are downloaded into the mobile device from the remote databases. We would first examine cases where the two different servers that the users need to obtain its information from to be integrated together are both using server strategies as being modeled in Figure 4.

Server strategy has limited functionalities since it provides dedicated point-to-point connections in accepting the mobile users request directly. This is due to the limited bandwidth that is available. Therefore, if suddenly there are many users wishing to send a request to the same server, the server may be congested. Thus, server strategy may cause an increase in exceeding usage of bandwidth especially when too many data requests are being sent out by the mobile users.

Figure 4. Example of on mobile query processing



The overwhelming mobile users requests may affect the query performance. This can easily cause a scalability bottleneck with a large mobile user population.

As far as the cost remains a major concern to a wide majority of mobile users, obtaining data via server strategy may be expensive or cost effective. This is because mobile users are establishing a direct communication to the server, which is how server strategy provides exclusive point-to-point communications between the user and server, which in this case the server processes the query that is being sent by the mobile users and returns the results back to the mobile users (Sun, Shi, & Shi, 2003).

In addition to the previous issues that users may face when obtaining data from servers that accept direct requests, there are several other additional complexities such as deciding which servers to download first in order to reduce memory consumptions and minimize transfer costs as well worthless or unnecessary data transfers. The techniques obtained from servers indicate there is a need to download in advance at least a list of data from one side of the server to the mobile device. Due the limitation of memory, it would be wise to use a technique that is able to utilize the minimum memory. Both response and access time are also a major concern because they may slow down the results from the query especially when the number of requesting queries is increasing.

Case Study 2: Server Strategy and On-Air Strategy

There are situations when certain data are broadcast on a public wireless channel, which requires the user to tune into the broadcast channel to filter out the relevant data. Users have no control in issuing queries directly to the servers. Therefore, we are concerned with how users can efficiently

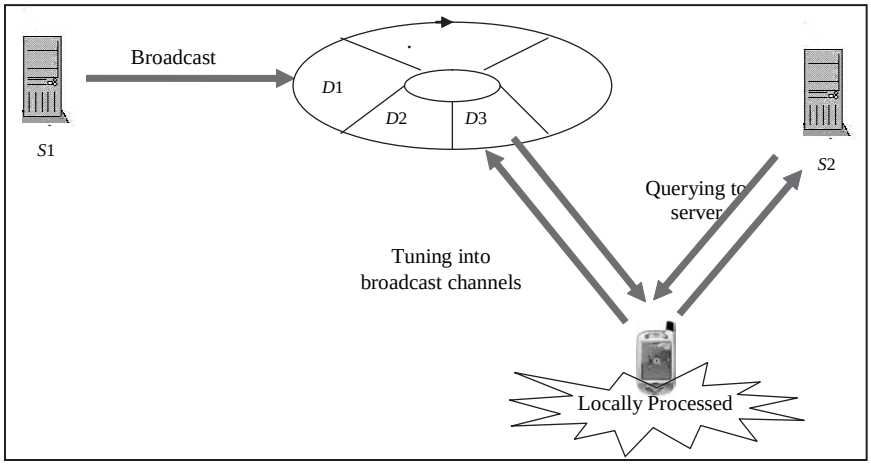
obtain their specific request without being able to send a query to the servers that use the broadcasting system. In this system, by broadcasting it actually lets an arbitrary number of users access the data simultaneously. Therefore, this may be acquainted with issued of over population in accessing a particular data that may slow down the access. In other words, when encountering a multiple non-collaborative servers setting, some servers may not able to accept queries that are directly issued by the mobile users but rather provide data broadcasting.

Figure 5 illustrates an example of a server that supports data broadcast in conjunction with another server that supports direct query. Example, in order to gather data from the two non-collaborative servers, whereby one server supports data broadcast and another server supports direct query, the mobile users would need to tune into the wireless channel to obtain the desired data from the server that supports data broadcast and issue a query to the other server, which accept direct query.

When determining the on-air strategy to be used over server strategy or client strategy, one important issue is to determine an optimal broadcast sequence for the data items that are to be distributed to the mobile users. This refers to data broadcast scheduling, which one must look at in order to have minimal access time and minimal tuning time in receiving the required data items. By prioritizing the data items and using a good selection mechanism can reduce the broadcast cycle length, which eventually is able to reduce the query response time (Chung et al., 2001; Lee, Lo, & Chen, 2002). The data items can be characterized as both "hot" and "cold" and this can be the determinant of which data item should be given a higher priority over the others (Zhang & Gruenwalk, 2002).

Another alternative to the selection mechanism, in taking into account of reducing response time, is to have more than one broadcast channel whereby the broadcast data can be distributed to more than one broadcast channel. In most cases, data items are broadcast over a single channel as it avoids additional issue of the organization of data and allocation while having more than one channel (Imielinski, Viswanathan, & Badrinath, 1997). Furthermore, the use of a single chan-

Figure 5. Example of on mobile querying broadcasted data



nel appears to be more problematic especially when there are a large number of data items to be broadcast, thus, with the adoption of multiple channels to broadcast data, the chance of reducing long delays before obtaining the desired data items can be achieved.

The next factor that could help reduce response time would be concerning the organization of the data items especially when retrieving multiple data items is required. An illustration of such a situation can be a mobile client wants to send a query to retrieve multiple stock prices concurrently. This is an example of multiple data items retrieval and in order to retrieve such query in a more efficient way, the need to consider the semantic relationship between the data items is required (Chung et al., 2001; Ren & Dunham, 2000). However, in order to predict which data item that the mobile client would be interested in next is difficult because there is not much knowledge of any future query that is available. Existing related work has investigated the use of access graphs to represent the dependency of the data items (Lee et al., 2002). Other existing algorithms that have been investigated to identify the most effective organization of the data items includes heuristics algorithm (Hurson et al., 2005) and randomized algorithm (Bar-Noy, Naor, & Schieber, 2000).

The last possible deciding factor for query response time can be determined by incorporating broadcast indexing scheme. Indexing scheme can reduce tuning time for the mobile client to access their required data item (Lee, Leong, & Si, 2002). By applying this scheme, mobile clients can conserve their battery life and thus, results in energy saving because the clients can switch to "doze" mode and back to "active" mode only when he or she knows the desired data item is about to arrive.

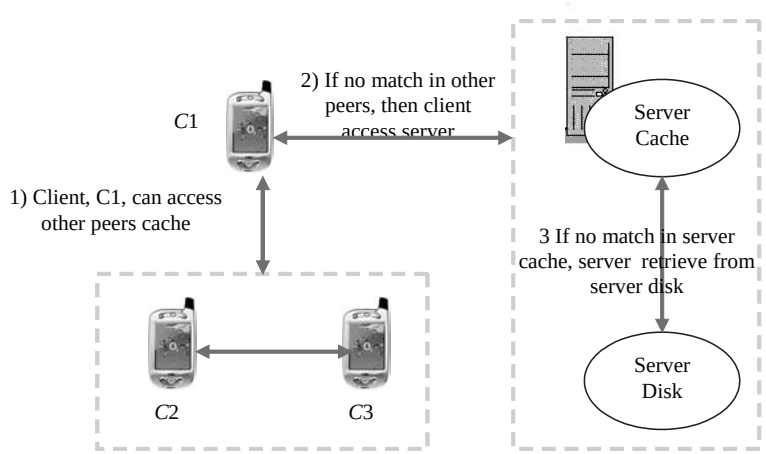
Although the on-air strategy appears to be more scalable in comparison to the server strategy, there are still limitations that it brings to the users because most users would find it easier to send a direct request to a specific server. In addition, since the data that are being broadcast are usually open to the public, there are privacy issues that may arise. Thus, if the mobile user wants to obtain private data, they would have to rely on the server strategy rather than the on-air strategy. Therefore, by being able to incorporate strategies that are able to accommodate the request of the users to bring it more flexibility like how server strategy does for the users maybe beneficial.

Case Study 3: Server Strategy and Client Strategy

Caching frequently accessed data in a client's local storage becomes prominent in improving the performance and data availability of data access queries (Chan, Si, & Leong, 1998). This is made available by caching the frequently accessed data items in the local mobile device storage as well as when frequent disconnection occurs, the query can still be partially processed from caches and at least some of the results from the previous queries can be returned to the users (Lee et al., 2002). This is because the mobile device is able to keep the existing data and if the user needs the same exact data, the downloading can be minimized if the mobile device recognizes that the data has been previously loaded into the device. Caching at the mobile client helps in relieving the low bandwidth constraints imposed in the mobile environment (Kara & Edwards, 2003). Issues that characterize the caching mechanism would include cache granularity, cache coherence, and cache replacement.

Figure 6 shows whenever a user issues a query, it first searches its cache and if a valid copy is found in the cache, it will return the results immediately. Otherwise it can also search the client's other local cache for the required results or it can be obtained either through the server or broadcast (on-air) strategy. Thus, it is often important to have cache management because often a user may download similar data repeatedly from the same source.

Figure 6. Example of on mobile querying with cache data



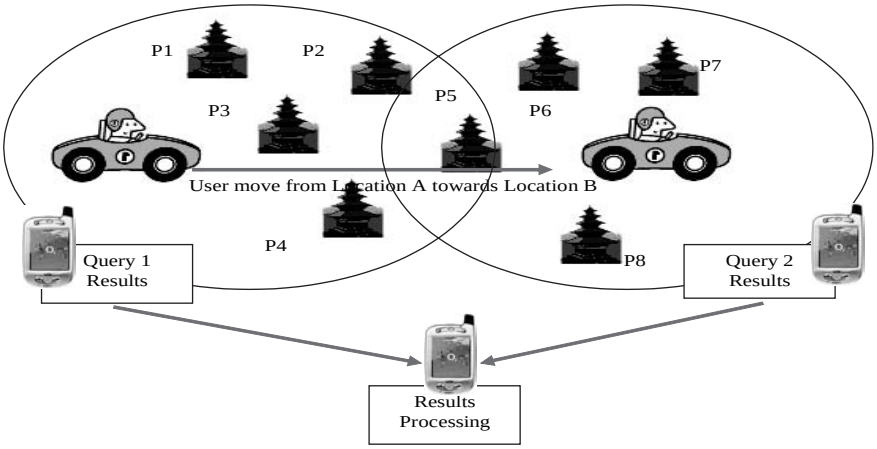
In general, the main limitation that limits the ability of having to cache everything on the mobile device mainly lies on the limited memory capacity. Therefore, one of the challenges that concerns the local cache memory is to exploit algorithms that can maximize the cache capacity to reduce the repeated transfer cost as much as possible and increase the respond time to the user's queries request. As we are concerned, the existing works on caching for mobile devices are still not sufficient for the new nomadic types of queries. A vast range of existing has been greatly being done on the issue of cache replacement and cache granularity and employing them into several possible cases in the real mobile environment situations. Index caching has been popular to save memory caching to improve query response time as well as managing space more efficiently, which is significant for location dependent queries. A few related works to this have also been done (Xu et al., 2003; Xu et al., 2004; Zheng et al., 2002). We also need to identify which mobile device has the request cache data that the other mobile users can access, as well as to make sure the cache data is still up to date before allowing the other interested users to access it (Elmargamid et al., 2003).

LOCATION DEPENDENT QUERY PROCESSING

Whenever a user moves from one location to another, the objects being queried can turn out to be different according to their geographical coordinates. Hence, location dependent plays an important role (Saltenis & Jensen, 2002; Sistla, Wolfson, Chamberlain, & Dao, 1997; Waluyo et al., 2005). It is important to show the mobile user, who is moving from one location to another location frequently, that the queries he or she sends, depends on the location that he or she is querying from.

Figure 7 shows that when a user is in location *A*, the query results are P1,P2, P3, P4, and P5, but as he or she moves toward location *B* and send the

Figure 7. Example of on mobile location dependent query processing



query again, the results now are P5, P6, P7, and P8. This shows that the change of user's query results are reflected by the change of the user's location. Basically with this, two query results that are obtained from Query 1 and Query 2 respectively, the user would like to process them together on the mobile device to obtain the just the desired data.

The main problem in this location dependent are the consistency problems that may arise, especially when the database is updated in the midst of processing a query. Furthermore, in order to ensure the shortest path, whereby we will first go for the server that stored the desired results, which can be obtained faster and easier or that can be obtained nearest to our current geographical coordinate compared to obtaining from another server. So, it is crucial to ensure the mobile users are able to obtain the shortest path to the desired destination. Some other issues would involve information processing when the results of the queries are obtained from different locations. We also need to learn how we are able to select the server to perform the query that is available from different locations so that we can answer the query more efficiently and correctly.

One important issue can be illustrated as follows. For instance, there are two locations, *A* and *B*. The user has a query in mind and based on the optimization in regards to the shorter path theory, the user will need to download information from location *B* and then send to location *A* for processing. But at the moment, the user is in location *A* and is going to location *B* soon. So, if following the optimization theory, this will require the user to first go to location *B* to download the desired data, and then move back to location *A* even though the current location of the user is now in *A*. In this method, there may arise a risk; maybe by the time the user goes to location *B*, the desired item is no longer available or there may have been network congestion and so on. If this occurs, the user would waste their time going to location *B* to get the desired data. Thus, we may need a different processing method where the user can start downloading from location *A* or just the partial key until the cache is full, and then when going to location *B*, send the request

to *B* to download the remaining items based on the key that is already in the cache.

For example, in Case Study 1, which involves querying to different servers that are utilizing the server strategy, it is obvious that in order to minimize the cost, we need to first download the list that has fewer records and then send it to the other server for matching. But if the location aspect is there, it might not be possible to choose which server to access first because it is dictated by the relative location. So this arises one important issue that needs to be looked at to what are the other aspect besides selecting servers that contain fewer records to be downloaded first.

Another example, based on Case Study 2, where we involve two servers in different locations, where the server in location *A* does not accept queries but the server in location *B* accepts queries. The issue may occur if the user is required to get the data from location *B* first, which accepts queries and then send to the server in location *A* that does not accept queries. This may create a problem because once we obtain the desired results from location *B* through sending a query to request the desired data, the results will then be sent to our mobile device. However, with this data, we are required to send to the server in location *A*, maybe to perform some comparison but that server does not accept queries, but only broadcasts data out to the mobile user. So our problem would be how can we then select another better technique that can reverse the situation so that we can get tune into the broadcast channel to get the data first and then only send the obtained data to the server to be process for the final results.

The last example based on Case Study 3 where caching is involved, a mobile user is currently in location *A* and wants to obtain data from location *A* before moving to location *B*. It might be a good idea while in location *A*, that the user requests the desired data from peer mobile users whether they have data from location *B* (maybe just partial), so that the user can "borrow" this data before having to personally go to location *B* to get those data. Or if they can only obtain location *B* data partially from the peer mobile user during their visit in location *A*, they can still benefit from less downloads transfer when they go to location *B* to obtain the desired data since they already have partial key, they can just request the exact information that is needed based on the partial key.

Existing related work has been done on computing the shortest path search by using compact exit hierarchy (CEH) and applying semantic location model (Lee et al., 2005), thus the issue is whether the method can be integrated into the situation when the need of combining the results with the other list of information are needed. Other previous work relates to investigating techniques in decreasing the access time and to also have the organizing time shorter especially when there are a number of updates at once and quick enough to respond to the users. Also being done in past research work about improving the consistency of data and response time for the mobile users in retrieving the required data. Since location dependent query deals with geographical coordinates of the mobile users, it is important to also look at minimizing movements of users. This refers to helping reduce the mobile user having to go back to the previous location to obtain additional data if he or she forgets when he or she was there before.

IMPLEMENTATION AND SYSTEM PROTOTYPE

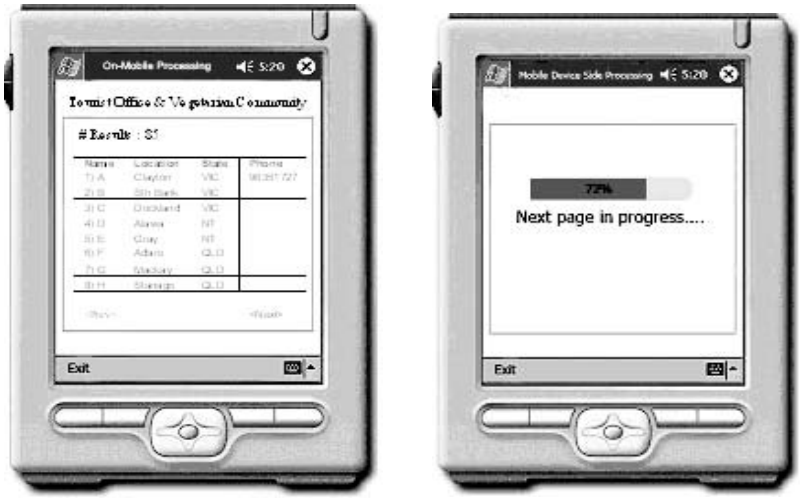
We have implemented our proposed methods on a mobile environment whereby the server and mobile device architecture consists of two desktop computers, which act as servers of two different locations, and a PDA as a mobile device, which wirelessly connects to both servers. Initially the PDA is connected to one server and requests the data from that server. When the PDA is moved, it requests data from the second server. In this environment, we have simulated location-based

query processing. The database in the servers uses MS SQL server, and both servers provides the mobile device with an access to the database. We use C# programming language within the .NET framework to program our proposed methods. Initially, the development is purely done at a desktop, and without involving the PDA. The testing was done using the Pocket PC emulator, which comes with the Visual Studio .Net. Once the testing is complete, the deployment is done by transferring down the executable from PC Emulator to the real PDA through the MS Active Sync, in which it copies not only the executable program, but also the visual .Net run time

In this section, we describe a query-processing prototype that involves multiple non-collaborative servers. This prototype is built on the idea from Example 1. Basically the prototype shows a sample interface design on how the final product would appear on the mobile user's PDA. Recalling Example 1, the mobile user is interested to know all vegetarian restaurants that are available in the country he or she is currently located. The mobile user is interested in obtaining recommendations from both servers, the tourist office and the vegetarian community servers. In this prototype design, we do not incorporate any location dependent processing and we assume that the current country (location) is Australia. Figure 8a models the final display on the PDA for the mobile user and Figure 8b models a sample screen shot of informing user the next page is being processing.

From this prototype, we can see that it only shows the basic features, which are the results in tabular format that is simple and straightforward. This can be a limitation especially when in today's world, multimedia has emerged as an important component in human interaction. A lot of people are demanding multimedia features now due to the vast benefits on what multimedia information can bring to the mobile users. Not only does the incorporation of multimedia elements enhance the appearance and make the information more

Figure 8. Final output of prototype design



a *b*

interesting, but it also gives a better interaction between the user and the device. For instance, a person who is blind may not read what is displayed on the PDA screen, but with the ability to incorporate multimedia feature, the results can be translated into "voice" talk instead of just displaying the results. This shows one importance on what multimedia information can bring around to the mobile users.

CONCLUSION AND FUTURE DIRECTION

In this article, we have presented possible applications that will be beneficial for information gathering from multiple non-collaborative sources. A brief taxonomy of the possible database operations involving multiple sources is also presented. We have also demonstrated not every server that is available in the wireless environment accepts direct queries from the users. There are some situations when the servers do not have the ability to accept direct queries and we need to process that data together with data that are obtained based on direct queries. As the wireless and mobile communication of mobile users has increased, location has become a very important constraint. A list of data obtained from different locations brings in different contents, and hence, there is a need to efficiently make these different lists of data into a single valuable piece of information for mobile users. All the issues and limitations have been outlined accordingly to where the lists of data are obtained via server, on-air, or client strategies. A sample prototype is being designed to demonstrate where the project may be applied in real life application.

Our future work is to further investigate the gathering processing techniques to further optimize the response and the data processing that is obtained from the non-collaborative servers. Since there are several issues that arise regardless of whether the lists are obtained from the server, on-air, or client strategy, they are difficult and very challenging to overcome. Thus, further investigation on choosing the right technique for each strategy according to situations should be done individually before processing several lists that are obtained from various strategies together. In addition, individually evaluating the best technique to obtain certain lists of data from each strategy should also be done to obtain the suitable technique. It is also beneficial to explore on the issues of scalability in terms of the servers that are needed to process together maintain the same efficiency or improve efficiency even though *n* servers are involved.

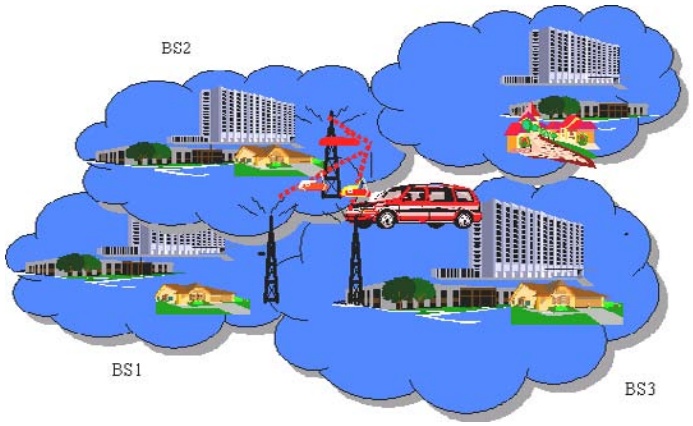
Chapter 7.41
A Bio-Inspired Approach for the Next Generation of Cellular Systems

Mostafa El-Said
Grand Valley State University, USA

INTRODUCTION

In the current 3G systems and the upcoming 4G wireless systems, *missing neighbor pilot* refers to the condition of receiving a high-level pilot signal from a Base Station (BS) that is not listed in the mobile receiver's neighbor list (LCC International, 2004; Agilent Technologies, 2005). This pilot signal interferes with the existing ongoing call, causing the call to be possibly dropped and

Figure 1. Missing pilot scenario



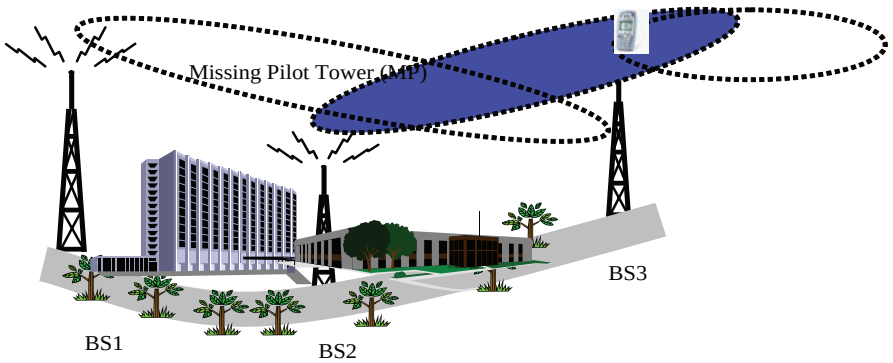
increasing the handoff call dropping probability. Figure 1 describes the missing pilot scenario where BS1 provides the highest pilot signal compared to BS1 and BS2's signals. Unfortunately, this pilot is not listed in the mobile user's active list.

The horizontal and vertical handoff algorithms are based on continuous measurements made by the user equipment (UE) on the Primary Scrambling Code of the Common Pilot Channel (CPICH). In *3G systems*, UE attempts to measure the quality of all received CPICH pilots using the Ec/Io and picks a dominant one from a cellular system (Chiung & Wu, 2001; El-Said, Kumar, & Elmaghraby, 2003). The UE interacts with any of the available radio access networks based on its memorization to the neighboring BSs. As the UE moves throughout the network, the serving BS must constantly update it with neighbor lists, which tell the UE which CPICH pilots it should be measuring for handoff purposes. In *4G systems*, CPICH pilots would be generated from any wireless system including the 3G systems (Bhashyam, Sayeed, & Aazhang, 2000). Due to the complex heterogeneity of the 4G radio access network environment, the UE is expected to suffer from various carrier interoperability problems. Among these problems, the missing neighbor pilot is considered to be the most dangerous one that faces the 4G industry.

The wireless industry responded to this problem by using an inefficient traditional solution relying on using antenna downtilt such as given in Figure 2. This solution requires shifting the antenna's radiation pattern using a mechanical adjustment, which is very expensive for the cellular carrier. In addition, this solution is permanent and is not adaptive to the cellular network status (Agilent Technologies, 2005; Metawave, 2005).

Therefore, a self-managing solution approach is necessary to solve this critical problem. Whisnant, Kalbarczyk, and Iyer (2003) introduced a system model for dynamically reconfiguring application software. Their model relies on considering the application's static structure and run-time behaviors to construct a workable version of reconfiguration software application. Self-managing applications are hard to test and validate because they increase systems complexity (Clancy, 2002). The ability to reconfigure a software application requires the ability to deploy

Figure 2. Missing pilot solution: Antenna downtilt



a dynamically hardware infrastructure in systems in general and in cellular systems in particular (Jann, Browning, & Burugula, 2003).

Konstantinou, Florissi, and Yemini (2002) presented an architecture called NESTOR to replace the current network management systems with another automated and software-controlled approach. The proposed system is inherently a rule-based management system that controls change propagation across model objects. Vincent and May (2005) presented a decentralized service discovery approach in mobile ad hoc networks. The proposed mechanism relies on distributing information about available services to the network neighborhood nodes using the analogy of an electrostatic field. Service requests are issued by any neighbor node and routed to the neighbor with the highest potential.

The autonomic computing system is a concept focused on adaptation to different situations caused by multiple systems or devices. The IBM Corporation recently initiated a public trail of its Autonomic Toolkit, which consists of multiple tools that can be used to create the framework of an autonomic management system. In this article, an autonomic engine system setting at the cellular base station nodes is developed to detect the missing neighbor (Ganek & Corbi, 2003; Haas, Droz, & Stiller, 2003; Melcher & Mitchell, 2004). The autonomic engine receives continuous feedback and performs adjustments to the cell system's neighboring set by requiring the UE to provide signal measurements to the serving BS tower (Long, 2001).

In this article, I decided to use this toolkit to build an autonomic rule-based solution to detect the existence of any missing pilot. The major advantage of using the IBM autonomic toolkit is providing a common system infrastructure for processing and classifying the RF data from multiple sources regardless of its original sources. This is a significant step towards creating a transparent autonomic high-speed physical layer in 4G systems.

PROPOSED SOLUTION

The proposed AMS relies on designing an autonomic high-speed physical layer in the smart UE and the BS node. *At the UE side,* continuous CPICH pilot measurements will be recorded and forwarded to the serving BS node via its radio interface. *At the BS node,* a scalable self-managing autonomic engine is developed using IBM's autonomic computing toolkit to facilitate the mobile handset's vertical/horizontal handover such as shown in Figure 3. The proposed engine is cable of interfacing the UE handset with different wireless technologies and detects the missing pilot if it is existed.

The autonomic engine relies on a generic log adapter (GLA), which is used to handle any raw measurements log file data and covert it into a standard format that can be understood by the autonomic manager. Without GLA, separate log adapters would have be coded for any system that the autonomic manager interfaced with. The BS node will then lump all of the raw data logs together and forward them to the Generic Log Adapter for data classification and restructuring to the common base event format. Once the GLA has parsed a record in real time to common base event format, the autonomic manager will see the record and process it and take any action necessary by notifying the BS node to make adjustments to avoid the missing pilot and enhance the UE devices' quality of service.

PERFORMANCE MEASUREMENTS AND KEY FINDINGS

To test the applicability of the proposed solution, we decided to use the system's response time, AS's service rate for callers experiencing missing pilot problem, and the performance gain as performance metrics. Also, we developed a Java class to simulate the output of a UE in a heterogeneous RF access network. Table 1 summarizes

Figure 3. Autonomic base station architecture

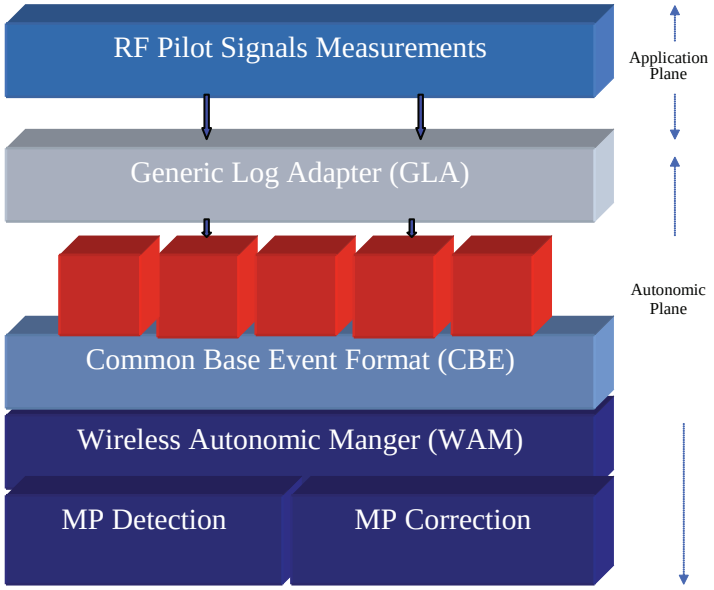


Table 1. Summary of the system performance analysis

	Log File Size in (# Records)	System Response Time in (Sec)	Processing Rate by the Base Station in (Records/Sec)
Trial Experiment 1	985	145	6.793103448
Trial Experiment 2	338	95	3.557894737
Trial Experiment 3	281	67	4.194029851
Trial Experiment 4	149	33	4.515151515
Average Processing Rate by the Base Station in (Records/Sec)	**4.765044888**		
Base Station Service Rate For callers experiencing missing pilot problem (Records/Sec)	**5.3**		
Performance Gain	**1.112266542**		

the simulation results for four simulation experiments with different log files size.

The results shown in Table 1 comply with the design requirements for the current 3G system. This is illustrated in the following simple example.

DESIGN REQUIREMENTS FOR 3G SYSTEMS

- The 3G cell tower's coverage area is divided into three sectors, with each sector having (8 traffic channel * 40 call/channel = 320 voice traffic per sector) and (2 control channels * 40 callers/channels = 80 control traffic per sector).
- The overlapped area between towers (hand-off zone) occupies 1/3 of the sector size and serves (1/3 of 320 = 106 callers (new callers and/or exciting ones)). If we consider having the UE report its status to the tower every 5 seconds, we could potentially generate 21.2 records in 1 second.
- It is practical to assume that 25% of the 21.2 reports/second accounts for those callers that may suffer from the missing pilot problem—that is, the tower's service rate for missing neighbor pilot callers is 21.2/4 = 5.3 records/second. This is the threshold level used by the tower to accommodate those callers suffering from the missing pilot problem.

ANALYSIS OF THE RESULTS

- Response time is the time taken by the BS to process, parse the incoming log file and detect the missing neighbor pilot. It is equal to (145, 95, 67, and 33) for the four experiment trials. All values are in seconds.
- Processing rate by the base station is defined as the total number of incoming records divided by the response time in (records/second). It is equal to (6.7, 3.5, 4.1, and 4.5) for the four experiment trials.
- The UE reports a missing pilot problem with an average rate of 4.7 records/second.
- The base station's service rate for callers experiencing the missing pilot problem = 5.3 records/second.
- The performance gain is defined as:

$$\frac{\text{Base Station Service Rate For callers experiencing missing pilot problem in (Records/Sec)}}{\text{Average Processing Rate by the Base Station in (Records/Sec)}}$$

$$= 5.3/4.7 = 1.1$$

- Here it is obvious that the service rate (5.3 records/second) is greater than the UE's reporting rate to the base station node (4.7 records/second). Therefore, the above results prove that the proposed solution does not overload the processing capabilities of the BS nodes and can be scaled up to handle a large volume of data.

FUTURE TRENDS

An effective solution for the interoperability issues in 4G wireless systems must rely on an adaptive and self-managing network infrastructure. Therefore, the proposed approach in this article can be scaled to maintain continuous user connectivity, better quality of service, improved robustness, and higher cost-effectiveness for network deployment.

CONCLUSION

In this article, we have developed an autonomic engine system setting at the cellular base station (BS) nodes to detect the missing neighbor. The autonomic engine receives continuous feedback and performs adjustments to the cell system's neighboring set by requiring the user equipment (UE) to provide signal measurements to the serving BS tower. The obtained results show that the proposed solution is able to detect the

missing pilot problem in any heterogeneous RF environment.

KEY TERMS

Adaptive Algorithm: Can "learn" and change its behavior by comparing the results of its actions with the goals that it is designed to achieve.

Autonomic Computing: An approach to self-managed computing systems with a minimum of human interference. The term derives from the body's autonomic nervous system, which controls key functions without conscious awareness or involvement.

Candidate Set: Depicts those base stations that are in transition into or out of the active set, depending on their power level compared to the threshold level.

Missing Neighbor Pilot: The condition of receiving a high-level pilot signal from a base sta-

tion (BS) that is not listed in the mobile receiver's neighbor list.

Neighbor Set: Represents the nearby serving base stations to a mobile receiver. The mobile receiver downloads an updated neighbor list from the current serving base station. Each base station or base station sector has a unique neighbor list.

Policy-Based Management: A method of managing system behavior or resources by setting "policies" (often in the form of "if-then" rules) that the system interprets.

Virtual Active Set: Includes those base stations (BSs) that are engaged in a live communication link with the mobile user; they generally do not exceed three base stations at a time.

Section VIII
Emerging Trends

This section highlights research potential within the field of mobile computing while exploring uncharted areas of study for the advancement of the discipline. Chapters within this section highlight evolutions in mobile services, frameworks, and interfaces. These contributions, which conclude this exhaustive, multi-volume set, provide emerging trends and suggestions for future research within this rapidly expanding discipline.

Chapter 8.1
Bridging Together Mobile and Service-Oriented Computing

Loreno Oliveira

Angelo Perkusich
Federal University of Campina Grande, Brazil

INTRODUCTION

The growing popularity of powerful *mobile devices*, such as modern cellular phones, smart phones, and PDAs, is enabling *pervasive computing* (Weiser, 1991) as the new paradigm for creating and interacting with computational systems. Pervasive computing is characterized by the interaction of mobile devices with embedded devices dispersed across *smart spaces*, and with other mobile devices on behalf of users. The interaction between user devices and smart spaces occurs primarily through services advertised on those environments. For instance, airports may offer a notification service, where the system registers the user flight at the check-in and keeps the user informed, for example, by means of messages, about flight schedule or any other relevant information.

In the context of smart spaces, *service-oriented computing* (Papazoglou & Georgakopoulos, 2003), in short SOC, stands out as the effective choice for advertising services to mobile devices (Zhu, Mutka, & Ni, 2005; Bellur & Narendra, 2005). SOC is a computing paradigm that has in services the essential elements for building applications. SOC is designed and deployed through *service-oriented architectures* (SOAs) and their applications. SOAs address the flexibility for dynamic binding of services, which applications

need to locate and execute a given operation in a pervasive computing environment. This feature is especially important due to the dynamics of smart spaces, where resources may exist anywhere and applications running on mobile clients must be able to find out and use them at runtime.

In this article, we discuss several issues on bridging mobile devices and service-oriented computing in the context of smart spaces. Since smart spaces make extensive use of services for interacting with personal mobile devices, they become the ideal scenario for discussing the issues for this integration. A brief introduction on SOC and SOA is also presented, as well as the main architectural approaches for creating SOC environments aimed at the use of resource-constrained mobile devices.

BACKGROUND

SOC is a distributed computing paradigm whose building blocks are distributed services. Services are self-contained software modules performing only pre-defined sets of tasks. SOC is implemented through the deployment of any software infrastructure that obeys its key features. Such features include loose coupling, implementation neutrality, and granularity, among others (Huhns & Singh, 2005). In this context, SOAs are software architectures complying with SOC features.

According to the basic model of SOA, service providers advertise service interfaces. Through such interfaces, providers hide from service clients the complexity behind using different and complex kinds of resources, such as databanks, specialized hardware (e.g., sensor networks), or even combinations of other services. Service providers announce their services in service registries. Clients can then query these registries about needed services. If the registry knows some provider of the required service, a reference for that provider is returned to the client, which uses this reference for contacting the service provider. Therefore, services must be described and published using some machine-understandable notation.

Different technologies may be used for conceiving SOAs such as grid services, Web services, and Jini, which follow the SOC concepts. Each SOA technology defines its own standard machineries for (1) service description, (2) message format, (3) message exchange protocol, and (4) service location.

In the context of pervasive computing, services are the essential elements of smart spaces. Services are used for interacting with mobile devices and therefore delivering personalized services for people. Owning to the great benefits that arise with the SOC paradigm, such as interoperability, dynamic service discovery, and reusability, there is a strong and increasing interest in making mobile devices capable of providing and consuming services over wireless networks (Chen, Zhang, & Zhou, 2005; Kalasapur, Kumar, & Shirazi, 2006; Kilanioti, Sotiropoulou, & Hadjiefthymiades, 2005). The dynamic discovery and invocation of services are essential to mobile applications, where the user context may change dynamically, making different kinds of services, or service implementations, adequate at different moments and places.

However, bridging mobile devices and SOAs requires analysis of some design issues, along with the fixing of diverse problems related to using resources and protocols primarily aimed at wired use, as discussed in the next sections.

INTEGRATING MOBILE DEVICES AND SOAS

Devices may assume three different roles in a SOA: service provider, service consumer, or service registry. In what follows, we examine the most representative high-level scenarios of how mobile devices work in each situation.

Consuming Services

The idea is to make available, in a wired infrastructure, a set of services that can be discovered and used by mobile devices. In this context, different designs can be adopted for bridging mobile devices and service providers. Two major architectural configurations can be derived and adapted to different contexts (Duda, Aleksy, & Butter, 2005): direct communication and proxy aided communication. In Figure 1 we illustrate the use of direct communication.

In this approach, applications running at the devices directly contact service registries and service providers. This approach assumes the usage of fat clients with considerable processing, storage, and networking capabilities. This is necessary because mobile clients need to run applications coupled with SOA-defined protocols, which may not be suited for usage by resource-constrained devices.

However, most portable devices are rather resource-constrained devices. Thus, considering running on mobile devices applications with significant requirements of processing and memory footprint reduces the range of possible client devices. This issue leads us to the next approach, proxy-aided communication, illustrated in Figure 2.

In this architectural variation, a proxy is introduced between the mobile device and the SOA infrastructure, playing the role of mobile device proxy in the wired network. This proxy interacts via SOA-defined protocols with registries and service providers, and may perform a series of content adaptations, returning to mobile devices results using lightweight protocols and data formats.

This approach has several advantages over the previous one. The proxy may act as a cache, storing data of previous service invocations as well as any client relevant information, such as bookmarks and profiles. Proxies may also help client devices by transforming complex data into lightweight formats that could be rapidly delivered through wireless channels and processed by resource-constrained devices.

Advertising Services

In a general way, mobile devices have two choices for advertising services (Loureiro et al., 2006): the push-based approach and the pull-based approach. In the first one, illustrated in Figure 3, service providers periodically send the descriptions of the services to be advertised directly to potential clients, even if they are not interested in such services (1). Clients update local registries with information about available services (2), and if some service is needed, clients query their own registries about available providers (3).

Figure 1. Direct communication between mobile client and SOA infrastructure

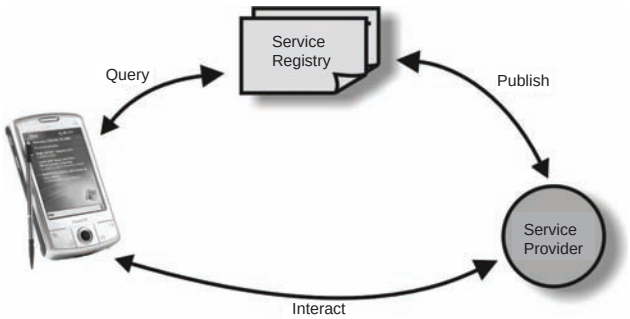

Figure 2. Proxy intermediating communication between mobile client and SOA

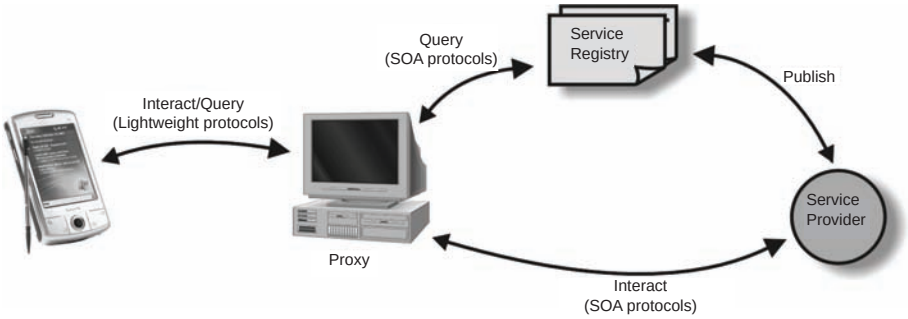

Figure 3. Push-based approach

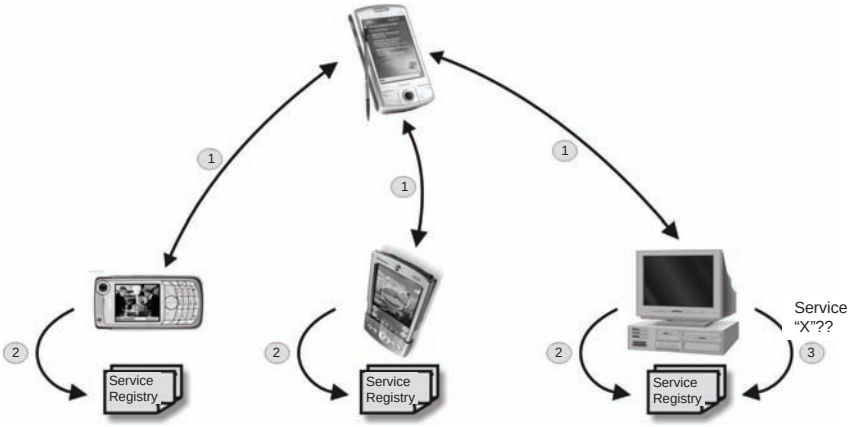

Figure 4. Pull-based approach with centralized registry

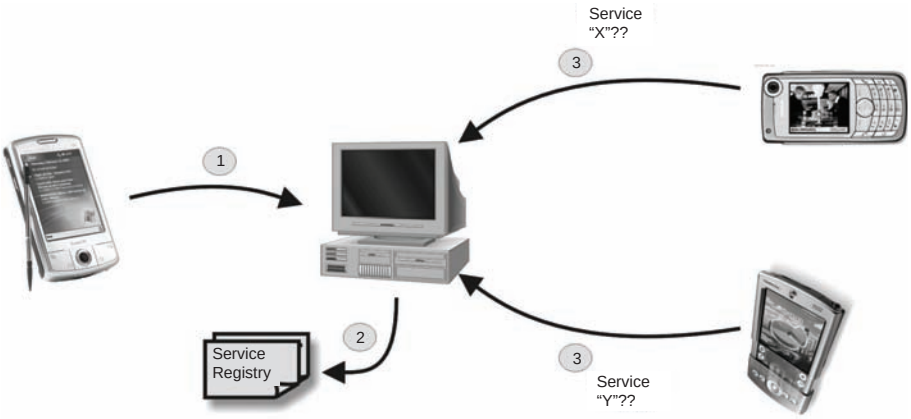

Figure 5. Pull-based approach with distributed registries

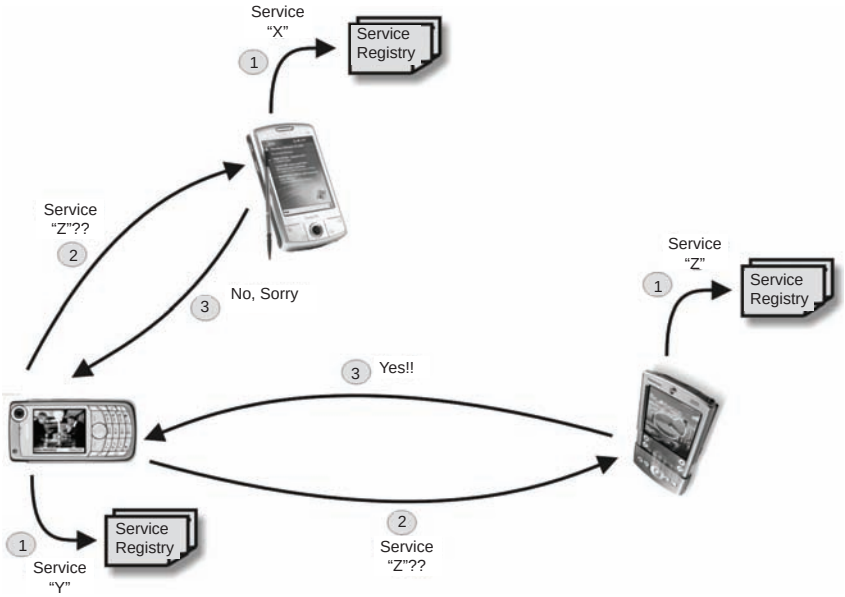

In the pull-based approach, clients only receive the description of services when they require a service discovery. This process can be performed in two ways, either through centralized or distributed registries. In the former, illustrated in Figure 4, service descriptions are published in central servers (1), which maintain entries about available services (2). Clients then query this centralized registry in order to discover the services they need (3).

In the distributed registry approach, illustrated in Figure 5, the advertisement is performed in a registry contained in each provider (1). Therefore, once a client needs to discover a service, it will have to query all the available hosts in the environment (2) until discovering some service provider for the needed service (3).

ISSUES ON INTEGRATING MOBILE DEVICES AND SOAs

Regardless of using mobile devices for either consuming or advertising services in SOAs, both *mobility* and the *limitations* of these devices are raised as the major issues for this integration. Designing and deploying effective services aimed at mobile devices requires careful analysis of diverse issues related to this kind of service provisioning.

Next, we depict several issues that arise when dealing with mobile devices in SOAs. This list is not exhaustive, but rather representative of the dimension of parameters that should be balanced when designing services for mobile use.

Suitability of Protocols and Data Formats

SOAs are primarily targeted at wired infrastructures. Conversely, small mobile devices are known by their well-documented limitations. Thus, protocols and formats used in conventional SOAs may be inadequate for use with resource-constrained wireless devices (Pilioura, Tsalgatidou, & Hadjiefthymiades, 2002; Kilanioti et al., 2005).

For instance, UDDI and SOAP are, respectively, standard protocols for service discovery and messaging in Web services-based SOAs. When using UDDI for service discovery, multiple costly network round trips are needed. In the same manner, SOAP messages are too large and require considerable memory footprint and CPU power for being parsed. Hence, these two protocols impact directly in the autonomy of battery-enabled devices.

Disconnected and Connected Services

In the scope of smart spaces, where disconnections are the norm rather than the exception, we can identify two kinds of services (Chen et at., 2005): disconnected and connected services. The first ones execute by caching the inputs of users in the local device. Once network connectivity is detected, the service performs some sort of synchronization. Services for messaging (e.g., e-mail and instant messages) and field research (e.g., gathering of data related to the selling of a specific product in different supermarkets) are some examples of services that can be implemented as disconnected ones.

Connected services, on the other hand, are those that can only execute when network connectivity is available in the device. Some examples of connected services include price checking, ordering, and shipment tracking. Note, however, that these services could certainly be implemented as disconnected services, although their users will generally need the information when demanded, neither before nor later. Therefore, there is no precise categorization of what kind of services would be connected or disconnected, as this decision is made by the system designer.

User Interface

User interfaces of small portable devices are rather limited in terms of screen size/resolution and input devices, normally touch screens or small built-in keyboards. This characteristic favors services that require low interaction to complete transactions (Pilioura et al., 2002). Services requiring many steps of data input, such as long forms, tend to: stress users, due to the use of non-comfortable input devices; reduce device autonomy, due to the extra time for typing data; and increase the cost of data transfer, due to larger amounts of data being transferred.

A possible alternative for reducing data typing by clients is the use of context-aware services (Patterson, Muntz, & Pancake, 2003). Context-aware services may reduce data input operations of mobile devices by inferring, or gathering through sensors, information about a user's current state and needs.

Frequent Temporary Disconnections

Temporary disconnections between mobile device and service provider are common due to user mobility. Thus, both client applications and service implementations must consider the design of mechanisms for dealing with frequent disconnections.

Different kinds of services require distinct solutions for dealing with disconnections. For instance, e-business applications need machineries for controlling state of transactions and data synchronization between mobile devices and service providers (Sairamesh, Goh, Stanoi, Padmanabhan, & Li, 2004). Conversely, streaming service requires seamless reestablishment and

transference of sessions between access points as the user moves (Cui, Nahrstedt, & Xu, 2004).

Security and Privacy

Normally, mobile devices are not shared among different users. Enterprises may benefit from this characteristic for authenticating employees, for instance. That is, the system knows the user and his/her access and execution rights based on profiles stored in his/her mobile devices. However, in commercial applications targeted at a large number of unknown users, this generates a need of anonymity and privacy of consumers. This authentication process could cause problems, for example in case of device thefts, because the device is authenticated and not the user (Tatli, Stegemann, & Lucks, 2005).

Security also has special relevance when coping with wireless networks (Grosche & Knospe, 2002). When using wireless interfaces for information exchange, mobile devices allow any device in range, equipped with the same wireless technology, to receive the transferred data. At application layer, service providers must protect themselves from opening the system to untrusted clients, while clients must protect themselves from exchanging personal information with service providers that can use user data for purposes different than the ones implicit in the service definition.

Device Heterogeneity and Content Adaptation

Modern mobile devices are quite different in terms of display sizes, resolutions, and color capabilities. This requires services to offer data suitable for the display of different sorts of devices. Mobile devices also differ in terms of processing capabilities and wireless technologies, which makes harder the task of releasing adequate data and helper applications to quite different devices.

Therefore, platform-neutral data formats stand out as the ideal choice for serving heterogeneous sets of client devices. Another possible approach consists of using on-demand data adaptation. Service providers may store only one kind of best-suited data format and transform the data, for example, using a computational grid (Hingne, Joshi, Finin, Kargupta, & Houstis, 2003), when necessary to transfer the data to client devices. Moreover, dynamic changes of conditions may also require dynamic content adaptation in order to maintain pre-defined QoS threshold values. For instance, users watching streamed video may prefer to dynamically reduce video quality due to temporary network congestion, therefore adapting video data, and to maintain a continuous playback instead of maintaining quality and experiencing constant playback freezing (Cui et al., 2004).

Consuming Services

As discussed before, system architects can choose between two major approaches for accessing services of SOAs from mobile devices: direct communication and proxy-aided communication. The two approaches have some features and limitations that should be addressed in order to deploy functional services. Direct communication suffers from the limitations of mobile devices and relates to other discussions presented in this article, such as adequacy of protocols and data formats for mobile devices and user interface.

If, on the one hand, proxy-aided communication seems to be the solution for problems of the previous approach, on the other hand it also brings its own issues. Probably the most noted is that proxies are single points of failures.

Furthermore, some challenges related to wired SOAs are also applicable to both approaches discussed. Service discovery and execution need to be automated to bring transparency and pervasiveness to the service usage. Moreover, especially in the context of smart spaces, services need to be personalized according to the current user

profile, needs, and context. Achieving this goal may require describing the semantics of services, as well as modeling and capturing the context of the user (Chen, Finin, & Joshi, 2003).

Advertising Services

A number of issues and technical challenges are associated with this scenario. The push-based approach tends to consume a lot of bandwidth of wireless links according to the number of devices in range, which implies a bigger burden over mobile devices.

Using centralized registries creates a single point of failure. If the registry becomes unreachable, it will not be possible to advertise and discover services. In the same manner, the discovery process is the main problem with the approach of distributed registries, as it needs to be well designed in order to allow clients to query all the hosts in the environment.

Regardless of using centralized or distributed registries, another issue rises with mobility of service providers. When service providers move between access points, a new address is obtained. This changing of address makes service providers inaccessible by clients that query the registry where it published its services. Mechanisms for updating the registry references must be provided in order for services to continue to be offered to their requestors.

FUTURE TRENDS

The broad list of issues presented in this article gives suggestions about future directions for integrating SOC and mobile devices. Each item depicted in the previous section is already an area of intensive research. Despite this, both SOC and mobile computing still lack really functional and mature solutions for the problems presented.

In particular, the fields of context-aware services and security stand out as present and future hot research fields. Besides, the evolution itself of mobile devices towards instruments with improved processing and networking power, as well as better user interfaces, will reduce the complexity of diverse challenges presented in this article.

CONCLUSION

In this article we have discussed several issues related to the integration of mobile devices and SOC. We have presented the most representative architectural designs for integrating mobile devices to SOAs, both as service providers and service consumers.

While providing means for effective integration of mobile devices and service providers, SOC has been leveraging fields such as mobile commerce and pervasive computing. Nonetheless, several issues remain open, requiring extra efforts for designing and deploying truly functional services.

KEY TERMS

Grid Service: A kind of Web service. Grid services extend the notion of Web services through the adding of concepts such as statefull services.

Jini: Java-based technology for implementing SOAs. Jini provides an infrastructure for delivering services in a network

Mobile Device: Any low-sized portable device used to interact with other mobile devices and resources from smart spaces. Examples of mobile devices are cellular phones, smart phones, PDAs, notebooks, and tablet PCs.

Proxy: A network entity that acts on behalf of another entity. A proxy's role varies since data

relays to the provision of value-added services, such as on-demand data adaptation.

Streaming Service: One of a number of services that transmit some sort of real-time data flow. Examples of streaming services include audio streaming or digital video broadcast (DVB).

Web Service: Popular technology for implementing SOAs built over Web technologies, such as XML, SOAP, and HTTP.

Chapter 8.2
Context-Awareness and Mobile Devices

Anind K. Dey
Carnegie Mellon University, USA

Jonna Häkkilä
Nokia Research Center, Finland

ABSTRACT

Context-awareness is a maturing area within the field of ubiquitous computing. It is particularly relevant to the growing sub-field of mobile computing as a user's context changes more rapidly when a user is mobile, and interacts with more devices and people in a greater number of locations. In this chapter, we present a definition of context and context-awareness and describe its importance to human-computer interaction and mobile computing. We describe some of the difficulties in building context-aware applications and the solutions that have arisen to address these. Despite these solutions, users have difficulties in using and adopting mobile context-aware applications. We discuss these difficulties and present a set of eight design guidelines that can aid application designers in producing more usable and useful mobile context-aware applications.

INTRODUCTION

Over the past decade, there has been a widespread adoption of mobile phones and personal digital assistants (PDAs) all over the world. Economies of scale both for the devices and the supporting infrastructure have enabled billions of mobile devices to become affordable and accessible to large groups of users. Mobile computing is a fully realized phenomenon of everyday life and is the first computing platform that is truly ubiquitous. Technical enhancements in mobile computing, such as component miniaturization, enhanced computing power, and improvements in supporting infrastructure have enabled the creation of more versatile, powerful, and sophisticated mobile devices. Both industrial organizations and academic researchers, recognizing the powerful combination of a vast user population and a sophisticated computing platform, have focused tremendous effort on improving and enhancing the experience of using a mobile device.

Since its introducion in the mid-1980s, the sophistication of mobile devices in terms of the numbers and types of services they can provide has increased many times over. However, at the same time, the support for accepting input from users and presenting output to users has remained relatively impoverished. This has resulted in slow interaction, with elongated navigation paths and key press sequences to input information. The use of predictive typing allowed for more fluid interaction, but mobile devices were still limited to using information provided by the user and the device's service provider. Over the past few years, improvements to mobile devices and back-end infrastructure has allowed for additional information to be used as input to mobile devices and services. In particular, context, or information about the user, the user's environment and the device's context of use, can be leveraged to expand the level of input to mobile devices and support more efficient interaction with a mobile device. More and more, researchers are looking to make devices and services *context-aware*, or adaptable in response to a user's changing context.

In this chapter, we will define context-awareness and describe its importance to human-computer interaction and mobile devices. We will describe some of the difficulties that researchers have had in building context-aware applications and solutions that have arisen to address these. We will also discuss some of the difficulties users have in using context-aware applications and will present a set of design guidelines that indicate how mobile context-aware applications can be designed to address or avoid these difficulties.

What is Context-Awareness

The concept of context-aware computing was introduced in Mark Weiser's seminal paper 'The Computer for the 21st Century' (Weiser, 1991). He describes ubiquitous computing as a phenomenon '*that takes into account the natural human environment and allows the computers themselves to vanish into the background*.' He also shapes the fundamental concepts of context-aware computing, with computers that are able to capture and retrieve context-based information and offer seamless interaction to support the user's current tasks, and with each computer being able to *'adapt its behavior in significant ways'* to the captured context.

Schilit and Theimer (1994a) first introduce the term *context-aware computing* in 1994 and define it as software that "adapts according to its location of use, the collection of nearby people and objects, as well as changes to those objects over time." We prefer a more general definition of context and context-awareness:

Context is any information that can be used to characterize the situation of an entity. An entity is a person, place or object that is considered relevant to the interaction between a user and an application, including the user and applications themselves, and by extension, the environment the user and applications are embedded in. A system is context-aware if it uses context to provide relevant information and/or services to the user, where relevancy depends on the user's task. (Dey, 2001)

Context-aware features include using context to:

- Present information and services to a user
- Automatically execute a service for a user and
- Tag information to support later retrieval

In supporting these features, context-aware applications can utilize numerous different kinds of information sources. Often, this information comes from sensors, whether they are software sensors detecting information about the networked, or virtual, world, or hardware sensors detecting information about the physical world. Sensor data can be used to recognize the usage situation for instance from illumination, temperature, noise level, and device movements (Gellersen, Schmidt & Beigl, 2002; Mäntyjärvi &

Seppänen, 2002). Typically, sensors are attached to a device and an application on the device locally performs the data analysis, context-recognition, and context-aware service.

Location is the most commonly used piece of context information, and several different location detection techniques have been utilized in context-awareness research. Global positioning system (GPS) is a commonly used technology when outdoors, utilized, for example, in car navigation systems. Network cellular ID can be used to determine location with mobile phones. Measuring the relative signal strengths of Bluetooth and WLAN hotspots and using the hotspots as beacons are frequently used techniques for outdoors and indoors positioning (Aalto, Göthlin,Korhonen et al., 2004; Burrell & Gay, 2002; Persson et al., 2003). Other methods used indoors include ultrasonic or infrared-based location detection (Abowd et al., 1997; Borriello et al., 2005).

Other commonly used forms of context are time of day, day of week, identity of the user, proximity to other devices and people, and actions of the user (Dey, Salber & Abowd, 2001; Osbakk & Rydgren, 2005). Context-aware device behavior may not rely purely on the physical environment. While sensors have been used to directly provide this physical context information, sensor data often needs to be interpreted to aid in the understanding of the user's goals. Information about a user's goals, preferences, and social context can be used for determining context-aware device behavior as well. Knowledge about a user's goals helps prioritize the device actions and select the most relevant information sources. A user's personal preferences can offer useful information for profiling or personalizing services or refining information retrieval. The user may also have preferences about quality of service issues such as cost-efficiency, data connection speed, and reliability, which relate closely to mobile connectivity issues dealing with handovers and alternative data transfer mediums. Finally, social context forms an important type of context as mobile devices are commonly used to support communication between two people and used in the presence of other people.

Relevance to HCI

When people speak and interact with each other, they naturally leverage their knowledge about the context around them to improve and streamline the interaction. But, when people interact with computers, the computing devices are usually quite ignorant of the user's context of use. As the use of context essentially expands the conversational bandwidth between the user and her application, context is extremely relevant to human-computer interaction (HCI). Context is useful for making interaction more efficient by not forcing users to explicitly enter information about their context. It is useful for improving interactions as context-aware applications and devices can offer more customized and more appropriate services than those that do not use context. While there have been no studies of context-aware applications to validate that they have this ability, anecdotally, it is clear that having more information about users, their environments, what they have done and what they want to do, is valuable to applications. This is true in network file systems that cache most recently used files to speed up later retrieval of those files, as well as in tour guides that provide additional information about a place of interest the user is next to.

Relevance to Mobile HCI

Context is particularly relevant in mobile computing. When users are mobile, their context of use changes much more rapidly than when they are stationary and tied to a desktop computing platform. For example, as people move, their location changes, the devices and people they interact with changes more frequently, and their goals and needs change. Mobility provides additional opportunities for leveraging context but also requires additional context to try and understand how the user's goals are changing. This places extra burden on the mobile computing platform, as it needs to sense potentially rapidly changing context, synthesize it and act upon it. In the next section, we will discuss the difficulties that application builders have had with building

context-aware applications and solutions that have arisen to address these difficulties.

BUILDING MOBILE CONTEXT-AWARE APPLICATIONS

The first context-aware applications were centered on mobility. The Active Badge location system used infrared-based badges and sensors to determine the location of workers in an indoor location (Want et al., 1992). A receptionist could use this information to route a phone call to the location of the person being called, rather than forwarding the phone call to an empty office. Similarly, individuals could locate others to arrange impromptu meetings. Schilit, Adams and Want,(1994b) also use an infrared-based cellular network to location people and devices, the PARCTAB, and describe 4 different types of applications built with it (Schilit et al., 1994b). This includes:

- **Proximate selection:** Nearby objects like printers are emphasized to be easier to select than other similar objects that are further away from the user;
- **Contextual information and commands:** Information presented to a user or commands parameterized and executed for a user depend on the user's context;
- **Automatic contextual reconfiguration:** Software is automatically reconfigured to support a user's context; and
- **Context-triggered actions:** If-then rules are used to specify what actions to take based on a user's context.

Since these initial context-aware applications, a number of common mobile context-aware applications have been built: tour guides (Abowd et al., 1997; Cheverst et al. 2000; Cheverst, Mitchell & Davies, 2001), reminder systems (Dey & Abowd, 2000; Lamming & Flynn, 1994) and environmental controllers (Elrod et al., 1993; Mozer et al., 1995). Despite the number of people building (and re-building) these applications, the design and implementation of a new context-aware application required significant effort, as there was no reusable support for building context-aware applications. In particular, the problems that developers faced are:

- Context often comes from non-traditional devices that developers have little experience with, unlike the mouse and keyboard.
- Raw sensor data is often not directly useful to an application, so the data must be abstracted to turn it into useful context.
- Context comes from multiple distributed and heterogeneous sources, and this context often needs to be combined (or fused) to be useful. This process often results in uncertainty that needs to be handled by the application.
- Context is, by its very nature, dynamic, and changes to it must be detected in real time and applications must adjust to these constant changes in order to provide a positive user experience to users.

These problems resulted in developers building every new application from scratch, with little reuse of code or design ideas between applications.

Over the past five years or so, there has been a large number of research projects aimed at addressing these issues, most often trying to produce a reusable toolkit or infrastructure that makes the design of context-aware applications easier and more efficient. Our work, the Context Toolkit, used a number of abstractions to ease the building of applications. One abstraction, the context widget is similar to a graphical user interface widget in that it abstracts the source of an input and only deals with the information the source produces. For example, a location widget could receive input from someone manually entering information, a GPS device, or an infrared positioning system, but an application using a location widget does not have to deal with the details of the underlying sensing technology, only with the information the sensor produces: identity of the object being located, its location and the time when the object was located. Context interpreters support the

interpretation, inference and fusion of context. Context aggregators collect all context-related to a specific location, object or person for easy access. With these three abstractions, along with a discovery system to locate and use the abstractions, an application developer no longer needs to deal with common difficulties in acquiring context and making it useful for an application, and instead can focus on how the particular application she is building can leverage the available context. Other similar architectures include JCAF (Bardram, 2005), SOCAM (Gu, Pung & Zhang, 2004), and CoBRA (Chen et al., 2004).

While these architectures make mobile context-aware applications easier to build, they do not address all problems. Outstanding problems needing support in generalized toolkits include representing and querying context using a common ontology, algorithms for fusing heterogeneous context together, dealing with uncertainty, and inference techniques for deriving higher level forms of context such as human intent. Despite these issues, these toolkits have supported and continue to support the development of a great number of context-aware applications. So, now that we can more easily build context-aware applications, we still need to address how to design and build *usable* mobile context-aware applications. We discuss this issue in the following section.

USABILITY OF MOBILE CONTEXT-AWARE APPLICATIONS

With context information being provided as implicit input to applications and with those applications using this context to infer human intent, there are greater usability concerns than with standard applications that are not context-aware. Bellotti and Edwards discuss the need for context-aware applications to be *intelligible*, where the inferences made and actions being taken are made available to end-users (Bellotti & Edwards, 2001). Without this intelligibility, users of context-aware applications would not be able to decide what actions or responses to take themselves (Dourish, 1997).

To ground our understanding of these abstract concerns, we studied the usability and usefulness of a variety of context-aware applications (Barkhuus & Dey, 2003a; 2003b). We described a number of real and hypothetical context-aware applications and asked subjects to provide daily reports on how they would have used each application each day, whether they thought the applications would be useful, and what reservations they had about using each application. All users were given the same set of applications, but users were split into three groups with each group being given applications with a different level of proactivity. One group was given applications that they would personalize to determine what the application should do for them. Another group was provided with information about how their context was changing, and the users themselves decided how to change the application behavior. The final group was evaluating applications that autonomously changed their behavior based on changing context. Additional information was also gathered from exit interviews conducted with subjects.

Users indicated that they would use and prefer applications that had higher degrees of proactivity. However, as the level of proactivity increased, users had increasing feelings that they were losing control. While these findings might seem contradictory, it should be considered that owning a mobile phone constitutes some lack of control as the user can be contacted anywhere and at anytime; the user may have less control but is willing to bear this cost in exchange for a more interactive and smoother everyday experience. Beyond this issue of control, users had other concerns with regards to the usability of context-aware applications. They were concerned by the lack of feedback, or intelligibility, that the applications provided. Particularly for the more proactive versions of applications, users were unclear how they would know that the application was performing some action for them, what action was being performed, and why this action was being performed. A third concern was privacy. Users were quite concerned that the context data that was being used on mobile platforms could

be used by service providers and other entities to track their location and behaviors. A final concern that users had was related to them evaluating multiple context-aware applications. With potentially multiple applications vying for a user's attention, users had concerns about information overload. Particularly when mobile and focusing on some other task, it could be quite annoying to have multiple applications on the mobile device interrupting and requesting the user's attention simultaneously or even serially.

In the remainder of this chapter, we will discuss issues for designing context-aware applications that address usability concerns such as these.

Support for Interaction Design

Despite all of the active research in the field of context-aware computing, much work needs to be done to make context-awareness applications an integral part of everyday life. As context-awareness is still a very young field, it does not have established design practices that take into account its special characteristics. The development of applications has so far been done primarily in research groups that focus more on proof-of-concept and short-term use rather than deployable, long-term systems. For most of these applications, the interaction design has rarely been refined to a level that is required for usable and deployable applications. Particularly for applications aimed at consumers and the marketplace, robustness, reliability and usability must be treated more critically than they are currently, as these factors will have a significant impact on their success.

Currently, the lack of existing high-quality, commercial, and publicly available applications limits our ability to assess and refine the best practices in interaction design of context-aware mobile applications. As there is very little experience with real-life use of these applications, the ability of developers to compare and iterate on different design solutions is very restricted. As user groups for a particular application mostly do not exist yet, much of the current research is based on hypothesized or simulated systems rather that actualized use situations. Knowledge of what device features people fancy and which they just tolerate, and when application features become insignificant or annoying, are issues that are hard to anticipate without studies of long-term real-life usage.

As with any other novel technology, bringing it to the marketplace will bring new challenges. Bringing context-awareness to mobile devices as an additional feature may lead to situations where the interaction design is performed by people with little experience in context-aware computing. Using well-established commercial platforms such as mobile phones or PDAs often means that user interface designers only have experience with conventional mobile user interfaces. On the other hand, the technical specifications of an application are often provided by people who have no expertise in human-computer interaction issues. When entering a field that involves interdisciplinary elements, such as mobile context-awareness, providing tools and appropriate background information for designers helps them to recognize the risks and special requirements of the technology.

Hence, there are several factors which make examining context-awareness from the usability and interaction design perspective relevant. Failures in these may lead not only to unprofitable products, but may result in an overall negative effect—they may slow down or prevent the underlying technology from penetrating into mass markets.

Usability Risks for Mobile Context-Aware Applications

A system and its functionality are often described with mental models that people form from using the system. According to Norman (1990), one can distinguish between the designer's mental model and the user's mental model. The designer's model represents the designer's understanding and idea of the artefact being constructed, whereas the user's model is the user's conceptual model of the same artefact, its features and functionality, which has developed through her interaction with the system. In order to respond to the user's

needs, efficiently fulfil the user's goals and satisfy the user's expectations, the designer's and user's understanding of the device or application should be consistent with each other, in other words, the user's model and designer's model should be the same (Norman, 1990).

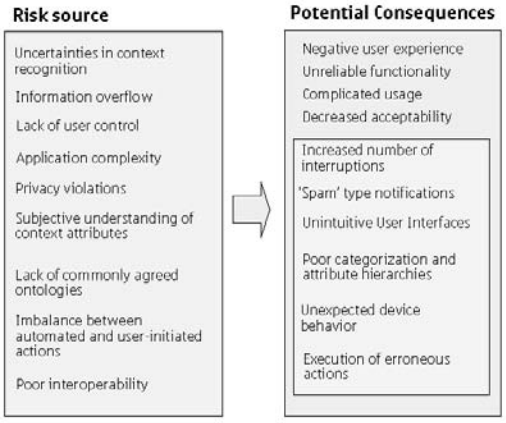
To ensure the best possible result, the mental models of different stakeholders in application development and use have to meet each other. First, the mental models of the application's technical designer and user interface designer should be consistent. This means that the user interface designer should have a basic understanding of the special characteristics of context-aware technology. Second, the designer's and user's mental models of the application should be the same. People's perception of context may differ significantly from each other, and both attributes and the measures used to describe context may vary greatly (Hiltunen, Häkkilä & Tuomela, 2005; Mäntyjärvi et al., 2003). The relationship between the designer's and the user's mental models should be checked with user tests several times during the design process. Without this careful design, there are two significant usability risks that may result: users will be unable to explain the behavior of the context-aware application, nor predict how the system will respond given some user action. While this is true of all interactive systems, it is especially important to consider for context-aware systems as the input to such systems is often implicit.

Context-awareness has several characteristics that can be problematic in interaction design. Figure 1 summarizes potential usability risks with context-aware applications.

A fundamental cause of potential usability risks is *uncertainty in context recognition*, which can be due to different reasons, such as detection accuracy, information fusion, or inferring logic. This is a key issue for designing the user interface for a mobile context-aware application, as it affects the selected features, their functionality and accuracy. In practice, features such as the proactivity level may be designed differently if the confidence level in context recognition can be estimated correctly. Uncertainty is a part of the nature of context-aware applications. Thus, it is important that the application and UI designers share a common understanding of the matter and take it into account when designing both the application and its user interface.

Application complexity has a tendency to grow when functions are added and it forms a potential risk for context-aware applications, as they use a greater number of information sources than

Figure 1. Sources of usability risks and their potential consequences related to context-aware mobile applications. Consequences that are unique to context-aware mobile applications are in the smaller rectangle on the right.



traditional mobile applications. Hiding the complex nature of the technology while maintaining a sufficient level of feedback and transparency so that the user can still make sense of the actions the device is performing (i.e., intelligibility) is a challenging issue. Here, the involvement of user-centric design principles is emphasized. Usability testing and user studies performed in an authentic environment combined with iterative design are key elements to producing well-performing user interface solutions.

Poor interoperability of services and applications relates to the absence of standardization in this maturing field and it limits the application design, available services, and seamless interaction desired across a wide selection of devices and users. Interoperability issues have gained much attention with the current trend of mobile convergence, where different mobile devices resemble each other more and more, yet providing services for them must be performed on a case-by-case basis.

Subjective understanding of context attributes creates a problem for user interface design, as the measures, such as the light intensity or noise level in everyday life are not commonly understood by end-users in terms of luxes or decibels but in relative terms such as 'dark,' 'bright,' 'silent' or 'loud.' This issue is connected to the *lack of commonly agreed ontologies*, which would guide the development of context-aware applications. The difficulties in categorizing context attributes and modeling context is evident from the literature (Hiltunen, Häkkilä & Tuomela, 2005; Mäntyjärvi et al., 2003).

As indicated earlier, *privacy violations* are possible with mobile context-aware systems collecting, sharing and using a tremendous amount of personal information about a user. When such information is shared with a number of different services, each of which will be contacting the user, *information overflow* often results. One can imagine a potential flow of incoming advertisements when entering a busy shopping street, if every shop within a radius of one hundred meters was to send an advertisement to the device. Information overflow is particularly a problem for the small screens that are typical with handheld devices.

As our earlier studies illustrated, the *lack of user control* can easily occur with mobile device automation, when context-triggered actions are executed proactively. However, the promise of context-awareness is that it provides "ease of use" by taking over actions that the user does not want to do or did not think to do for themselves. Any solution for correcting the *imbalance between the set of automated actions and user-initiated actions*, must take user control into account.

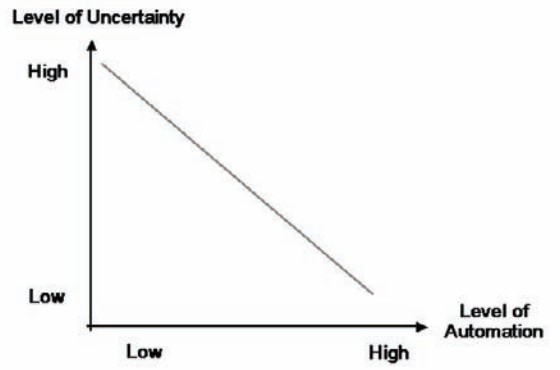
The consequences resulting from these usability risks are numerous. The general outcome can be a negative user experience. This may result from an increased number of interruptions, spam, and the execution of erroneous or otherwise unintuitive device behavior. Unreliable device functionality, and unintelligible user interfaces can lead to reduced acceptability of context-aware applications in the marketplace.

Design Guidelines for Mobile Context-Aware Applications

Context-awareness typically contains more risks than conventional, non-context-aware technology. At the same time, context-awareness can offer much added value to the user. In order to provide this value to end-users and avoid these negative design consequences and minimize usability risks, we have sought to provide a set of design guidelines that can offer practical help for designers who are involved in developing context-aware mobile applications (Häkkilä & Mäntyjärvi, 2006). These general guidelines have been validated in a series of user studies (Häkkilä & Mäntyjärvi, 2006) and should be taken into account when selecting the features of the application and during the overall design process.

GL1. Select appropriate level of automation. A fundamental factor with context-awareness is that it incorporates uncertainty. Uncertainty in context-recognition is caused by several different sources, such as detection accuracy, information fusion, or inferring logic. This is a key issue in designing user interfaces, as it affects the selected

Figure 2. How uncertainty in context-recognition should affect the selected level of automation/proactivity



features, their functionality and accuracy. In practice, features such as the automation level or level of proactivity may be designed differently if the confidence level of context recognition can be estimated correctly. The relationship between uncertainty and selected application automation level is illustrated in Figure 2. As shown in Figure 1, *uncertainties in context recognition* create significant usability risks, however, by selecting an appropriate level of automation, an application designer can acknowledge this fact and address it appropriately. The greater the uncertainty is in the context-recognition, the more important it is not to automate actions. The automation level has also a direct relationship with user control, and its selection has a large impact on the number of expected interruptions the system creates for the user. The level of automation must be considered in relation to the overall application design, as it affects numerous issues in the user interface design.

GL 2. Ensure user control. The user has to maintain the feeling that he is in the control over the device. The user, who normally has full control over his mobile device, has voluntarily given some of it back to the device in order to increase the ease of use of the device. To address this *lack of user control*, an important usability risk, the user must be able to take control of the device and context-aware application at any time. The desire to take control can happen in two basic circumstances—either the device is performing erroneous actions and the user wants to take a correcting action, or the user just wishes to feel in control (a feeling that users often have). The user has to have enough knowledge of the context-aware application and the device functionality in order to recognize malfunctioning behavior, at least in the case where context-recognition errors lead to critical and potentially unexpected actions. The perception of user control is diminished if the device behaves in unexpected manner or if the user has a feeling that the device is performing actions without him knowing it. User control can be implemented, for example, with confirmation dialogues however, this must be balanced with the need to minimize unnecessary interruptions, our next guideline.

GL3. Avoid unnecessary interruptions. Every time the user is interrupted, she is distracted from the currently active task, impacting her performance and satisfaction with the system. In most cases, the interruption leads to negative consequences, however if the system thinks that the interruption will provide high value or benefit to the user, allowing the interruption is often seen as positive. Examples of this are reminders and alarm clocks. The user's interruptibility depends on her context and the user's threshold for putting up with intrusion varies with each individual and her situation. Some context-aware functionality is so important that the user may want the application

to override all other ongoing tasks. This leads to a tension between avoiding unnecessary interruptions and supporting user control (GL2).

GL4. Avoid information overflow. The throughput of the information channel to each user is limited, and users can fully focus only on a small number of tasks at one time. In order to address the usability risk of *information overflow* where several different tasks or events compete for this channel, a priority ordering needs to be defined. Also, the threshold for determining the incoming event's relevancy in the context must be considered in order to avoid unnecessary interruptions (GL3). Systems should not present too much information at once, and should implement filtering techniques for to avoid messages that may appear to be spam to users. Also, information should be arranged in a meaningful manner to maintain and maximize the understandability of the system.

GL 5. Appropriate visibility level of system status. The visibility level of what the system is doing has to be sufficient for the user to be aware of the application's actions. While this guideline has been co-opted from Nielsen and Molich's user interface heuristics (1990), it has special meaning in context-aware computing. The implicit nature of context-awareness and natural *complexity of these types of applications* means that users may not be aware of changes in context, system reasoning or system action. When uncertainty in context-awareness is involved, there must be greater visibility of system state in order to allow the user to recognize the risk level and possible malfunctions. Important actions or changes in context should also be made visible and easily understandable for the user, despite the fact that users may have *subjective understandings of context attributes* and that there may be *no established ontology.* System status need not be overwhelming and interrupting to the user but can be provided in an ambient or peripheral fashion, where information is dynamically made more visible as the importance value grows, and may eventually lead to an interruption event to the user if its value is high enough.

GL 6. Personalization for individual needs. Context-awareness should allow a device or application to respond better to the individual user's personal needs. For instance, an application can implement filtering of interruptions according to the user's personal preferences. Personalization may also be used to improve the subjective understanding of context attributes. Allowing the user to name or change context attributes, such as location names or temperature limits, may contribute to better user satisfaction and ease of use. User preferences may change over time, and their representation in the application can be adjusted, for example implicitly with learning techniques or explicitly with user input settings.

GL 7. Secure user's privacy. *Privacy* is a central theme with personal devices, especially with devices focused on supporting personal communication, and impacts, for example trust, frequency of use, and application acceptability. Special care should be taken with applications that employ context sharing. Privacy requirements often vary between who is requesting the information, the perceived value of the information being requested and what information is being requested, so different levels of privacy should be supported. If necessary, users should have the ability to easily specify that they wish to remain anonymous with no context shared with other entities.

GL 8. Take into account the impact of social context. The social impact of a context-aware application taking an action must be part of the consideration in deciding whether to take the action or not. The application and its behavior reflects on users themselves. In some social contexts, certain device or user behavior may be considered awkward or even unacceptable. In such situations, there must be an appropriate *balance of user-initiated and system-initiated actions.* Social context has also has an effect on interruptibility. For example, an audible alert may be considered as inappropriate device behavior in some social contexts.

Once an application has been designed with these guidelines, the application must still be

evaluated to ensure that the usability risks that have been identified for mobile context-aware systems have been addressed. This evaluation can take place in the lab, but is much more useful when conducted under real, *in situ*, conditions.

SUMMARY

Context-aware mobile applications, applications that can detect their users' situations and adapt their behavior in appropriate ways, are an important new form of mobile computing. Context-awareness has been used to overcome the deficit of the traditional problems of small screen sizes and limited input functionalities of mobile devices, to offer shortcuts to situationally-relevant device functions, and to provide location sensitive device actions and personalized mobile services.

Context-awareness as a research field has grown rapidly during recent years, concentrating on topics such as context-recognition, location-awareness, and novel application concepts. Several toolkits for enabling building context-aware research systems have been introduced. Despite their existence, there exist very few commercial or publicly available applications utilizing context-awareness. However, the multitude of research activities in mobile context-awareness allow us to make reasonable assumptions about tomorrow's potential applications. For example, navigation aids, tour guides, location-sensitive and context-sensitive notifications and reminders, automated annotation and sharing of photographs, use of metadata for file annotation, sharing or search are topics which frequently appear in the research literature and will likely be relevant in the future. In addition, using context-awareness to address the needs of special user groups, for example in the area of healthcare also appears to be a rich area to explore.

Despite the active research in context-awareness, there is much that remains to be addressed in interaction design and usability issues for context-aware mobile applications. Due the novelty of the field and lack of existing commercial applications, design practices for producing usable and useful user interfaces have not yet evolved, and end-users' experiences with the technology are not always positive. We have presented a set of 8 design guidelines which have been validated and evaluated in a series of user studies, which point to areas where user interface designers must focus efforts in order to address the usability issues that are commonly found with mobile context-aware applications.

While context-aware applications certainly have more usability risks than traditional mobile applications, the potential benefits they offer to end-users are great. It is important that application designers and user interface designers understand each other's perspectives and the unique opportunities and pitfalls that context-aware systems have to offer. With context-aware applications, careful application and interface design must be emphasized. The consequences resulting from usability risks include an overall negative user experience. Unsuccessful application design may result in diminished user control, increased number of interruptions, spam, and the execution of erroneous device actions or otherwise unintuitive behaviour. Unreliable device functionality and an unintuitive user interface can lead to decreased acceptability of the context-aware features in the marketplace.

In this chapter we have discussed the notion of context-awareness and its relevance to both mobile computing and interaction design in mobile computing. We have described technical issues involved in building context-aware applications and the toolkits that have been built to address these issues. Despite the existence of these toolkits in making context-aware applications easier to build, there are several additional issues that must be addressed in order to make mobile context-aware applications usable and acceptable to end-users. We have presented a number of design guidelines that can aid the designers of mobile context-aware applications in producing applications with both novel and useful functionality for these end-users.

KEY TERMS

Context: Any information that can be used to characterize the situation of an entity. An entity is a person, place or object that is considered relevant to the interaction between a user and an application, including the user and applications themselves, and by extension, the environment the user and applications are embedded in.

Context-Awareness: A system is context-aware if it uses context to provide relevant information and/or services to the user, where relevancy depends on the user's task.

Design Guidelines: Guidelines or principles that, when followed, can improve the design and usability of a system.

Interaction Design: The design of the user interface and other mechanism that support the user's interaction with a system, including providing input and receiving output.

Mobile Context-Awareness: Context-awareness for systems or situations where the user and her devices are mobile. Mobility is particularly relevant for context-awareness as the user's context changes more rapidly when mobile.

Usability Risks: Risks that result from the use of a particular technology (in this case, context-awareness) that impact the usability of a system.

ABSTRACT

Mobile computing is associated with mobility of hardware, data and software in computer applications. With growing mobile users, dynamicity in catering of mobile services becomes and important issue. Polices define the overall behavior of the system. Policy based approaches are very dynamic in nature because the events are triggered dynamically through policies, thereby suiting mobile applications. Much of the existing architectures fail to address important issues such as dynamicity in providing service, Service Level provisioning, policy based QoS and security aspects in mobile systems. In this chapter we propose policy based architectures and test results catering to different needs of mobile computing

INTRODUCTION

Policies are rules that govern the overall functioning of the system. *Policy computing* is used in a variety of areas. *Mobile computing*, with its ever-expanding networks and ever-growing number of users, needs to effectively implement a policy-based approach to enhance data communication. This can result in increasing customer satisfaction as well as efficient mobile network management.

POLICY COMPUTING AND NEED FOR POLICY-BASED MOBILE COMPUTING

Policies in society and organizations are often captured and enforced as laws, rules, procedures, contracts, agreements, and memorandums. Policies are rules that govern the choices of system

behavior. A policy is defined as "a definite goal, course or method of action to guide and determine present and future decisions." Security policies define what actions are permitted or not permitted, for what or for whom, and under what conditions. Management policies define what actions need to be carried out when specific events occur within a system or what resources must be allocated under specific conditions. They are widely used for the mobile user whose requirements are dynamic.

Policy-based computing is the art of using policy-based approaches for effective and efficient computing; it is widely used because of its dynamicity. Hence in areas such as mobile computing, policy computing can be effectively used.

Much of the existing network systems' are configured statically (Fankhauser, Schweikert, & Plattner, 1999). In the present-day scenario, the number of mobile/wireless network users increases day by day. With the static systems being deployed, it is very difficult to achieve the needed dynamicity for mobile computing resulting from changing user base. In order to achieve efficient communication for fluctuating user base, policy-based systems need to be implemented in different areas of the existing wireless mobile network infrastructure.

POLICY IN MOBILE COMPUTING

Mobile computing is conducted by intermittently connected users who access network resources that need to escalate with increasing computing needs. Mobile computing has expanded the role of broadcast radio in data communication, and with increasing users, providing quality service becomes a challenging issue. The mobile users must be provided with the best possible service so that the service provider can stay in competition with peer service providers. In order for the best possible service to be provided to the mobile users, there are certain criteria that should be met. They are:

- The quality of service should be guaranteed.
- There should be effective service-level agreement (SLA) between the mobile user and the service provider.
- Security should be foolproof.

With the existing system (without a policy-based approach), it becomes very difficult to achieve the mentioned criteria. It is very difficult to provide a guaranteed quality of service (QoS), which is also dynamic (not statically configured). Moreover SLA is a very static procedure. Because of the mobility and dynamicity of mobile networks, SLAs also must be made very dynamic. Similarly, security should also be made very dynamic and efficient. To overcome all these shortcomings of the existing system, *a policy-based approach should be used in mobile networks.*

Policy computing can be effectively implemented in mobile networks using policy compilers. Policies can be written in different ways. There are different languages for writing policies that are used for different purposes of specifying policies. In order that the "security policies" be specified, languages such as Trust Policy Language (TPL), LaSCO, and so forth are used. In a similar way, for specifying management-related policies, languages such as Ponder, Policy Maker, and so forth are used. Thus for different scopes of application of policies, specific languages are used.

Policy validation checks a solution's conformance to the policy file. The actual process of policy validation has three primary stages. First, a node or hierarchy change event in Solution Explorer (such as add, drag, or delete event) begins the validation process. Then the validation process maps items discovered in the solution (such as files, references, classes, or interface definitions) to a corresponding Template Description Lan-

guage (TDL) policy ELEMENT node. Finally, for recognized ELEMENT nodes, the validation process checks the parent ELEMENT for policy compatibility with the child ELEMENT. When the policies are compatible, the validation process applies any ELEMENT-specific policy.

APPLICATIONS OF POLICY COMPUTING

Policy-based management is an over-arching technology for an automated management of networks (Lewis, 1996). Policy-based management is being adopted widely for different domains like quality of service, wireless networks, service-level agreement, virtual private networks (VPNs), network security, and IP address allocation. Therefore policy-based networking configures and controls the various operational characteristics of a network as a whole, providing the network operator with a simplified, logically centralized, and automated control over the entire network. In a wireless/mobile network, events are user and time based. These events are very dynamic in nature in order to provide the best service to the mobile users and also to maximize the profit of the service provider. But most of the existing systems are very static in nature. With the static systems being deployed, it is very difficult to achieve the needed dynamicity for mobile computing. In order to achieve this, policy-based systems need to be implemented in different areas of the existing wireless mobile network infrastructure such as QoS in wireless networks (especially differentiated networks), security, and SLAs.

Policy-Based Architecture for Security

Some of the key issues involved in providing services for wireless networks are (Sivanandam, Santosh Rao, Pradeep, & Rajeev, 2003):

1. **Bandwidth Cost:** Depending upon the number of users connected, the location (e.g., urban or remote), and the type of service (e.g., video, audio, etc.) being offered, dynamic allocation of bandwidth plays an important role.
2. **Limited Memory:** Today's wireless device places constraints on the amount of data that it can hold. Moreover, this limit depends upon the device being used and hence causes greater concern with low memory devices.
3. **Access Cost:** Optimizing the cost (Boertien, Janssen, & Middelkoop, 2001) of accessing and transferring data is more complex in wireless networks than in wired networks. If the number of servers used by a service or the number of services provided by an enterprise increases, then maintaining service consistency would turn out to be a cost factor in itself.
4. **Scalability Requirements:** These requirements force the service provider to think in terms of developing a solution that would support increasing and decreasing the number of services offered by the enterprise.

These constraints adversely affect the process of implementation of wireless/mobile services over the existing architecture. To overcome this, an identity management architecture for a wireless differentiated service schema that could be implemented using LDAP (lightweight directory access protocol) (Hodges & Morgan, 2002), directory structures are constructed.

Policy Warehouse

The concept of differentiated services entitles the maintenance of a large amount of information pertaining to the user (e.g., user names, passwords, services registered, premium amount, etc.) and an efficient quick access mechanism to retrieve the relevant details. This overhead increases when

it comes to wireless services. Here, the policy warehouse acts as the information backbone of the service provisioning system. The service provisioning engine contacts the policy warehouse whenever the service provider forwards to it a request from the user, after the right user has been authenticated.

1. **Id-Synch and P-Synch:** The synchronization of user identities and passwords pertaining to a single user is highly crucial in providing a hassle-free connection to services that require subscription to external back-end service providers. This architecture uses Id-Synch and P-Synch mechanisms for identity synchronization and password synchronization respectively.
2. **Meta Directories:** In general, service providers need to maintain a global user profile to uniquely identify a user over the various services provided to him. This information, which mainly comprises a collection of information pertaining to the user sign-on details of various services, is stored in meta directories. This profile makes it easy for the service provisions engine to authenticate the user. The architecture has a provision of compiling as well as retrieving meta directory information.
3. **LDAP Access Engine and Directory Structures:** Information pertaining to the user is stored in lightweight directory structures that can be retrieved using the LDAP. Directory structures are used to store user information because they provide a systematic mechanism for organizing data under a common head like user profiles, user services, user privileges, and so forth that are organized in a hierarchical manner on multiple workstations that are distributed over a network. This not only makes data retrieval fast, querying complexity less, and volume of data storage minimum, but it also makes easy implementation of policies that depend on the enterprise using the system.

The LDAP engine acts as an interface between the various servers like Id-Synch and P-Synch, and directories like meta directories and the underlying LDAP directory structures. They process the request for data from the higher layers and hand over the appropriate data to the requested application in the required format.

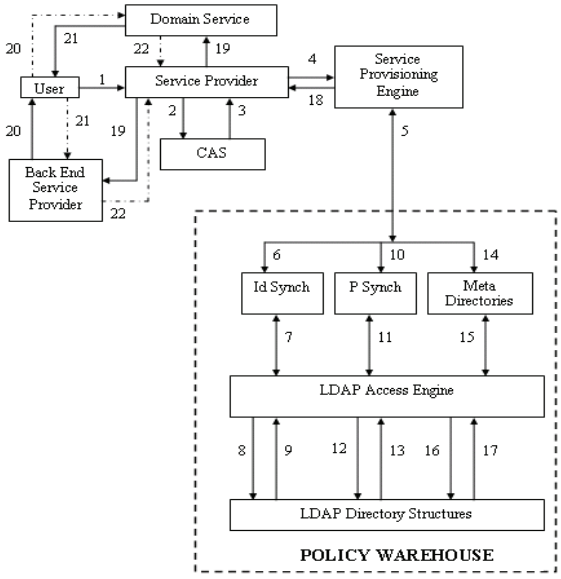
The LDAP directory services are part of the directory-enabled network services (DEN) that provide standard APIs for the access of network objects.

Service Provisioning Mechanism

The service provisioning system can be generally viewed in the following stages:

- **User Login:** In this stage, the user sends his details like User Name, Password, and Chip Index Number to the service provider for authentication.
- **Service Provider:** The Service Provider has to perform the following two actions on a service request:
  1. **Authentication:** The authentication is accomplished using the DSAP (distributed substring authentication protocol) (Sivanandam et al., 2003). This is done by fragmenting the user details into sub-strings and distributing them over a network which is monitored by a central authentication system. When the user is required to authenticate, the protocol fetches the appropriate sub-strings from the network and compares them to the user input. A match signifies a valid user. After this stage, the appropriate user policy is fetched from the policy warehouse using the service provisioning engine.

Figure 1. Policy-based provisioning



2. **Providing the Service:** This is the last step of the service provisioning. In this stage, the actual service that the user has requested is granted. The service could be from a back-end service provider or from the main service provider. This detail is an abstraction to the user who undertakes all transactions with the main service provider only. When the user disconnects from the service, intimation is sent to both the back-end service provider and to the main service provider. This has two implications: firstly, the main service provider's load is shared by the back-end service provider, and secondly, the intimation during the connection termination ensures that the main service provider gets the appropriate usage details. This can act as verification of the details that the back-end service provider will submit later.

Policy Based Architecture for QoS

The interface to the network device and the information models required for specifying policies are either standardized or being standardized in IETF and DMTF. An architecture for a policy-based QoS management system for Diffserv-based wireless networks, which are based on COPS for interfacing with the network device and on LDAP for interfacing with a directory server for storing policies, is constructed. The Diffserv policies are installed based on role combination assigned to the network device interfaces. The directory access could become a bottleneck in scaling the performance of the policy server, and it can be improved substantially by employing appropriate policy caching mechanisms. The framework considers various QoS parameters in the wireless network and proposes the policy-based architecture for QoS management in wireless networks.

Wireless Network QoS Parameters

The wireless/mobile network is affected by the following QoS parameters:

- **High Loss Rate:** Wireless/mobile networks are characterized by more frequent packet losses because of fading effects. The scheduler may think that a certain DSCP is being satisfied with the required number of packets scheduled, but the receiver is not receiving the packets at the required rate. It will be useful to have feedback from the receiver so that some compensation techniques can be employed. The base station (BS) can better handle compensation of lost bandwidth using this information.
- **Battery Power Constraints:** Current mobile battery technology does not allow more than a few hours of continuous mobile operation. Two of the major consumers of power in a mobile network are the network interface (14%) and the CPU/memory (21%). There-

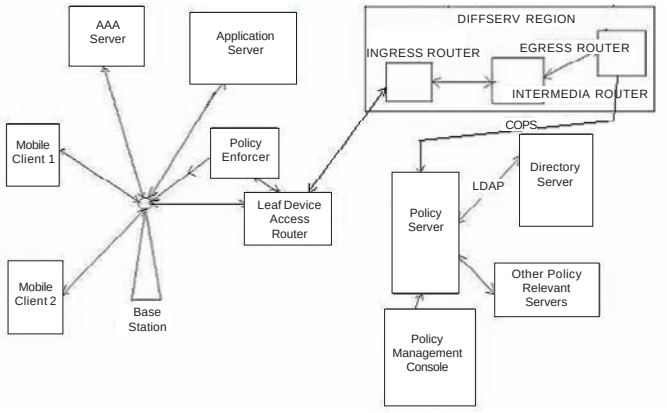
fore, network protocols should be designed to be more energy efficient (Agrawal, Chen, & Sivalingam, 1999). The mobile device can use the signaling mechanism to periodically send messages about its power level to the BS. The BS can then use this information to dynamically decide packet scheduling, packet dropping, and so forth.

- **Classification of Packets within a Flow:** Present Diffserv (Chan, Sahita, Hahn, & McCloghrie, 2003) mechanisms treat all packets within a flow identically. Even though a distinction can be made between packets as in-profile or out-of-profile, all in-profile packets are treated the same way. In many situations (e.g., while using layered video), it may be necessary to distinguish packets within a flow. This is because some packets from a flow level could be more important than the others, and a local condition like power level may lead to different treatments of these packets. Thus, the packets within a flow must be made distinguishable, and bits in the TOS field may be used for this purpose. To summarize, the various possible factors needed to make the Diffserv architecture suitable for wireless networks were discussed in this section.
- **Low Bandwidth:** Wireless networks available today are mostly low bandwidth systems. Most of the current LANs operate at 2 Mbps with migration up to 11 Mbps available. However, the available wireless LAN bandwidth is still an order of magnitude less than the typical wired LAN bandwidth of 100 Mbps. This leads to two decisions. First, the signaling protocol should be very simple and highly scalable. It is also better to modify an existing protocol for compatibility with other existing network protocols. Second, the mobile should not be swamped with too much data from a wired sender with higher network bandwidth. This can be handled to a large extent by transport protocol control, but the problem can be alleviated by handling it partially at the base station. Therefore, mechanisms may be used at the BS to send data to the mobile devices based on current conditions such as channel condition, bandwidth available, and so forth.

Policy-Based QoS

The IETF Resource Allocation Protocol (RAP) working group has defined, among other standards, the policy-based admission control framework, and the common open policy service (COPS) protocol and its extension—COPS for provisioning (COPS-PR). COPS is a simple query protocol that facilitates communication between the policy clients and remote policy server(s). Two policy control models have been defined: outsourcing and provisioning. While COPS supports the outsourcing model, its extension COPS-PR integrates both the outsourcing and provisioning models. The outsourcing model is tailored to signaling protocols such as the resource *r*eser*v*ation *p*rotocol (RSVP) (Braden, Zhang, Berson, Herzog, & Jamin, 1997), which requires traffic management on a per-flow basis. On the other hand, the provisioning or configuration model is used to control aggregate traffic-handling mechanisms such as the Differentiated Services (Diffserv) architecture. In the outsourcing model, when the PEP receives an event (e.g., RSVP reservation request) that requires a new policy decision, it sends a request (REQ) message to the remote policy decision point (PDP). The PDP then makes a decision and sends a decision (DEC) message (e.g., accept or reject) back to the PEP. The outsourcing model is thus PEP driven and involves a direct 1:1 relation between PEP events and PDP decisions. On the other hand, the provisioning or configurations model (Chan et al., 2001) makes no assumptions of such direct one-to-one correlation between PEP events and PDP decisions. The PDP may proactively provision the PEP reacting to external

Figure 2. Policy-based management system architecture



events, PEP events, and any combination thereof (N: M correlation). Provisioning thus tends to be PDP driven and may be performed in bulk (e.g., entire router QoS configuration) or in portions (e.g., updating a Diffserv marking filter).

Architecture of a Policy-Based Management System for a Diffserv-Based Wireless Network

Figure 2 illustrates the architecture of the policy-based management system for Diffserv-based wireless networks. The policy server is responsible for interpreting higher-level policies and translating them into device-specific commands for realizing those policies. For allocating resources on inter-domain links and for implementing SLAs, the policy server (especially the bandwidth broker component) has to communicate with the policy server in the provider.

The policy server is mainly responsible for the following:

- retrieving relevant policies created by the network administrator through the policy console after resolving any conflicts with existing policies;
- translating the policies relevant for each PEP into the corresponding policy information base (PIB) commands;
- arriving at policy decisions from relevant policies for policy decision requests, and maintaining those decision states; and
- taking appropriate actions such as deletion of existing decision states or modification of installed traffic control parameters in the PEP for any modifications to currently installed policies.

All the policies are stored in the LDAP server. The policy editor (PE) is the entity responsible for creating, modifying, or deleting policy rules or entries in the LDAP server. LDAP protocol provides access to directories supporting the X.500 models, while not incurring the resource requirements of the X.500 directory access protocol (DAP). It is specifically targeted at management applications and browser applications that provide read/write interactive access to directories. It does not have the mechanism to notify policy consumers of changes in the LDAP server. Therefore, it is the responsibility of the policy editor to indicate the changes in the LDAP server, as and when required, using an internal event messaging service. The

policy server, in addition to querying the LDAP server, queries other policy-relevant servers such as Certificate server, Time server, and so on.

The policy management client—also referred to as the policy editor—provides a high-level user interface, for operator input translates this input into the proper schema for storage in the directory server and pushes it out to the directory for storage. The authentication, authorization, and accounting (AAA) server is responsible for authentication, authorization, and accounting of the user after the relevant policies have been picked and enforced in the policy enforcers (routers). This AAA server is used by the base station to check if the user is authenticated and authorized for the resource he requests, and to check if he is accounted. The policy enforcer nearer to the base station enforces the policy decisions taken from the policy server. The base station then requests the nearest application server (after policies are enforced) and waits for the response from the application server.

The base station first sends the request to the leaf access router, which then sends it to the ingress router in the region. The ingress router then passes on the requests to the intermediate router. The request passes through the other intermediate routers and reaches the egress router, which sends the request to the policy server through COPS.

Policy-Based Architecture for SLA

Mobile ad hoc networks (MANETs) are autonomous networks operating either in isolation or as "stub networks" connecting to a fixed infrastructure. Depending on the nodes' geographical positions, transceiver coverage patterns, transmission power levels, and co-channel interference levels, a network can be formed and unformed on the fly. Ad hoc networks have found a growing number of applications: wearable computing, disaster management/relief and other emergency operations, rapidly deployable military battle-site networks, and sensor fields, to name a few. The main characteristics of ad hoc networks are:

- **Dynamic Topological Changes:** Nodes are free to move about arbitrarily. Thus, the network topology may change randomly and rapidly over unpredictable times.
- **Bandwidth Constraints:** Wireless links have significantly lower capacity than wired links. Due to the effects such as multiple accesses, multi-path fading, noise, and signal interference, the capacity of a wireless link can be degraded over time and the effective throughput may be less than the radio's maximum transmission capacity.
- **Multi-Hop Communications:** Due to signal propagation characteristics of wireless transceivers, ad hoc networks require the support of multi-hop communications; that is, mobile nodes that cannot reach the destination node directly will need to relay their messages through other nodes.
- **Limited Security:** Mobile wireless networks are generally more vulnerable to security threats than wired networks. The increased possibility of eavesdropping, spoofing, and denial-of-service (DoS) attacks should be carefully considered when an ad hoc wireless network system is designed.
- **Energy Constrained Nodes:** Mobile nodes rely on batteries for proper operation. As an ad hoc network consists of several nodes, depletion of batteries in these nodes will have a great influence on overall network performance. Therefore, one of the most important protocol design factors is related to device energy conservation.

To support mobile computing in ad hoc wireless networks, a mobile host must be able to communicate with other mobile hosts that may not lie within its radio transmission range. Therefore in order for one mobile host in the ad hoc network

to communicate with the other not lying in its transmission range, some other hosts in its transmission range should route the packets from the source to the destination host. The conventional routing protocols used in wired networks cannot be effectively used in ad hoc networks. Hence new routing mechanisms are suggested which may be used for routing in ad hoc networks. Routing issues in ad hoc networks are beyond the scope of this chapter and are not considered here.

Since many mobile hosts may be within transmission range of each other, there may be multiple routes for a packet to reach a destination. Therefore the source host should decide which route to use to send the packets to reach its destination. Obviously, the sending host has to decide on the best optimal route before sending its packets towards the destination. Thus, there should be a service level agreement between the source mobile host and the host which routes the packets to the destination host. Moreover there are certain constraints based on the characteristics of the ad hoc network which play a major role in deciding which route is optimal, given there are more routes to reach the destination.

Architectural Framework of the Policy-Based Mobile Ad Hoc Network

MANET is a collection of mobile hosts forming a temporary network without the aid of any centralized administration or standard support services. The architecture for the policy-based SLAs in ad hoc networks is given below. The architecture is designed where at least one host has connectivity with the wired network. In the architecture shown in Figure 3, the policy server is placed in the wired network. Polices are stored in the directory server. The ad hoc 'host1' is within the vicinity of both 'host2' and 'host3'. 'Host4' is not within the transmission region of 'host1'. So when 'host1' wants to send a packet to 'host4', intermediatory hosts, 'host2' and 'host3', help 'host1' with connection establishment.

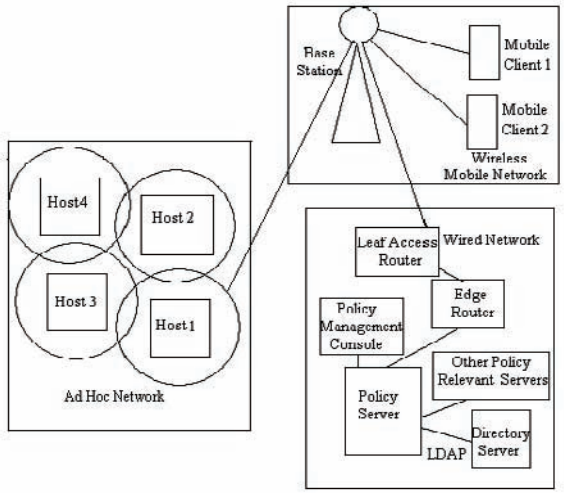
Assuming that both the host services satisfy the constraints of 'host1', 'host1' must choose a service level agreement among the two. In this case since 'host1' is connected to a base station, which in turn is connected to the wired network having the policy server, 'host1' can query the policy server through the base station and then the leaf access router and edge router. For simplicity we have shown the policy server being connected to the base station through only a few hops. But in practice it may be many hops away from it. Once the request reaches the policy server, it takes appropriate policies from the directory server through the LDAP.

The policy server also communicates with other relevant policy servers such as Time Servers, Certificate Servers, and AAA servers, and validates the host providing service by means of certificates and AAA. The policy server makes the decision on whether the host providing the service is an authenticated one, and his services are authorized with accountability and certificates. Then the policy server based on the higher level polices stored in the directory server chooses an agreement among the available agreements. The decision to choose an agreement from among the available ones may be done giving more weight to those performance metrics which affect the overall performance the most. Over a period of time, the history of the hosts providing the service will be stored; solutions based on a neural network model may be used for finding an optimal solution. Once the policy server chooses an agreement, it sends its reply back to 'host1', which agrees for the service with the appropriate host.

Policy Based E-Supply Chain Management Architecture

Internet-based e-purchases and e-supply chain management are now being widely used. This however has a major disadvantage of very limited mobility and the absence of a dynamic policy that will efficiently manage the entire supply chain.

Figure 3. Architecture of policy-based MANET



The activities that are required to provision mobile users comprise a surprisingly large number of steps that cross an entire enterprise. Policy setting and implementation, approval workflows, physical resource setup/teardown (provisioning), account maintenance, reconciliation of actual resource assignments with approved user lists, audit, and overall service management are some examples. They are together called policy-based provisioning. An extension to e-purchases through mobile phones using policy-based e-supply chain management is constructed.

Architecture of Policy-Based E-Supply Chain Management

The architectural framework of the e-purchase through policy based e-supply chain management is shown in Figure 4. Mobile customer, policy server, nodes (1-4), and suppliers (1 and 2) form the key elements of the proposed architecture. The mobile consumer requests the policy server of the service provider through the base station. The mobile user's authentication, authorization, and accounting rights are then verified by the AAA server. If the mobile user is found to be an authenticated one and his request for service is an authorized one, then the policy server fetches the corresponding policies for the user from the directory server through LDAP. The policy server of the service provider is connected to other nodes (Node 1 to Node 4) in the Internet. The nodes of the suppliers such as 'supplier1' and 'supplier2' are also connected to the nodes through the public network (Internet). When the relevant policies are fetched from the directory server, the user's request is sent to an efficient supplier who will supply the product to the mobile customer. The supply chain is made electronic as discussed earlier and is policy based. Once the user's request is sent to an efficient supplier relatively nearby to the customer, the ordered products will be delivered to the mobile customer through the shipping department. The billing of the products purchased is taken into the credit account of the mobile user and is charged along with the mobile phone bill, simplifying user billing and payment. The customer at the end of the month would pay the bill through the electronic account facility available with his existing bank account. Thus the whole process of placing the purchase order, delivering the product through the supply chain, and paying for the product is made electronically, thereby facilitating the customers, who are mostly travelers and tourists.

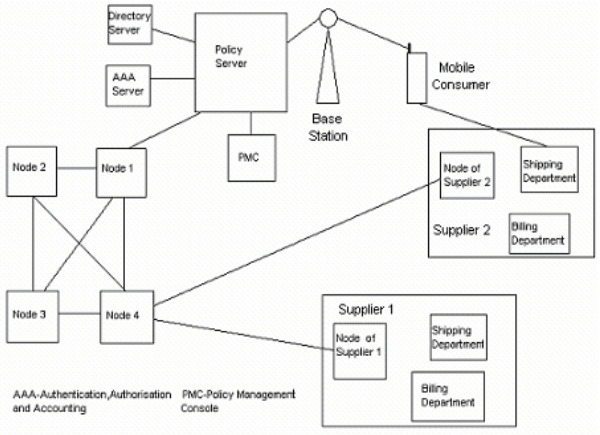
CASE STUDY

A simulation for the policy-based MANET shown in Figure 3 was performed using the QualNet Network Simulator, using the simplex method to solve the linear program model given below, and using the Ponder Toolkit. The mathematical model is given in the following section.

Mathematical Model

A mathematical model considered for policy-based MANET uses Linear Programming and Simplex Method to solve it. The following perfor-

Figure 4. Framework of e-purchase through policy-based e-supply chain management



mance metrics that are crucial for effective SLA trading and choice of route are considered in our model: (a) Bandwidth, (b) Delay, (c) Demand, (d) Packet Loss, (e) Congestion, (f) Queuing Delay, (g) Throughput, (h) Buffer Capacity, (i) Battery Consumption, and (j) Mobility. Let,

T_{ij} = Total (maximum) Bandwidth (channel capacity) available from host *i* to host *j*.
U_{ij} = Bandwidth being used for traffic flow between host *i* to host *j* at instant '*t*'.
R_{ij} = Reserved bandwidth from host *i* to host *j*.

Hence the bandwidth that can be leased to other hosts G_{ij} is given by $G_{ij} = T_{ij} - U_{ij} - R_{ij}$.

Let the required bandwidth—that is, the bandwidth consumed by the host *k* to reach host *j* through host *i*—be RB_{ij}.

And,

D_{ij} = Delay from host *i* to host *j*.
C_{ij} = Cost of reaching host *j* through host *i*.
F_{ij} = Fraction of bandwidth bought from host *i* to reach host *j*.

The objective here is to minimize the cost of reaching host *j* through other hosts.

$$Minimise \sum_{i,j} F_{ij} C_{ij} \quad (1)$$

As stated earlier, in the above equation represents the cost hostcharges to reach host through host.

Constraints

There are a set of constraints that define the model. The first constraint is the demand for bandwidth to reach host *j* through host *i*; De_{ij} should be less than or equal to the amount of bandwidth host *i* is ready to offer for cost to reach host *j*, G_{ij}.

$$DE_{ij} \leq \sum_{i,j} G_{ij} \quad (2)$$

The following constraints check if the service performance metrics in the service offered by the host *i* to reach host *j* fall within the predetermined and pre-calculated boundaries as expected by host *k* which needs the service. These boundary constants for the performance metrics can also be set dynamically and SLA negotiated accordingly.

Buffer Capacity B_{ij} should not be less than a bearable value given by the constant N=Number of packets that can be buffered.

$$B_{ij} \geq N \quad (3)$$

The time delay *D* should be set to a limit expressed by a constant '*p*1'as expected by the 'ISP k' which needs the service. The constant '*p*1' is arrived as derived as follows:

'*p*1' = Propagation Time + Transmission Time + Queuing Delay (+ Setup Time)
Propagation Time: Time for signal to travel length of network
= Distance/Speed of light
Transmission Time = Size/Bandwidth

Therefore, we have

$$D_{ij} \le p1 \quad (4)$$

Queuing Delay Q_{ij} should not exceed an allowable limit '$p2$' expressed as

$$p2 = \frac{D}{2} \times (N-1)$$

where, D = the time delay, N is the Buffer Capacity

$$Q_{ij} \le p2 \quad (5)$$

The Packet Loss P_{ij} for the service provided should not exceed a maximum limit set as constant '$p3$', and Congestion in the channel offered for service Co_{ij} should also be within the acceptable limits represented by the constant '$p4$', both of which are arrived at as shown as follows:

T_{min} = Minimum Inter-Arrival Time observed by the receiver.

P_0 = Out of order packet.

P_i = Last in-sequence packet received before P_0.

T_g = Time between arrival of packets P_0 and P_i.

n = Packets missing between P_i and P_0.

If $(n+1)\,T_{min} \le T_g < (n+2)T_{min}$, then n missing packets are lost due to transmission errors and hence '$p3$'='n'and

$$P_{ij} \le p3 \quad (6)$$

Else n missing packets are assumed to be lost due to congestion and hence '$p4$'='n' and

$$Co_{ij} \le p4 \quad (7)$$

Throughput TH_{ij} should be greater than or equal to '$p5$', which is given by

$$p5 = \{MSS / RTT\} \times C / (\sqrt{p})$$

where,

MSS = Maximum Segment size in bytes, typically 1460 bytes.

RTT = Round Trip Time in seconds, measured by TCP.

p = Packet loss.

C = Constant assumed to be 1.

$$TH_{ij} \ge p5 \quad (8)$$

The jitter J_{ij} should be within the acceptable limit '$p6$' given by

$$p6 = p6 + (|D(i-1,i)| - p6)/16$$

given

$$D(i,j) = (R_j - S_j) - (R_i - S_i)$$

where, S_i, S_j are sender timestamps for packets i, j and R_i, R_j are receiver timestamps for packets i, j.

Therefore

$$J_{ij} \le p6 \quad (9)$$

The Battery Consumption BC_{ij} for the offered service should be within the boundary constant '$p7$',

$$BC_{ij} \le p7 \quad (10)$$

The Mobility Factor M_{ij} which gives the idea of how long the host j will be in the transmission range of host for which packets need to be routed should not be smaller than a particular constant represented by '$p8$',

$$M_{ij} \ge p8 \quad (11)$$

This mobility factor M_{ij} plays a crucial role in ad hoc networks because the hosts are all mobile. It may be minutes or in any preferred time unit as the case may be. We generally assume that a mobile which has joined the ad hoc has more probability of staying in the network than the ones which came earlier than that. But the exact nature of the mobility of a host can be predicted only based on past performances of the mobile.

Non-Negativity Constraints

The following are the non-negativity constraints applied in the model:

Cost C_{ij} should always be positive,

$$C_{ij} \geq 0 \qquad (12)$$

Table 1. Performance metrics and other parameters of the hosts

Performance Metrics	Host 1	Host 2	Host 3
Total Bandwidth Allocated (MBps)	3	6	5
Bandwidth Used at Instant (MBps)	2	2	1
Reserve Bandwidth (MBps)	0	1	1
Remaining Bandwidth G_{ij} (MBps)	1	3	3
Demand for Bandwidth to Reach 'host4' (MBps)	1	0	0
Delay (x 10-3/sec)	7	8	10
Packet Loss Factor	7	5	6
Congestion Factor	30 2	0	25
Queuing Delay (x 10-4sec)	8	7	10
Throughput (x 103 Bits/sec)	100	100	90
Buffer Capacity (No. of Packets)	9	10 8	
Battery Consumption (mWh)	-	8	9
Mobility Factor? Minutes	-	25 1	8

Fraction of bandwidth bought from host *i* to reach host *j*, F_{ij} should also be positive,

$$F_{ij} \geq 0 \qquad (13)$$

The bandwidth that can be offered for cost to other hosts by host *i* should be positive,

$$G_{ij} \geq 0 \qquad (14)$$

Given the objective, for example, to minimize the agreement cost along with the performance metrics constraints, the proposed linear programming model solved using simplex method suffices for arriving at a suitable agreement for service with other hosts. There are always cases that the above model will fetch more than one solution if other solutions exist. Hence in such cases the decision of choosing the most appropriate of the available solutions should be taken which is described in the next section.

Table 2. Performance metrics and other parameters of 'host2' and 'host3'

Performance Metrics	Host 2	Host 3
Delay (x 10-3/sec)	2.9	3.1
Packet Loss Factor	0.2	0.3
Congestion Factor	0.3	0.3
Queuing Delay (x 10-4sec)	0.2	0.2
Throughput (x 103 Bits/sec)	4.2	4.2
Buffer Capacity (No. of Packets)	20 1	5
Battery Consumption (mWh)	8	9
Mobility Factor (minutes)	25 1	8
Jitter (x 10-4sec)	3.9	4.1
Fraction of Bandwidth that Can Be Given F_{ij} (MBps)	1	1
Cost C_{ij} ($)	2	6

The test environment has four ad hoc hosts from 'host1' to 'host4', as shown in Figure 3. The total bandwidth, used bandwidth, reserve bandwidth, battery consumption, mobility factor, and other performance metrics of the hosts are tabulated below.

In the simulation test environment, 'host1' needs to communicate with 'host4', which is not in its transmission range. So both 'host2' and 'host3' offer the service to 'host1'. Using the mathematical model proposed, 'host1' decides upon the suitable service among the offers using the SLA trading algorithm (Rajeev, Sivanandam, Sreenaath, & Bharathi Manivannan, 2005) and the mathematical model given previously. Since only the service offered by 'host2' adheres to the performance metric constraints, 'host1' chooses the service offered by 'host2'. All the simulation is done with respect to the packet flow from 'host1' to 'host4'.

The trade for the service is decided by using the simplex method to solve the linear programming model and SLA trading algorithm, by which a feasible solution is obtained. The performance constraints and other parameters of the hosts are given in Tables 1 and 2. According to the constraints given by 'host1' for the required service, the simplex method and SLA trading algorithm are used, and the best bid among the bids offered by the two hosts ('host2' and 'host3') is selected. Since only the bid for the service offered by 'host2' satisfies the constraints of 'host 1', SLA between 'host1' and 'host 2' takes place. The LP model is solved by using the simplex method. As only the trade provided by 'host2' satisfies all the constraints with the objective of minimum cost, the Service offered by 'host2' is agreed upon for trade.

From the performance metrics and the constraints on performance metrics, the objective of minimizing cost is arrived at (see Figure 5 and Table 3). Thus an effective SLA is traded between 'host1' and 'host2', satisfying the constraints on the performance metrics which affect the service.

CONCLUSION AND FUTURE DIRECTIONS

Policy computing can be effectively used in mobile computing in various arenas such as QoS, security, SLA, and e-purchase. The architectural framework demonstrated in the case study gives insight as to how QoS, SLA, and security can be implemented in mobile networks. Policy-based architectures for billing in mobile networks are currently being constructed which could bring transparency in mobile billing with added dynamicity.

Table 3. Original and final value of the objective

Objective	Original Value	Final Value
$\sum_{i,j} F_{ij} G_{ij} C_{ij}$ of 'host2' ($)	12 6	
Cost of 'host2' ($)	4 2

ABSTRACT

This chapter presents a usability evaluation method for context aware mobile applications deployed in semi-public spaces that involve collaboration among groups of users. After reviewing the prominent techniques for collecting data and evaluating mobile applications, a methodology that includes a set of combined techniques for data collection and analysis, suitable for this kind of applications is proposed. To demonstrate its applicability, a case study is described where this methodology has been used. It is argued that the method presented here can be of great help both for researchers that study issues of mobile interaction as well as for practitioners and developers of mobile technology and applications.

INTRODUCTION

Mobile devices are part of many peoples' everyday life, enhancing communication, collaboration, and information access potential. Their vital charac-

teristics of mobility and anywhere connectivity can create new forms of interaction in particular contexts, new applications that cover new needs that emerge, and change the affordances of existing tools/applications.

A case of use of such devices, with particular interest, concerns *public places rich in information* for their visitors, in which mobile technology can provide new services. Examples of such places, are *museums* and other sites of culture (Raptis, Tselios, & Avouris, 2005), *public libraries* (Aittola, Parhi, Vieruaho, & Ojala, 2004; Aittola, Ryhänen, & Ojala, 2003), and *exhibition halls* and *trade fairs* (Fouskas, Pateli, Spinellis, & Virola, 2002). In these places, mobile devices can be used for information collection and exchange, for ad hoc communication with fellow visitors, and for supporting face-to-face interaction.

Usability evaluation of mobile applications is of high importance in order to discover, early enough, the main problems that users may encounter while they are immersed in these environments. Traditional usability evaluation methods used for desktop software cannot be directly applied in these cases since many new aspects need to be taken in consideration, related to mobility and group interaction. Therefore, there is a need either to adapt the existing methods in order to achieve effective usability evaluation of mobile applications or to create new ones. An important issue, that is discussed here, is the *process* and *media* used for recording user behaviour.

Data collection during usability studies is a particularly important issue as many different sources of data may be used. Among them, *video and audio* recordings are invaluable sources for capturing the context of the activity including the users' communication and interaction. It has been reported that in cases of studies that audio and video recordings were lacking, it was not possible to explain why certain behaviour was observed (Jambon, 2006). Recording user behaviour is a delicate process. Video and audio recording must be as unobtrusive as possible in order not to influence the behaviour of the subjects while, on the other hand, the consent of the users for their recording should be always obtained. In addition, questions related to the frame of the recorded scene, viewing angle, and movement of the camera are significant. It must be stressed that there is a trade off between capturing the interaction with a specific device and capturing the overall scene of the activity. For example, often, crucial details may be missing from a video if recording the scene from a distance. Therefore, this video has to be complemented by other sources of related information, like screen captures of the devices used.

In order to conduct a successful usability evaluation, apart from collecting activity data, techniques and tools are needed for analysis of the collected information. In the last years, new usability evaluation techniques have emerged, suitable for mobile applications. Many of these methods focus mainly on user interaction with the mobile device, missing interaction between users, and user interaction with the surrounding environment.

Taking into consideration these aspects, the aim of this chapter is to discuss techniques and tools used first, for collecting data during usability evaluation studies of mobile devices, and then for the analysis of these data. In the process, a combination of a screen capturing technique and some tools that can be used for analysis of data of usability studies are presented.

BACKGROUND

The usability of a product has been traditionally related with the ease of use and learn to use, as well as with supporting users during their interaction with the product (Dix, Finley, Abowd, & Beale, 2003; Schneiderman & Plaisant, 2004). There have been many attempts to decompose further the term and render it operational through attributes and apt metrics. According to ISO 9241-

11 standard, usability is defined as the "*extend to which a product can be used with effectiveness, efficiency and satisfaction in a specified context of use*" (ISO 9241). According to this view, a product's usability is directly related to the *user*, the *task*, and the *environment*. Consequently, usability cannot be studied without taking into consideration the goals and the characteristics of typical users, the tasks that can be accomplished by using the product, and the context in which it is going to be used. Making a step further on defining usability, the same standard suggests three potential ways in which the usability of a software product can be measured:

a. By analysis of the *features of the product* required for a particular context of use. Since ISO 9241 gives only partial guidance on the analysis process, in a specific problem there can be many potential design solutions, some more usable than others.
b. By analysis of the *process of interaction*. Usability can be measured by modeling the interaction with a product for typical tasks. However, current analytic approaches do not produce accurate estimates of usability since interaction is a dynamic process which is directly related to human behaviour that cannot be accurately predicted.
c. By analyzing the *effectiveness and efficiency*, which results from use of the product in a particular context, that is, measuring performance as well as the satisfaction of the users regarding the product.

Having in mind the three perspectives, there is a need for combining methods that capture the specific situation of use in a specific domain. Usability evaluation methods can be grouped in four categories (Nielsen, 1993): *Inspection, user testing, exploratory, and analytic methods.* Many techniques have been devised along these lines and have been extensively used in usability evaluation of desktop applications. Therefore the first approach in evaluating mobile applications was to apply these existing techniques. Such an approach can be found in Zhang. and Adipat's (2005) survey of usability attributes in mobile applications which identified nine attributes that are most often evaluated: learnability, efficiency, memorability, user errors, user satisfaction, effectiveness, simplicity, comprehensibility, and learning performance. Such an approach is, however, limited, given the special characteristics of mobile devices with respect to desktop environments (Kjeldskov & Graham, 2003).

The mobile applications introduce new aspects to evaluate. The evaluation cannot be limited only to the device (typical scenario in desktop applications) but it must be extended to include aspects of context. The context in which the application is used is highly relevant to usability issues and often bears dynamic and complex characteristics. There is the possibility that a single device is used in more than a single context, in different situations, serving different goals and tasks of a single or a group of users. Also, group interaction, a common characteristic in mobile settings, gives a more dynamic character to the interaction flow of a system and increases the complexity of the required analysis as well as the necessity of observational data.

Along these lines, a new breed of methods for usability evaluation has been proposed (Hagen, Robertson, Kan, & Sadler, 2005; Kjeldskov & Graham, 2003; Kjeldskov & Stage, 2004). The process of selecting appropriate usability attributes to evaluate a mobile application depends on the nature of the mobile application and the objective of the study. A variety of specific measures (e.g., task execution time, speed, number of button clicks, group interactions, seeking support, etc.) have been proposed to be used for evaluation of different usability attributes of specific mobile applications. In the next section problems of data collection during mobile usability studies will be discussed.

Data Collection Techniques

A significant step during a usability evaluation study is to collect appropriate observational data to be analyzed. Hagen, Robertson, Kan, and Sadler (2005) classify the data collection techniques for mobile human-computer interaction in three categories: (a) *Mediated data collection (MDC)*, access to data through participant and technology, *do it*—the user makes himself the data collection; *use it*—data is collected automatically through logs; *wear it*—user wears recording devices that collect the data. (b) *Simulations and enactments (SE)* where some form of pretending of actual use is involved and (c) *combinations* of the above techniques. A review of different techniques of data collection, according to Hagen, Robertson, & Kan (2005) is shown in Table 1.

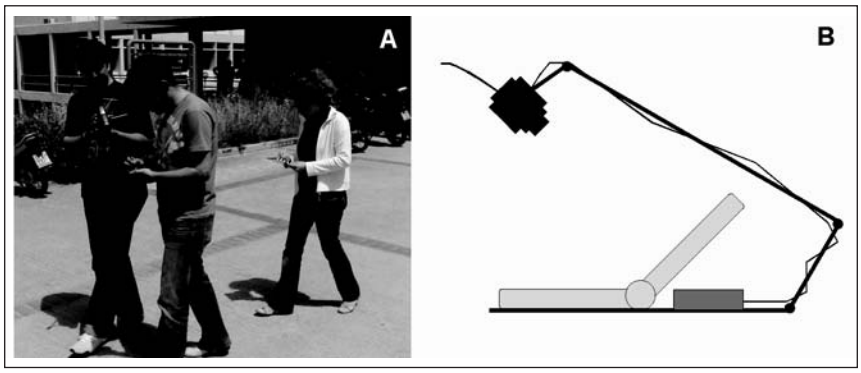
The data that are collected by these techniques come either directly from the user (through interviews, questionnaires, focus groups, diaries, etc.), by the evaluator (i.e., notes gathered during the experiment, observation of videos, etc.) or by raw data (log files, etc). All types of data need to be analyzed in order to become meaningful. Such data, in most cases, are in the following forms:

- *Log files* which contain click streams of user actions. These data can be derived by the application itself or by an external tool that hooks into the operating system message handler list. The latter case for mobile devices requires many system resources and therefore is not technologically feasible today, even in the most powerful mobile devices, like PDAs.
- *Audio/video recordings* of the users made through various means, like wearable mini cameras and/or audio recorders, static video cameras, operator or remote controlled cameras, from close or a far distance.
- *Screen recordings* by video cameras or by direct screen capturing through software (running on the device) the interaction

Table 1. Existing techniques for data collection used in studies of mobile technology. Adapted from Hagen, Robertson, and Kan (2005). F=Field, L=Laboratory, MDC=Mediated Data Collection, SE=Simulation and Enactments

Method	Description	Site*	Category
Artefacts (e.g. documents)	The use of objects or documents as sources for data collection. They may be objects (or photos of objects) from daily life or documents that users have created with devices being tested.	F	MDC
User Diaries	Users document information about their actions or thoughts, or impressions, often daily, for a period of time. Entries can be open and interpretive, or highly structured depending on the study.	F	MDC
Emulators	Emulators on desktop computers are used to simulate the interface of a potential mobile application.	L	SE
Focus Groups	Small groups of people are facilitated in unstructured discussion about an issue.	F, L	SE
Heuristics	Heuristics, often usability guidelines or design principles are applied by expert users to predict usability problems.	F, L	SE
Interviews	Interviews capture subject data from talking directly to participants. They can be open or structured and conducted in the field (including contextual interviews), online, over the phone and in labs.	F, L	SE
Log File analysis	Use logs are generated automatically (such as internet log files) or from systems specifically developed to capture content data and meta data.	F	MDC
NASA Task Load Analysis	Used in usability testing to determine work load.	F, L	SE
Observation/ Shadowing	Observation is used in field studies to capture use in context and can include, covert observation, participant observation, observing a place, or following a person. Data collection can include note taking, photography, and video.	F	MDC
Online data	Researchers gain access to information about the lives of users, and use practices from websites, forums and mailing lists.	F	MDC
Questionnaires	Quantitative or qualitative questionnaires are used to collect user opinions, feedback in evaluation, create user profiles or collect data about existing use practices. They can be done in person, or via phone or web.	F	SE
Role playing	Users and researchers play out different roles, or act out tasks or scenarios to explore existing and future use concepts	F, L	SE
Scenarios	Scenarios provide information about use situations giving examples of how technologies are used in practice.	F, L	SE
Think-Aloud	Participants describe out loud what they are thinking while they complete tasks using a device or prototype.	F, L	SE

Figure 1. A) Shadowing technique (see also Kjeldskov & Stage, 2004); B) Recording screen with wireless camera (see also Betiol & de Abreu Cybis, 2005)



flow in form of screen snapshots. This is a sequence of image representations of the user interface at certain instances that are usually taken at varying frequencies, usually a few snapshots per second. The screen snapshots can be stored either locally on the device (since it is feasible to store a large amount of data in memory cards) or on a central server over a wireless network connection

Screen recordings of mobile devices are invaluable resources that can greatly help evaluators identify usability problems. Various techniques can be used for capturing the screen of a mobile device: One is the recording of the screen by using a mini wireless camera (Figure 1B). It can be very helpful in cases of individual users but it is not suitable in the case of an application that involves beaming actions (e.g., Bluetooth, infrared) and/or interaction with the physical space because it can influence negatively the use of the device and can create obstacles in the infrared beams, sensors, or readers attached to the device (i.e., to an RFID reader). The main advantage of this technique is that the camera records, besides the screen, the movements of the users fingers or stylus, capturing valuable data identifying potential interaction problems (for example, the user hesitates to click something because the interface or the dialogs are confusing).

An alternative technique is the shadowing technique which can effectively work for individual users (Figure 1A). Again, this technique is not suitable for group activities, where the subjects often form groups and move continuously. Even in cases that it is considered possible to record properly, there could be many events missing because of the frequent movements of the subjects or the shielding of the screen by their body and hands.

The direct observation technique has also certain limitations (Cabrera et al., 2005; Stoica et al., 2005) because the observer must distribute his attention to many subjects. In case there are observers available for each user they will restrict the mobility of the users and they will distract their attention when being in so close range. Consequently, all these techniques impose the presence of the observer to the users, thus affecting their behavior.

Another significant issue that directly affects the usability evaluation is related to the location in which the study is conducted. There are many arguments in favour of *field usability studies* (Nardi, 1996; Kjeldskov, Skov, Als, & Hoegh, 2004; Zhang & Adipat, 2005; Kaikkonen, Kallio, Kekalaien, Kankainen, & Cankar, 2005). Comparative studies between laboratory and field evaluation studies have drawn, however, contradictory conclusions. In a recent survey of

evaluation studies of mobile technology (Kjeldskov & Graham, 2003), 71% of the studies were performed in the laboratory, which revealed a tendency towards building systems based on trial and error and evaluating systems in controlled environments at the expense of studying real use of them. So the question of what is useful and what is perceived problematic from a user perspective often is not adequately addressed.

In summary, in order to conduct a usability evaluation of a mobile application/system, there is a need to take into consideration the attributes that are going to be measured, the data collected for these measurements, the location in which the evaluation will take place, and finally, the appropriate tools to analyze them, having always in mind the user and the context of interaction.

Data Analysis

Usability evaluation of mobile applications is more complex than desktop software evaluation since new characteristics such as group activity and the interaction with the surrounding environment need to be taken into consideration. In order to acquire an understanding of group activity and performance, huge amounts of structured and unstructured data of the forms discussed in the previous section need to be collected. These data should capture the activity of subjects, including their movements, facial expressions, gestures, dialogues, interaction with the devices, and objects in the environment. Analysis of these data require special attention on details as well as the context of use, thus it can be a tedious process which can be facilitated by a suitable analysis tool (Benford et al., 2005).

Various tools have been developed to support usability evaluation studies and, in general, to record and annotate human activity. These tools often handle video and audio recordings and synchronize them with text files, containing hand-taken notes. This combination creates a dataset that is rich in information which is then annotated through an adequate annotation scheme, which creates quantitative and qualitative measures of the observed user-device interaction. Typical examples of such tools are: the *Observer XT* (Noldus, 2006), *HyperResearch* (Hesse-Biber, Dupuis, & Kinder, 1991; ResearchWare, 2006), *Transana* (Transana, 2006), *NVivo* (QSR, 2006; Rich & Patashnick, 2002; Welsh, 2002), and *Replayer* (Tennent & Chalmers, 2005). From them, only *Replayer* and *Observer XT* have special provisions for mobile settings. The extra characteristics in evaluation of mobile applications (group activity and interaction with the surrounding space) demand the extended use of multimedia files that thoroughly capture the activity. Thus, there is a need for a tool that combines and interrelates all of the observational data in a compact dataset and gives to the usability expert the ability to easily navigate them from multiple points of view (access in user—device interaction, access in user—space interaction).

All of the tools utilize video sources at a different extend, with the exception of *NVivo* that focuses more in textual sources. *NVivo* allows linking of evaluator's notes with video extracts, without permitting more fine grained handling of video content. On the other hand, *HyperResearch* and *Transana* do support flexible handling of video sources but they do not allow the integration and synchronous presentation of multiple video sources in the same study. Thus, *NVivo*, *HyperResearch*, and *Transana* cannot successfully respond to the extra characteristics of mobile applications. On the other hand, *Replayer* is a distributed, cross platform toolkit that allows the integration of multiple video sources and presents analysis data in various forms such as histograms and time series graphs. Although *Replayer* efficiently supports usability analysis of mobile applications, its failure to handle and to compare data that come from various studies makes it not suitable for cases of multiple studies

Table 2. Characteristics of usability evaluation tools

in which there is need to aggregate and generalise the findings. On the contrary, *Observer XT* is a powerful commercial tool, widely used in observation studies, that enables the synchronous presentation of multiple video files and also the derivation of overall results about the activity of multiple subjects. Although *Observer XT* meets the requirements of new characteristics of mobile applications, its use requires a prior lengthy training period.

A tool that has been especially adapted for analysis of data from mobile applications' evaluation studies is the *ActivityLens* which attempts to tackle some of the limitations of existing tools. Its main advantage is its ability to integrate multiple heterogeneous qualitative but also quantitative data. It allows the usability expert to directly access the collected data, thus to simultaneously focus on users' movements on the surrounding environment and user-device interaction. To sum up, *ActivityLens* supports analysis of collected data and produces results that cover the overall activity concerning all the participants.

Weitzman and Miles (as cited in Berkowitz, 1997) suggest that a criterion for the selection of an adequate analysis tool is related to the amount, types, and sources of data to be analyzed and the types of analyses that will be performed. In Table 2 a description is provided about how the tools support the extra characteristics of usability evaluation studies of mobile applications.

Data Analysis through ActivityLens

ActivityLens is a tool that embodies features especially designed for usability evaluation of mobile applications. *ActivityLens* is an evolution of the earlier Collaboration Analysis Tool (ColAT) (Avouris, Komis, Margaritis, & Fiotakis, 2004; Avouris, Komis, Fiotakis, Margaritis, & Voyiatzaki, 2005), originally designed for video analysis of collaborative learning activities. It was found particularly suitable for the proposed approach which involves multiple perspectives of the activity, based on different multimedia data.

In *ActivityLens*, all the collected data are organized into *Studies*. An example of a *Study* is the usability evaluation that was conducted in a Historical Cultural museum, described in the next sections. The tool allows *Projects* that belong to a specific *Study* to be defined. A *Project* is defined by the evaluator and can have different perspectives depending on the situation. For example, a *Project* can be defined as the set of data gathered from various groups over a set period of time, or it can be defined as a set of data of a specific group of users.

These data can be video and audio files, log files, images, and text files, including hand-taken notes of the observers. *ActivityLens* supports almost all the common video and audio file formats including file types that are produced by mobile devices such as .mp4 and .3gp. The

Figure 2. The usability evaluation tool—ActivityLens

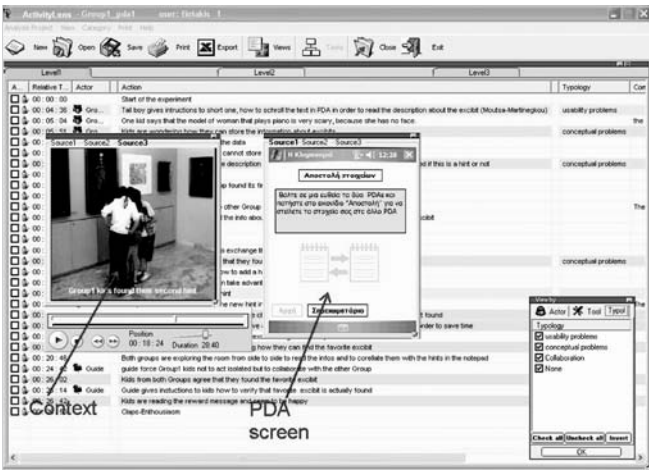

Figure 3. Event filtering tool through ActivityLens

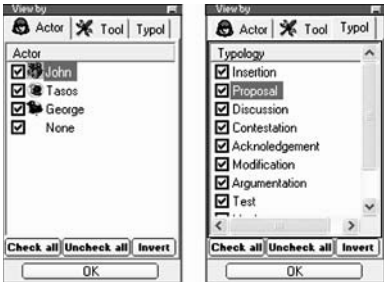


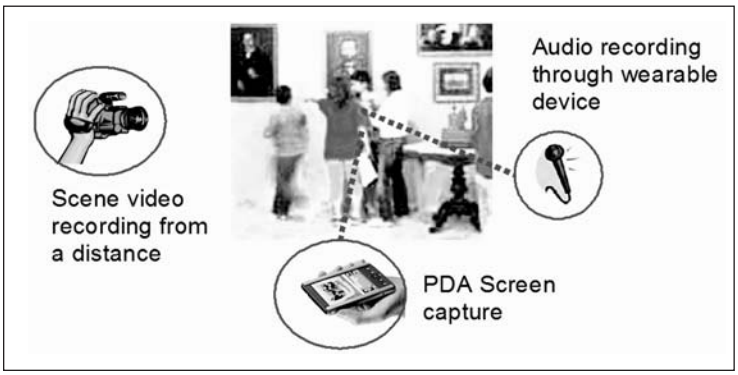
observed activity is reported in an XML log file. This file describes the activity as a set of events, reported in sequential order, following this typical structure:

<event id>, <time-stamp>, <actor>, <tool>, <event-description>, <type of event>, <comments of evaluator>

The log file events are presented via a simple spreadsheet view in order to be easily accessible for inspection and annotation. In addition, *ActivityLens* permits integration and synchronization of the collected multimedia files.

All the data can be reproduced and annotated on-the-fly in order to highlight interesting events. An example is shown in Figure 2, in which an overview video and a PDA screen are synchronized and annotated. The annotation of the observed events is based on a classification scheme defined by the evaluator. For example, an evaluator is analyzing videos that describe the activity of a group of students that try to solve a problem. During the activity some students propose ways to solve the problem and argue about it. Thus, one representative type of event could be defined as "Proposal." For usability studies, an evaluator can define typologies based on usability attributes, concerning for instance, user errors, comments expressing subjective view, and events marking successful completion of tasks.

Figure 4. Sources of observational data



ActivityLens provides the evaluator with the ability to reduce the huge amount of collected data through an event filtering mechanism. This feature is of high importance because it helps the evaluator to focus on interesting sequences of events and makes them emerge from the "noise." The evaluator is allowed to define criteria for specific Actors, tools used, and types of events or any combination between them. For example, the evaluator can choose to view all occurrences of "Proposals" made by "George" or "John." The criteria selection tool is shown in Figure 3.

PROPOSED METHODOLOGY

Based on the outlined data and analysis requirements, in this section a methodology suitable for usability evaluation of mobile applications is proposed. This method is proposed for applications deployed in places like museums, libraries, and so forth, in which groups of users interact among themselves and with the environment, in various ways. These semi-public spaces represent 'living organisms' that project, in a visible and tangible form, the various facets of information. For example, in a museum such applications assist the visitors in discovering and acquiring knowledge. A museum can be characterized as an ecology (Gay & Hebrooke, 2004) that is constituted by two main entities, the exhibits and the visitors, populating the same space. Items of the collection are exhibited to visitors, who react by discovering them in a way that is, at a large extent, influenced by the surrounding space. Also, visitors usually interact with each other, for example, because they comment the exhibits independently from the use of technology. This methodology involves, initially, the preparing study phase, the recording activity phase, and then the analysis of the activity.

Preparing the Study

Usually, activities that are expected to take place in semi-public spaces are desirable to be conducted in the field. For example, visitors inside a museum enjoy an experience that cannot be fully reproduced inside a laboratory. Therefore, the evaluator needs to conduct a study in a representative place, which should be adapted accordingly without disturbing its normal operation. Issues to be tackled are related with technological restrictions (e.g., wireless network infrastructure), recruitment of an adequate number of typical users, the extent of the study, and so forth. Consequently, it is evident that the preparation phase of the evaluation is a very important one, as it builds the foundation for a subsequently successful study.

Recording Activity Phase

A prerequisite in such environments is the low level of activity interference by the observers in order to minimize the behavioral change caused to the participants by the uncomfortable feeling of being observed and thus "disorienting the balance" in the ecology. The proposed recording activity includes an innovative combination of existing data gathering techniques in order to achieve the considered goal. The sources of data (Figure 4) include: (a) screen recordings of the mobile devices, (b) audio recordings using wearable recorders, (c) video recordings from the distance, where the camera is operated by an operator or preferably by remote control, and as complementary source (d) interviews and questionnaires to the users. A brief discussion of the process of collecting these data is included next.

(a) Screen Grabbing on the Mobile Device

In order to tackle problems related to the application nature (collaboration, interaction with the environment) it is proposed that the mobile device also be used as a screen recording device. The collected information can be in the form of screen-shots or aggregated in a low frame-rate video. The main requirement for a mobile device to become a screen recording device is that it must run a multitasking operating system in order to allow a background process to run in parallel with the main application. At the current technological status, this is the case for most mobile devices (PDAs and smart phones), as the main operating systems are multitasking: Symbian OS, Windows Mobile, Palm OS (version 6.0 onwards), Java OS, and so forth. Also, the needs of the market drove the mobile devices to handle large amounts of data that have to be consulted, edited, and updated by the user while speaking, browsing, watching TV, and so forth. As a result, mobile devices evolved from a single process, sequential to multitasking, and obtained increased storage capacities which permit the users to store a lot of information on them. Therefore, a mobile device can capture, by a parallel process, the screen and either save the pictures on their memory or send them directly to a server via a wireless connection.

A prototype application that is suitable for the Pocket PC/Windows Mobile environment has been developed and runs in parallel with the application which has to be evaluated. It captures screen snapshots and stores them on the device at a predefined time interval. In the tests, a compressed quarter VGA (240x320) screen shot was at most 32 KB that at a rate of 4 per second lead to a needed storage of about 450 MB/hour. It must be stressed that far better compression rates can be achieved by using video encoders.

The decision to grab the screen with a steady frequency and not per number of events, that would make sense in order to stop recording when the device is not used, was imposed by the technical current limitation: the scarce support for global system hooks on the Windows Mobile operating system. The lack of support is due to the fact that such hooks can critically affect the performance of the device.

(b) Audio Recording with Wearable Devices

Audio can capture dialogs between users that express difficulty in interacting with the application and the environment, or disagreement. Audio recordings can often reveal problems that users do not report during interviews or questionnaires.

The audio recordings from the inbuilt microphone of the video camera are sometimes not very useful due to the noise and to the fact that usually the dialogues are in a low voice. Also, the distance between the subject and the camera does not allow recording of good quality sound. The ideal solution would be that the mobile device itself could record both the screen and the

audio. Unfortunately, this is not feasible because of several reasons:

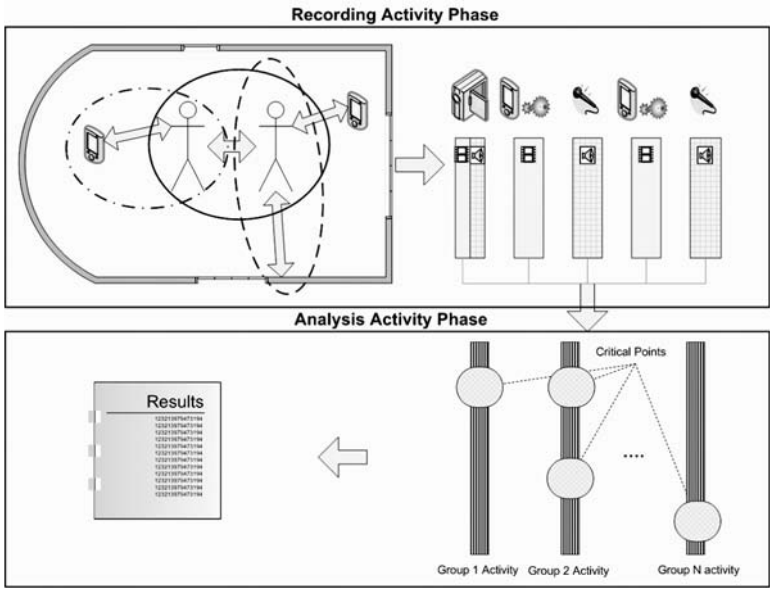
- The performance of the device degrades significantly by having two background processes running simultaneously, the one related to screen grabbing, discussed in (a) and the one to audio recording.
- The sounds that are produced by the device itself, in most cases, cover any other sound in the surrounding environment (i.e., a narration played back covers the dialogue.
- The storage might be a problem. Depending on the audio quality and compression used, 1 hour of recorded sound can take from 50 MB to 700 MB.

For these reasons, it seems that the most suitable solution is to use a wearable audio recorder that can store several hours of sound. These devices are very light; they weight less than 50 grams, including the battery. The user can wear it with the help of a neck strap or put it in a pocket and adjust a clip microphone. The wearable audio recorders guarantee that rich information concerning the dialogs between the subjects will not be lost, collaborating and interacting with the application and the environment.

(c) Discrete/Unobtrusive Video Recording

To complement the dialogs and the screen recordings, it is necessary to capture, in video, the ensemble. From this video, recording the context of the events, the social interactions between the group members (peers) and/or between groups can be depicted. In order to decrease as much as possible the level of obtrusion, the camera must be preferably maneuvered through remote control (allowing zoom and angle changes) or at least by a cameraman that will keep a large enough distance from the activity in order not to disturb the users. Often, many video recordings may need to be

Figure 5. Recording and analysis phases of proposed methodology: Interesting incidents are observed in the media files and are cross-checked for better understanding. These incidents are analyzed in terms of device and activity usability issues.



made from various angles, distance, or focusing in different aspects. These may be mixed in a single video stream if adequate equipment is used, or, more often, may be kept as separate sources of information. By studying these video recordings the evaluator can obtain a clear idea about the place in which the activity took place.

(d) Interviews and Questionnaires

Considering that the sources constitute the objective information, the users' subjective view through interviews and questionnaires also need to be obtained. Through these sources, which vary depending on the situation, someone can formulate results regarding *user's satisfaction, learning performance,* and so forth; attributes sometimes difficult to obtain simply through observation.

Analysing Activity Phase

The purpose of the analysis is to identify instances of use of the devices and the infrastructure, which identify usability problems of the technology used. Analysis of recorded activity of groups in semi-public spaces is not a simple process. Researchers have not only to focus just on the devices but to take into account more complicated issues concerning the interaction between groups, the interaction between peers in a certain group, and the interaction with the surrounding space. This analysis has to be meticulously performed in order to cover the above issues. During analysis all the collected sources that describe the group activity have to be combined and iteratively inspected. Initially, a quick inspection of recorded activity helps usability experts to isolate the segments that need thorough analysis. Then, detailed inspection of these segments is required to interpret the observed interaction and depict the usability problems. This process can help usability experts to detect certain critical points of interaction that can be further examined in order to measure their frequency and dispersion between groups and to be clear how they affect the use of mobile applications. The proposed methodology concerning the recording and analysis process can be seen in Figure 5.

EVALUATING USABILITY OF A COLLABORATIVE CONTEXT AWARE EDUCATIONAL GAME

An example of a study in which the proposed technique was applied was a usability evaluation of a collaborative mobile learning application supported by PDAs in a cultural-historical museum (Tselios et al., 2006). The study involved 17 students of the 5th-grade of an elementary school (11 years old) who were invited to visit the museum and use the prototype of an educational application that was temporarily installed there. All the students were familiar with the use of mobile phones but they had no former experience with PDAs. Furthermore, most of them described themselves in a pre-study questionnaire, as users of desktop computer systems on a daily basis.

The study took place in two of the museums' halls in which portraits and personal objects of important people of the local community were exhibited. First, a short introduction to the activity was provided by a member of the research team who undertook the role of the guide. The educational activity was designed in a way that students were motivated to read information about these important people and collaboratively search in order to locate a specific exhibit according to the activity scenario. The children were divided in two groups and each group consisted of two teams of 4 or 5 children each. Each group participated in a different session for approximately 1 hour.

In order to achieve the scenario's goal, each team was provided with a PDA equipped with a RFID tag reader. They used this equipment to locate hints that were hidden inside textual descriptions of the exhibits. These were obtained

by scanning the exhibit RFID tags. The students could store the hints it in a notepad of the PDA. After collecting all or most of the hints the teams were encouraged to share their hints, through beaming, to each other.

Then the students, using the found information, had to locate a specific-favorite exhibit which matched the description provided by the hints. When two teams agreed that they had found the favorite exhibit, they checked the correctness of their choice by scanning with both PDA's the RFID tag. A correct choice was indicated by the system with a verification message while a wrong one suggested a new search. When the study was over each student was requested to answer a set of questions related to the group activity in the museum.

Preparation of the Evaluation Study

During the preparation of the study the museum was contacted and the permission to run the evaluation study was obtained. The space of the museum was examined well in advance (e.g., for determining wireless network setup options) and afterwards a small scale pilot was run in a simulated environment in order to check the suitability of the technological infrastructure. In order to ensure the participation of subjects, a school in the vicinity of the museum was contacted and participation of a school party was requested for the study.

Collecting Data

In order not to miss important contextual information, three video cameras were used in this study. Two of them were steadily placed in positions overlooking the halls while the third one was handled by an operator who tenderly followed the students from a convenient distance. One student per team wore a small audio recorder in order to capture the dialogues between them, while interacting with the application and the environment. Furthermore, snapshots of the PDA screens were captured during the collaborative activity and stored in the PDA's memory. After the completion of the study, the guide, who was a member of the evaluator team, had an interview with the students, asking them to provide their opinion and experiences from the activity in the museum; while back at school a week later, their teacher asked them to write an essay describing their experience.

Figure 6. A) Instance of user—RFID tag interaction problem. B) and C) Photos from the collaboration activity inside the museum

Analysing Data with ActivityLens

In order to analyse all the collected data according to the proposed methodology, ActivityLens, that has already been effectively used in similar studies was used (Cabrera et al., 2005; Stoica et al., 2005).

The main reasons that ActivityLens was used among the discussed tools was its capacity of organizing observations into Studies (collection of projects) and its ability to present multiple perspectives of the whole activity (by integrating multiple media sources). Although Observer XT provides even more capabilities than ActivityLens, the choice of ActivityLens seemed to fit better the specific use case since its use did not require a long training time. In addition, ActivityLens permits easy access to the activities of the subjects recorded in different data sources.

Three usability experts, with different levels of experience, analysed the collected data in order to increase the reliability of the findings. Initially, a new *ActivityLens Study* including four projects (each project concerns the observations of a team) was created. The integrated multimedia files were extensively studied and the most interesting situations were annotated. It must be clarified that it was not wanted for the behaviour of each individual team member to be studied but wished that the performance of the whole team be evaluated. The performed analysis through ActivityLens revealed several problems related to the children's interaction with the device and the overall setting, given the surrounding physical space and groups.

Several problems were identified when the students interacted with the handheld devices.

The analysis indicated that almost all the groups could not successfully scan the Exhibits tags in their initial attempts and get information about the exhibits. The RFID tags were located underneath each exhibits label. Since the users had no clear indication of where to place the tag scanner, some of them experienced difficulties interacting with them. Also, there was an unexpected delay in the scanning process between tag and PDA (the PDA needed about 2 seconds to scan the tag). While from the scene, video recording, it seemed that the user was repeatedly scanning the same label, combining this with the PDA screen recording gave the real reason of this behavior—repeated unsuccessful tries to scan the tag. The users learned after a few frustrating attempts that they should target the center of the tags and hold the device for a couple of seconds.

A problem that troubled a specific group was the use of a scrollbar in the textual description of the exhibits. The users were not familiar with the procedure of scrolling on a PDA and they repeatedly discussed it amongst themselves. This problem was identified through the combined use of the audio and screen recording and was not visible from the scene video.

An unexpected problem was related to the content of some exhibits descriptions. They contained the word "hints" which confused the children and they were not sure if this was or was not a hint that they could add to the notepad. This was spotted from the complementary use of the overview video with the dialogue audio recordings. The problem was overcome by asking the help of the guide.

With the use of ActivityLens many problems that were related to the interaction with the physical space were managed to be detected. The most important one was that some of the exhibits tags were placed on the walls in such positions that they were not accessible by short students. In Figure 6 an instance of this problem is shown.

Another interesting element that was made clear through the students' dialogues and the videos was that in a certain area of the room an exhibit inspired fear to some of the children (e.g., a faceless piano player). Particularly, one student was clearly afraid to get near the puppet and said to the other members: "I am not going near her. She is very scary!!! Look at her, she has no face!" This situation made the team avoid that area,

which contained exhibits with useful information for the activity.

The children that participated in the study often expressed their concern about being delayed in their play due to the presence of other museum visitors (at a certain point an independent school party crowded the hall). Through the audio it was obvious that the kids expressed their frustration because they were delayed in playing the game and the visitors, because they were disturbed by the kids. These problems escape from the traditional usability analysis that focuses only on the device, because they contain the interaction between the user and the surrounding physical space.

The third dimension of the evaluation concerned investigation of the collaborative nature of the activity and the learning performance. An interesting observation was that by having two teams searching for hints at the same time, and the fact that one of the teams was more successful than the other, constituted a powerful motivation for the second team to search for hints. This was observed from the complementary scene video (pinpointing the event) and the dialog recordings (exclamations, etc.). Also, that some kids were too excited in using the PDAs and did not allow anyone else to use them was observed. Thus, disputes over use of the device influenced negatively the team spirit. From the audio streams, the disappointment of the kids that were not allowed to use the device were managed to be spotted.

Regarding the learning performance through the audio files and the PDA's screen it was found that one team was not reading the descriptions to locate the hints but they were searching for the parentheses that indicated the existence of a hint. It must be said that the solution with the parentheses and not colored text was adopted because it was wanted that those specific situations be avoided, but this did not actually work in all teams. In the future version, the hints will be visible only when the users click on them inside the description of the exhibits.

The results are also based on a study of questionnaires, independently of the ActivityLens analysis. In this point, the limitation of ActivityLens in analyzing user questionnaires has to be underlined. This weakness is a matter of further development and research.

In order to have a general view about the educational value of the activity when the children returned to their classrooms, they wrote an essay in which they reported on the museum experience. The teacher's view after going through these texts was that almost all the kids that participated in the activity learned something meaningful in a funny and enjoyable way. However, a more systematic study on these issues should involve a more quantitative experimental approach through a pre and post-test questionnaire and a control group.

CONCLUSION

This chapter has presented a brief overview of usability evaluation techniques for mobile applications, including collection of multiple observational data and their analysis. Due to the growing use of mobile devices, it is evident that there is a need for established techniques that support the collection and analysis of data while conducting usability evaluations. Since there are considerable differences between desktop and mobile environments, researchers are obliged to develop and fine tune these new techniques. Through this chapter a methodology for evaluating mobile applications focusing on collection and use of observational data was proposed. The proposed methodology was demonstrated through a usability study of an educational game in a Historical Museum.

The proposed recording activity technique can be characterized as unobtrusive regarding the users and allows evaluators to study the activity in conditions as close as possible to the typical conditions of use of the application, through various perspectives. The ActivityLens tool was used for analysis of the collected data which facilitates

interrelation and synchronization of various data sources and was found particularly useful since the collected data were of particularly high volume and often a finding was based on a combination of data sources. The methodology revealed usability problems of the application as well as issues about collaboration and interaction with the environment that would not be easy to discover in the laboratory and without the combined use of the multiple media data.

Studies that take place in semi-public spaces and involve groups of people have to tackle various problems. In most cases the willingness of people but also the availability of spaces is difficult to be guarantied for the long periods of time. Researchers that conduct such studies have to be as unobtrusive as possible to the users and pay special attention in order to minimize interference with the environment.

A limitation of the proposed approach is that it requires the users to carry light equipment (audio recorders) and also that a screen capturing software had to be installed in the mobile devices. However, these limitations did not inhibit the users to act naturally and recreate a realistic but controlled context of use. The typical studies of the proposed approach lasted a short time and thus, it is difficult to measure long term usability aspects like memorability and long term learning attitudes. It is still under investigation how to extend this technique to long term mobile usability studies involving different contexts of use.

What is however, missing from the story is an analysis scheme that can describe user interaction with the surrounding physical and information space and metrics that map usability attributes. Such a scheme would describe usability as a set of attributes that refer to interaction with the device, interaction with the space, and group interactions. This scheme could be supported by a tool like ActivityLens which facilitates easy navigation of the collected media data, allowing creation of pointers to incidents in the data, justifying the calculated values of the usability attributes. Definition of such a scheme should however, be the result of a wider research community process.

KEY TERMS

ActivityLens: A usability analysis tool used to support usability studies for mobile and collaborative applications analyzing multiple media data.

Context: Any information that can be used to characterize the situation of an entity. An entity should be treated as anything relevant to the interaction between a user and an application, such as a person, a place, or an object, including the user and the application themselves. (Dey, 2001).

Context Aware: A device, a system, or an application that has the ability to sense aspects of context and change its behaviour accordingly.

Data analysis tool: A software package that supports extracting meaningful information and conclusions from collected data.

Data Collection: The process of gathering raw or primary specific data from a single source or from multiple sources.

Screen Recording: The operation of capturing the output of a devices' screen.

Semi-Public Space: A place which is public to people and imposes a set of common, and uni-

versally acceptable rules regarding their behaviour i.e. a museum, library, theatre.

Usability Evaluation: The process of assessing the usability of a given system or product.

Chapter 8.5
Mobile Design for Older Adults

Katie A. Siek
University of Colorado at Boulder, USA

ABSTRACT

The global population of older people is steadily growing and challenging researchers in the human computer interaction community to design technologies to help them remain independent and preserve their quality of life. Researchers are addressing this challenge by creating assistive technology solutions using information appliances, such as personal digital assistants and mobile phones. Some have questioned whether older people can use information appliances because of age related problems. This chapter discusses work related to designing, implementing, and evaluating mobile applications for the aging. A discussion about what researchers should consider during the design process for information appliances shows the unique challenges posed by this population.

INTRODUCTION

Our world population is aging. The United States National Institute of Health estimates that the global older adult[1] population grows by 795,000 each month. They project that by 2030, the global older population will grow by 847,000 per month (Kinsella & Velkoff, 2001). In response to this increase, researchers in human computer interaction, social sciences, and ubiquitous computing communities are developing applications to help older people live independent and productive lives. Researchers use *information appliances* (Norman, 1999), such as personal digital assistants (PDAs) (Carmien, DePaula, Gorman, & Kintsch, 2004; Coroama & Rothenbacher, 2003) and mobile phones (Helal, Giraldo, Kaddoura, & Lee, 2003), to create *assistive technologies* for older people.

We contend that older adults can use information appliances if the physical and virtual interfaces are designed to meet their varying needs. Some may argue that older adults do not use information appliances and thus, researchers do not have to adjust designs for this population. However, a recent report in the United Kingdom revealed that 49% of older adults own a mobile phone and of that group, 82% make one or more calls per week (Office of Communications [OfCom], 2006). Thus, older adults are using information appliances, but they do encounter numerous problems, such as font and icon readability and interface complexity issues, discussed in greater detail in the background section.

Other people argue that since younger adults use information appliances now, they will not have a problem using similar technology in the future. Indeed, 82% of all United Kingdom residents own a mobile phone, whereas only 36% of people over 75 years old own a mobile phone (Office of Communications [OfCom], 2006). However, we know that (1) as people age their physical and cognitive abilities do not remain constant and (2) the *digital divide* is still present; factors such as age, socioeconomic status, and disabilities affect individuals' access to technology. Although *walk-up-and-use* systems are becoming more prevalent in our everyday lives, we cannot assume that by giving older people new technology, they will be able to easily interact with the device and application. We must work together now to create a set of guidelines to help inform the design and development of future technologies for older people to avoid problems associated with *technology determinism* (Warschauer, 2003).

In this chapter, we discuss issues that must be addressed when designing information appliance interfaces for older adults. We begin by highlighting design related work with older people and technology - traditional computers and information appliances. We then discuss best practices for conducting user studies with older populations and design issues to consider when developing applications and devices. We conclude the chapter with ideas for future work and challenges to the design, interaction, and technical communities.

BACKGROUND

We discuss how older people interact with traditional computers and information appliances in this section. The related work delves into design and interaction studies because interactions, physical and cognitive, have a major influence on design. Researchers have looked at how older populations interact with traditional desktop computers. Researchers are just beginning to look at how older populations interact with information appliances.

There has been a proliferation of information appliances designed for the general public, including PDAs, mobile phones, remote controls, digital cameras, digital music players, and game playing devices. The interfaces to these vary considerably, suggesting there may be variable age-related performance effects. Hence, when creating applications for older populations, designers must consider age-related abilities such as vision, dexterity, coordination, and cognition. Researchers have discovered that within older populations, there are noticeable differences in abilities, and that different design methodologies, such as universal design (Abascal & Civit, 2001) and user sensitive inclusive design (Newell & Gregor, 2001) should be used. Here we discuss some of the research that has been done to better understand older populations' interaction with technology.

Older People and Traditional Computers

Bernard, Liao, and Mills (2001) found that older people could read faster with a larger, more legible 14-point san serif font on websites. Researchers at

Georgia Tech studied how multimodal feedback (sound, touch, visual effect) could assist participants with varying vision problems perform basic mouse tasks (drag and drop). They found that all groups performed better when sound was added; however, groups performed the best when all three modal feedbacks were used (Jacko, Scott, Sainfort, Barnard, Edwards, Emery, et al., 2003).

A number of recent studies focused on the ability of older populations to use PC input devices (Chaparro, Bohan, Fernandez, & Choi, 1999; Charness, Bosman, & Elliott, 1995; Laursen, Jensen, & Ratkevicius, 2001; Smith, Sharit, & Czaja, 1999). The studies showed that older people completed tasks slower than younger groups. Charness et al. (1995) evaluated control key, mouse, and light-pen input devices and found older people preferred the light pen, followed by the mouse and control keys.

Smith et al. (1999) and Laursen et al. (2001) found older people made more mistakes than younger people and had difficulty with fine motor control tasks such as double clicking. Chaparro et al. (1999) found older people performed "point and click" and "click and drag" tasks slower than younger people, but with the same amount of accuracy. The researchers believed the reason that older people were slower was because of reduced fine motor control, muscle strength, and pincher strength associated with older age.

Older People and Information Appliances

Most of the human computer interaction studies on older adults and technology focus on the usability of traditional desktop computers. The usability of information appliances will be scrutinized more carefully as pervasive computing technology applications become more widespread. Researchers are already assessing the needs of older people with respect to mobile phones.

Maguire and Osman (2003) found that older people primarily considered mobile phones as a way to assist in emergencies, whereas younger people saw mobile phones as a way to interact socially. Older people were interested in small phones with large buttons and location aware systems. More specifically, older women were interested in finding the nearest retail shop that met their needs with location aware systems, whereas older men wanted to know how to get places with various forms of transportation. Abascal and Civit (2001) looked at the pros and cons of older adults using mobile phones. They found that older adults liked the safety and increased autonomy mobile phones gave them. But, they were primarily concerned about social isolation and loss of privacy by using a mobile phone. Sri Hastuti Kurniawan (2006) found that older women felt safer with a mobile phone. Unlike younger counterparts, older women wanted brightly colored, bulkier phones with an antenna so it would be easily identifiable in a cluttered purse.

Ziefle and Bay (2005) looked at the cognitive complexity of older adults using mobile phones. They found that older adults performed just as well as younger adults on less cognitively complex mobile phones. They also reported that as the mobile phone interaction became more complex, older participants' performance suffered. Irie, Matsunaga, and Nagano (2005) created a mobile phone for elders by relying heavily on speech input technologies to help decrease complexity and input methods.

Most of the findings in these studies for mobile phones can apply to PDAs as well; however, the needs assessments differ because PDAs have larger physical interfaces and different input mechanisms. The lack of research in the area of PDA technology use by the older adults prompted Darroch, Goodman, Brewster, and Gray (2005) to evaluate a suitable font size for older people who needed to read text on a PDA screen. They found older people preferred reading 12-point font on PDAs, but could read fonts as small as 10 points. The authors pointed out that the lower resolution of their PDA screen could account for

the smaller font size preferred by participants than what Bernard and colleagues had previously reported. We looked at how older adults physically interacted with PDAs. We found that older adults had no problem pushing buttons, identifying icons, voice recording, or barcode scanning. Similar to the Darroch study, we found that although older participants preferred to read icons 25-mm large, they could read icons less than 15-mm large (Siek, Rogers, & Connelly, 2005).

Researchers must take into consideration what drives older adults to adopt new technologies for assistive applications to help the target population. Melenhorst, Rogers, and Caylor (2001) found that older adults must understand the benefits of information appliances and alternative communication mediums before they will consider the necessary training to use new technology. In addition, researchers found that for older adults to adopt a new technology, they must feel the technology is useful, convenient, safe, and simple to use, especially in older adults with varying cognitive and physiological abilities (Smither & Braun, 1994).

The findings from this body of research suggest that older people can use information appliances; however, designers and researchers must look at these findings to help inform their designs. More specifically, researchers must look at the physical device capabilities, interface design, and interaction techniques.

MAIN FOCUS OF THE CHAPTER

In this chapter, we broadly define older adults as people over 65 years old. It is difficult to define an ideal older adult because of the variability in older populations' abilities affected by age, illness, and cognitive or physiological decline. Thus, when designing for older populations, it is important to carefully define the target population, recruit older adults who meet the defined criteria, conduct meaningful requirements gathering and user studies, and design *prototypes* with older adults in mind. Here we discuss each of these items in more detail from our experiences in developing assistive applications for older adults.

Recruiting Older Target Populations

The first thing designers and researchers must figure out is what type of older population they would like to target. Will the application or device be for older people with cognitive impairments? Will it be for older people with physical disabilities? Or will the design be for *all* older people? Eisma and colleagues (Eisma, Dickinson, Goodman, Mival, Syme, & Tiwari, 2003) recommend bringing in older people early on in the design process to assist with requirements gathering and prototype development. They found that the different backgrounds of older people and designers mutually inspired the group to create realistic aims for the project. Older people on the design team can help answer questions specific about the abilities of the targeted population. Researchers must keep in mind that if the design is for all older people, the target population will have to be large enough to test people with varying physical, mental, and social abilities.

Researchers typically post fliers, e-mail calls for participations on mailing lists, and recruit participants from their work or university. This may not be the best way to find a pool of older adult participants. Older participants may not have the same *social networks* as the researchers. Thus, researchers should branch out and connect with community centers, religious groups, veteran meetings, assisted living centers, disability support groups, alumni associations, or adult communities to recruit an older diverse population. Typically, researchers can set up a meeting with the activities coordinator, technology group, or outreach liaison to meet older adults.

I would have no need for one of these, so I don't have to touch it. [PDA handed to audience mem-

ber] But, what if I break it? [Grabs PDA more confidently after researcher says she does not have to worry about breaking it. Pushes a few buttons on the screen.] Well look at that – I could show pictures to my friends.

– Audience member speaking to presenter after recruiting presentation

Similar to any participant population, older adults want to know what is expected of them and what the researcher will do with the data. When recruiting older participants, it is easiest to volunteer to give a presentation about the intended study that includes why the research is being done, what type of person you are looking for (e.g., user profile data), what the participant will have to do, and how the data will be used. The researchers can field questions from the audience to assuage future participants' concerns. Presentations are also the perfect time to hand out preliminary questionnaires to audience members and schedule future meetings for *focus groups*, *interviews*, or user studies. If participants are expected to use technology that may be unfamiliar to them, bring along the information appliance and let audience members play with the technology after the presentation. Emphasize that you are not testing the participants, but the device or application, and that the device or application cannot be broken with simple interactions. Guided hands-on interactions can change a person's view of the technology as shown in the audience member quoted previously.

Meeting with Older Adults

Designers and researchers will inevitably have to meet with the older adults in their target population during requirements gathering and user studies. There has been quite a bit of research (Eisma et al., 2003; Kurniawan, 2006; Zajicek, 2004) that looks into the best way to meet with older adults. Focus groups and semistructured interview sessions are the most popular meeting methods for requirements gathering and user studies. In this section, we briefly summarize the pros and cons of each method and give tips for best practices.

I have my walking group at 9, craft group at 10:30, doctors at 11:30, lunch at 1…

– Participant and facilitator attempting to schedule another meeting time

A common misconception is that older adults have plenty of time to meet with designers and researchers because they may be retired or work fewer hours. However, researchers may quickly find that some older adults have equally busy schedules. Taking notes about what each person is interested in based on the person's schedule can give insight into how the information appliance would fit into the person's everyday life. The quote about scheduling a meeting shows the participant's varied activities. Would the information appliance always be with her/him during the study? If so, how would she/he carry it when attending each meeting? If not, how can we remind her/him to bring the information appliance to only certain activities? We found that older adults with lower social-economic status have busy schedules too because they were more likely to have chronic illness or responsible for caring for family members.

Participant 1: I do not understand what you are saying. I have to see your lips!

Participant 2: I cannot see the screen because of glare.

– Participants' comments during a focus group

Focus groups typically allow researchers to get peoples' opinions, test ideas for specifications, evaluate prototypes, and learn more from the group by spontaneous discussions. Researchers

are divided on how beneficial focus groups are when working with older adults. Zajicek (2004) found that focus groups with over three older people are challenging because of hearing impairments, visual impairments, cognitive abilities, and the ability to follow a conversation. Kurniawan (2006) reported no problems and found that focus groups with over three older people tended to work together and help with *cooperative learning* exercises.

For prototypes that run on information appliances, we found focus groups challenging because of screen glare problems and complex interactions. Information appliances are small; thus, when trying to show a feature or explain an interaction, it is difficult to show it to all participants at once. We have issued each participant an information appliance in focus groups, with multiple researchers on hand to help the facilitator explain concepts, interface components, and interactions. This method allows the participants to see the proposed application and associated small interface components. It also gives the participants the chance to interact with the device and see how input methods are different for information appliances than with traditional desktop computers. Participants typically talked with the facilitator or to the people next to them to compare what they saw and discuss what they thought. Unfortunately, this type of focus group requires more time, preparation, and coaching by researchers. In addition, time must be set-aside for the group to discuss their ideas about the information appliance or application.

Alternatively, we have projected the interface or device onto a larger viewing surface so everyone sees the screen and can discuss the issue at hand. Participants were more likely to talk openly and start new discussions about interface components. The latter method allowed us to guide the discussion more efficiently, but it did not give the participants' the same realistic feel for the interface with smaller buttons and less-controlled interactions as the former method. Designers will have to take into consideration the focus group interaction method to receive appropriate feedback from participants.

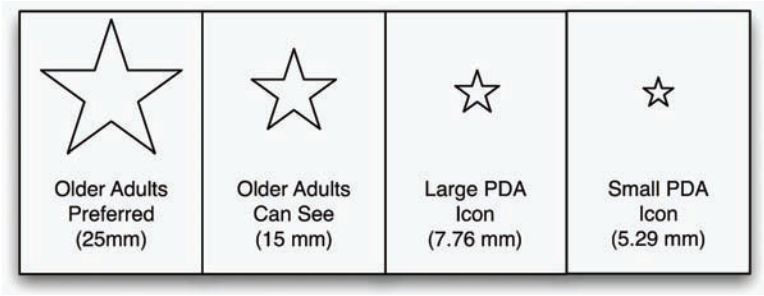
Interviews allow the facilitator to work one-on-one with a participant and ask more in-depth questions, or evaluate applications and devices more carefully. We found that we get the most detailed information about interface usability during semistructured interviews with accompanying task-centered user studies. The interview typically is quieter and has fewer distractions for the older user. In addition, the older user has a chance to interact with the device without worrying what others may think of him for not knowing how to do something on the information appliance.

My daughter thinks I am not smart because I cannot use a computer. But you know what—my daughter is not as smart as she thinks she is. One time when she was twelve, she came home from school and…

– Participant comment during interview

Our main problem with interviews, and sometimes with focus groups, is keeping on schedule. Older participants are more likely to share stories with the facilitator about their feelings towards technology when interacting in a one-on-one session. This rich data is useful, but there is a fine balance between keeping the conversation going and making sure the conversation does not diverge too much from the subject at hand, as shown in the previous quote. Another problem we encountered is that older people are more determined to finish each task than their younger counterparts, and will spend extra time to complete the tasks. We found that one-on-one interviews typically lasted one third longer than when working with younger participants.

Figure 1. Example of icon sizes older adults can view (preferred size and smallest viewable size) on a PDA



Physical Interfaces

In this section, we discuss some basic guidelines for the physical design of information appliances based on related work and our experiences. We found that older populations are interested in somewhat larger, more colorful physical devices and input components, although designers must find a balance between size and the perception of size.

When researchers conduct ethnographic studies or conduct studies where technology is discussed, but may not be necessarily used for data analysis, we find a persistent theme; most older adult populations want larger information appliances and input components (e.g., buttons, track wheels, etc.). A larger, bulky information appliance is easier to find, identify, and hold in one hand. Larger input components allow for quicker input. Indeed, a study found that older populations would prefer less overall functionality in exchange for larger buttons (Kurniawan, 2006). In terms of output, older adults would prefer to see a screen with more colors or contrast rather than have a larger screen.

In contrast, when studies have participants interact with the information appliance, they find that bigger is not always better. For example, participants in our studies were worried that their large fingers would press more than one button on an information appliance. The participants soon found that their perception of size was unfounded; they were able to interact with the smaller interface components (Siek et al., 2005). Another study found that older populations with specific physical ailments, such as paralysis, preferred smaller information appliances so they could be tucked into pockets easier (Eisma et al., 2003).

Since older populations are so diverse in abilities, it is difficult to create a strict guideline that specifies criteria of older adults who can use the information appliance. Instead, we have adopted an informal method of bringing information appliances to recruitment meetings and watching how older people interact with the devices. When we give an individual an information appliance, we collect her/his preliminary questionnaire and record comments about how she/he interacted with the device. After the recruitment meeting, the design team meets to discuss the interactions and questionnaire data to make correlations. Occasionally, we invite a clinician or an older adult to help us make conclusions about criteria needed to use the information appliance.

Virtual Interfaces

Similar to physical information appliance design, older adults are interested in the size of interface components and text. In addition, they prefer more common terminology to assist with interactions. Something that has not been studied with

information appliances is cognitive interactions and interactions with small widgets and interface components. In this section, we briefly discuss virtual interface guidelines that should be considered when designing information appliance applications for older people.

Older populations typically prefer larger fonts (e.g., 12-point font) (Darroch et al, 2005; Kurniawan, 2006) and icon sizes (e.g., 25mm) (Siek et al., 2005), as shown in Figure 1, but can read much smaller fonts (e.g., 10-point font) and icon sizes (e.g., 15mm). Design teams should take this information into consideration if they prefer to display interface information with text and icons. An application can be more appealing to older adults by using their font and icon size preferences; however, excess scrolling could make the application too complex. Indeed, we have found older populations have difficulty understanding the concept of scrolling on traditional computer Web browsers.

Besides the size of icons, older populations prefer realistic, picture-quality renderings to portray information in icons (Siek et al., 2005). Older participants prefer more detailed icons because the details helped them identify the function of the icon more efficiently.

Audience member 1: Why do I have to press Start to turn off my computer?

Audience member 2: Why do I have to press an apple to turn off my computer?

– Audience members' questions after recruiting presentation

Terminology used in virtual interfaces and user guides are often confusing to the general public. We found older users are more likely to voice their concerns and confusion about terminology. As the previous quote shows, audience members asked simple questions about the Windows and Apple desktop interfaces. At first it stumped the researcher; the reason why we press start and an apple symbol is because we always have. But just because we always have does not mean it is correct. If you would like to turn off your computer and in affect *end* all programs, why would one press start? These questions quickly prompted others to voice their concerns about e-mail and cell phone terminology. Researchers have documented older adults confusion about three-letter acronyms (e.g., SMS, MMS, etc.) and mobile phone terminology (e.g., What is a cell? What is roaming if I am always moving with a mobile phone?).

In this section, we described best practices that helped us and our fellow researchers develop successful information appliance applications for older adults. Since the older adults could use the applications and adopted them in their everyday lives, we assume these practices will help other researchers. We discuss in the next section future research directions for interface input components and interactions with these components. Research in this area will provide practitioners with guidelines to make consistently successful design decisions for information appliances.

FUTURE TRENDS

Information appliances are relatively new technologies, and mobile applications geared strictly towards older adult populations are only beginning to emerge. Researchers will continue to develop assistive applications for elders because of increases in the global older adult population. We must continue to address the issues proposed in this section to help further develop a guideline for information appliance development for older populations.

Researchers know how large common text and icons should be. We must look at how older populations use standard interface component widgets. Can they use standard size widgets with decreased fine motor skills? How large should the widget be?

I can only text people on my mobile phone if they text me first. I just push the reply button. I do not understand how to use the address book or how to enter people's names.

– Participant during interview

Cognitive interactions and interface complexity have been studied with traditional computers and Web sites. Currently, researchers have not delved into these issues for information appliances. Since information appliances have smaller screens and limited input capabilities, there will naturally be more interface screens and with it, increased complexity. As the participant noted in the quote, text messaging on mobile phones requires the user to input data from multiple sources (e.g., address book or alphanumeric key strokes) and send the message. However, once someone has sent a text message, it is easier to push one button and reply to the message. This interaction pattern could be a motivator for future research. How can we use this idea of one button interaction or precached contact data to increase communication mediums for older adults?

Interactions between the physical device and interface components are another area that must be researched for older adults to effectively use information appliances. For example, Charness and colleagues found that older adults had difficulties with traditional computer mouse and directional keyboard input because of varying fine motor control skills and the mapping between lateral movements with the mouse and the coordinate system on the screen. They found that light pens were optimal for older adults (Charness et al., 1995). In terms of information appliances, PDA screen input is similar to a light pen for optimal input. Despite this connection, designers must take into consideration that older adults may not have the fine motor control needed to select the standard, tiny interface components on PDA screens. In addition, current mobile phones pose an even bigger challenge, given the directional key presses needed to scroll and input information. It would be interesting to study if having these interactions close to the screen and on the same coordinate plane, such as in information appliances, will affect older peoples' perception of ease with information appliance input.

Along with standard interface development, researchers must strive to diversify the pool of older participants in their studies. Most studies summarized in this chapter worked with educated older populations. Indeed, recruitment from private assisted-living communities is fairly easy because the older adults who live in the community are educated and curious about technology. But a pessimistic view of the future may be that with such a large, ever growing population of older adults, the people who cannot afford private care will be monitored remotely by information appliances and *context aware* systems. If we create design guidelines and information appliance systems tested by people who are comfortable with technology, then we are leaving out the population who may need to use this technology one day. Researchers and designers must try to diversify their user pools by looking at education and socioeconomic status of their participants.

CONCLUSION

In this chapter, we looked at current research conducted with older adult populations using traditional desktop computers and information appliances. Research in the area of interface design for older adults is deficient because information appliances are relatively new, and design of assistive applications for older adults is just beginning to mature. We discussed issues and best practices that must be addressed when designing for information appliances. More specifically, we looked at the diversity of older adults, recruiting target populations, meeting with older adults in focus groups and interviews, and physical and virtual interface design considerations. We feel these best

practices are useful for researchers and the general practitioner because of our success with developing applications for older adults. Researchers and designers must strive to diversify their older adult target populations and consider people with different physical, cognitive, and emotional abilities. In addition, people from varying socioeconomic groups must be considered for the study to see how computing experience affects performance with information appliances.

KEY TERMS

Assistive Technologies: Applications and devices that pair human computer interaction techniques and technology to enhance the quality of life for people with various special needs.

Context Aware Systems: Technology embedded into our environments that communicates location, action, and other variables to help monitor the environment or individual.

Cooperative Learning: A method that allows individuals with different abilities to work together to improve their understanding of a subject.

Digital Divide: The gap between groups of people who do and do not have access to information technology.

Information Appliances: Electronic devices that allow people to send and receive various types of media (e.g., PDAs, mobile phones).

Focus Groups: A small group of selected participants who are asked questions about what they think about a specific topic or product (e.g., prototype); participants are free to discuss and build on what other participants say.

Interview: A participant is asked a series of questions by a facilitator to learn the participant's personal thoughts about a topic or product (e.g., prototype). Facilitators ask more open-ended ques-

tions in semistructured interviews and adapt future questions based on participants' feedback.

Prototype: A software or paper-based system that has a subset of the final application functionality; integral part of software development that allows researchers to get feedback from users before developing a fully functional system

Social Network: Connections between individuals with personal and professional relationships. Often the strength of the connections and influences of relationships are taken into account.

Technology Determinism: Idea that by introducing technology, people will understand and be able to use it.

Walk-Up-and-Use: Technologies that allow people to use the device or application without previous training or instruction (e.g., bank machines, self check-out kiosks at stores).

ENDNOTE

[1] Older people are defined here as 65 years old and over.

ABSTRACT

This chapter discusses the design challenges of mobile museum learning applications. Museums are undoubtedly rich in learning opportunities to be further enhanced with effective use of mobile technology. A visit supported and mediated by mobile devices can trigger the visitors' motivation by stimulating their imagination and engagement, giving opportunities to reorganize and conceptualise historical, cultural and technological facts in a constructive and meaningful way. In particular, context of use, social and constructivist aspects of learning and novel pedagogical approaches are important factors to be taken in consideration during the design process. A thorough study of existing systems is presented in the chapter in order to offer a background for extracting useful design approaches and guidelines. The chapter closes with a discussion on our experience in designing a collaborative learning activity for a cultural history museum.

INTRODUCTION

Use of mobile devices spreads in everyday human activities. These devices offer portability, wireless communication and connectivity to information resources and are primarily used as mobile digital assistants and communication mediators. Thus, it is no surprise that various attempts to use mobile appliances for learning purposes have been reported either inside or outside school (Roschelle, 2003). The term *mobile learning* or *m-learning* has been coined and concerns the use of wireless technologies, portable appliances and applications in the learning process without location or time restrictions. Practitioners' reports (Perry, 2003; Vahey & Crawford, 2002) and scientific findings (Norris & Soloway, 2004; Roschelle, 2003; Zurita & Nussbaum, 2004) communicate promising results in using these applications in various educational activities. The related bibliography proposes various uses of mobile appliances for learning. These Activities might concern access and management of information and communication and collaboration between users, under the frame of various learning situations.

A particular domain related to collaborative learning is defined as the support provided towards the educational goals through a coordinated and shared activity (Dillenbourg, 1999). In such cases, peer interactions involved as a result of the effort to build and support collaborative problem solving, are thought to be conducive to learning. On the other hand, traditional groupware environments are known to have various technological constraints which inflict on the learning process (Myers et al., 1998). Therefore, mobile collaborative learning systems (mCSCL) are recognized as a potential solution, as they support a more natural cooperative environment due to their wireless connectivity and portability (Danesh, Inkpen, Lau et al., 2001). While the mobility in physical space is of primary importance for establishing social interaction, this ability is reduced when interacting through a desktop system. It is evident that, by retaining the ability to move around it is easier to establish a social dialogue and two discrete communication channels may be simultaneously established through devices: one physical and one digital. Additionally, a mobile device can be treated as an information collector in a lab or in an information rich space (Rieger & Gay, 1997), as a book, as an organizing medium during transportation or even as a mediation of rich and stimulating interaction with the environment (i.e., in a museum). Effective usage of mobile appliances has been reported in language learning, mathematics, natural and social sciences (Luchini et al., 2002).

Furthermore, various technological constraints need to be taken in consideration during the design of activities which involve mobile devices. Such an example is the small screen, which cannot present all the information of interest while the lack of a full keyboard creates constraints in relation to data entry (Hayhoe, 2001). There is a need to provide the user with the possibility to 'go large' by getting information from both the virtual and physical world, while simultaneously 'going small,' by retrieving the useful and complementary information and getting involved into meaningful and easy to accomplish tasks (Luchini et al., 2002). In addition, despite the fact that technological solutions are proliferating and maturing, we still have a partial understanding of how users take effectively advantage of mobile devices. Specifically, in relation to communication and interaction, we need to investigate how mobile technology can be used for development of social networks and how it can provide richer ways for people to communicate and engage with others. In public spaces, like museums, a crucial question is if the serendipitous exchanges and interactions that often occur should be supported through mobile technology, how and where the interaction between people takes place and how is affected by this novel technology. Clearly, a better understanding of social activities and social interactions in public spaces should emerge to answer these questions.

A number of the aforementioned issues are discussed next in the context of a museum visit. First, we analyse how the context can affect any activity and application design. Then, we outline the most promising mobile learning applications and finally, we present our experiences of introducing collaborative learning activities using a novel approach based on the best practices surveyed previously, in a large scale project for a cultural history museum.

INTERACTION DESIGN FOR MOBILE APPLICATIONS

Interaction design is one of the main challenges of mobile applications design. Direct transfer of knowledge and practices from the user-desktop interaction metaphor, without taking in consideration the challenges of the new interaction paradigm is not effective. A new conceptualization of interaction is needed for ubiquitous computing. The traditional definition (Norman, 1986) of the user interface as a "means by which people and computers communicate with each other," becomes in ubiquitous computing, the means by which the people and the environment communicate with each other *facilitated* by mobile devices. As a result, interaction design is fundamentally different. In the traditional case, the user interacts with the computer with the intention to carry out a task. The reaction of the computer to user actions modifies its state and results in a dialogue between the human and the machine.

On the other hand, the user interaction with mobile devices is triadic, as the interaction is equally affected not only by the action of the user and the system's response, but by the context of use itself. The level of transparency of the environment, taking into account the presence of the mobile device and the degree of support to 'environmental' tasks meaningful to the user, are new issues to be considered. Consequently, new interaction design and evaluation criteria are required, since the design should not only focus on the user experience but pay also attention to the presence of other devices or objects of interest, including the level of awareness of the environment. By building the virtual information space into the real, the real is enhanced, but conversely, by drawing upon the physical, there is the opportunity to make the virtual space more tangible and intuitive and lower the overall cognitive load associated with each task.

To summarize, a number of design principles are proposed for mobile applications design:

a. Effective and efficient *context awareness* methods and models, with respect to the concept of context as defined by Dey (2001): 'Context is any information that can be used to characterize the situation of an entity. An entity is a person, place, or object that is considered relevant to the interaction between a user and an application, including the user and applications themselves.'
b. Presentation of useful information to the user *complementary* to the information communicated by the environment.
c. A*ccurate and timely update* of environmental data that affect the quality of interaction.
d. Contextualized and personalized information according to *personal needs.*
e. Information should be *presented to the user* rather than having the user searching for it.

Failure to look into these design issues can lead to erroneous interaction. For example, delays of the network, lack of synchronization between two artifacts of the environment or slight repositioning of the device can lead to misconceptions and illegal interaction states. In addition, information flow models should be aligned according to the information push requirement and relevant user modeling and adaptation techniques to support

this flow of information should be defined. Finally, new usability evaluation techniques, concerning mobile applications should emerge to shape a novel interaction paradigm.

Dix et al. (2000) present a framework to systematically address the discussed design issues and successive context awareness elements are inserted in the design process: (a) the *infrastructure* level (i.e., available network bandwidth, displays' resolution), (b) the *system* level (type and pace of feedback and feed through), (c) the *domain* level (the degree of adaptability that a system must provide to different users) and (d) the *physical* level (physical attributes of the device, location method and the environment). All these elements should be tackled independently and as a whole in order to study the effect of every design decision to each other.

We formulate the interaction design aspects discussed through the problem of designing a mobile learning application for a museum. During the visit a user has only a partial understanding of the available exhibits. This situation can be supported by complementary information included in the physical environment, for example alternative representations, concerning the historical role of the people or the artifacts presented the artistic value of a painting (Evans & Sterry, 1999), and so forth. This cognitive process of immersion into the cultural context, represented by the museum exhibits, could be supported by drawing upon the stimuli produced during the visit using context aware mobile devices. Therefore, these devices should be viewed as tools to enhance the involvement of a user in the cultural discovery process, tools that challenge the user to imagine the social, historical and cultural context, aligning her to a meaningful and worthy experience.

It is not argued here that the infusion of mobile technologies in museums will necessarily result to meaningful learning processes. Our analysis involves the potential use of the technology when integrated in educational activities (Hall & Bannon, 2006), which will offer a structured learning activity according to the characteristics of museums' content and the functionalities of the technologies used. To better illustrate this point (a) we briefly present a set of selected exemplary cases which demonstrate different ways of integrating mobile educational applications in museums and (b) we provide a more detailed account of such an application that we designed for a museum in Greece.

In the next section a number of approaches supporting such a visit are reviewed and examined using the design aspects as guiding paradigm and point of reference. Since the goal of the visitor is to see and learn more and not to explicitly use technology, a deep understanding of visitors' needs is important during the design phase, to avoid disturbances that can destruct her from her objective. Therefore, decisions made for the technology used and the styles of interaction, with the involved devices, have to deal with user's patterns of visit. Having the above requirements in hand, we use the framework proposed by Dix et al. (2000) to organize a coherent characteristics inspection of some representative examples of mobile museum guides.

MOBILE DEVICES AS MUSEUM GUIDES

In this section, some representative design approaches for mobile museum applications are discussed. An extended survey is included in Raptis, Tselios and Avouris (2005). The first system named "Electronic Guidebook," deployed in the Exploratorium science museum (Fleck et al., 2002), tries to involve the visitors to directly manipulate the exhibits and provides instructions as well as additional science explanations about the natural phenomena people are watching. The system of the Marble Museum of Carrara (Ciavarella & Paterno, 2004) stores the information locally in the PDA's memory, uses a map to guide the visitors around the museum and presents

content of different abstraction levels (i.e., room, section and exhibit). The "ImogI" system uses Bluetooth to establish communication between the PDAs and exhibits and presents the closest exhibits to the user, (Luyten & Coninx, 2004). The "Sotto Voce" system gives details about everyday things located in an old house (Grinter et al., 2002) by having pictures of the walls on the PDA's screen and asking from the user to select the exhibit she is interested in, by pressing it. The "Points of Departure" system (www.sfmoma.org) gives details in video and audio form by having 'thumbnails' of exhibits on the PDA's screen. It also uses 'Smart Tables' in order to enrich the interaction. A system, in the Lasar Segall Museum, Sao Paolo, Brazil (Dyan, 2004), automatically delivers information to the PDA, about more than 3,000 paintings. In the Tokyo University Digital Museum a system uses three different approaches to deliver content. The PDMA, in which the user holds the device above the exhibit she is interested in, the Point-it, in which the visitor uses laser-pointer to select specific exhibits and finally the Museum AR in which visitors wear glasses in order to get details about the exhibits (Koshizuka & Sakamura, 2000).

The system developed in the C-Map project, (Mase, Sumi, & Kadobayashi, 2000), uses active badges to simulate the location of the visitor, allowing tour planning and a VR system, controlled by the gestures of the visitor. In a Tour guide (Chou, Lee, Lee et al., 2004), the information about the exhibits is automatically presented and there is no variation in the form of the visit, but subjec-

Table 1. Design decisions affecting system context

	Location technology	**Storage of information**	**Flow of information**	**Additional functions**
"Antwerp project"	IrDA	In Server	Active	Cameras
C-Map	IrDA	In Server	Active, exhibit recommendations	Active Badges, Screens
Hippie	IrDA	In Server	Active, info presented based on the history of visit

Points of departure		Locally stored info	Active	Screens
Rememberer	RFID	In Server	Passive	Cameras
Sotto Voce		Locally stored info	Active	
Tour Guide System (Taiwan)	IrDA	In Server	Passive, subjective tour guides	

tive tour guides are used. A different approach is the one adopted in the Museum of Fine Arts in Antwerp (Van Gool, Tuytelaars, & Pollefeys, 1999), in which the user is equipped with a camera and selects exhibits, or details of an exhibit by taking pictures. A tour guide in the PEACH project, (Rocchi, Stock, Zancanaro et al., 2004), which migrates the interaction from the PDA to screens and uses a TV-like metaphor, using 'newscasters' to deliver content. Finally, a nomadic information system, the Hippie, developed in the framework of the HIPS project, (Oppermann & Specht, 1999), allows the user to access a personal virtual space during or after the visit. In the latter system, an electronic compass is used to identify the direction of a visitor.

The *infrastructure* context concerns the connections between the devices that comprise the system and influence the validity of the information that is provided through them to the users and needs not only to be addressed in problematic situations. It is also related with the validity and timely updates of available information. This can be clearly seen in collaboration activities where the user constantly needs to know the location of other users, the virtual space, the shared objects, and so forth. In the specific museum domain the results may not be so critical but can lead the user to various misunderstandings.

The mentioned systems use an indirect way of informing the user that her requests have been carried out: the user sees and hears the reflection of her requests on the PDA. There is no clear notification that the user's demands are executed successfully or not. Some of the systems use external factors, as signs of success, such as a led light ("Rememberer") and audio signals ("Marble Museum"). But in general terms, the user is on his or her own when problems occur and the systems leave it up to her to find it out, by observing that, there is no progress. We have to point that it could be very distracting and even annoying to have feedback messages in every state of interaction, but it is important for designers, to include a non-intrusive approach to inform that there is a problem and provide constructive feedback to overcome it.

Regarding the *system* context we can distinguish four different approaches as a means of awareness technology. In the first approach (Table 1), the PDA is the whole system. There are no other devices or awareness mechanisms involved and the information presented to the user is stored locally in the PDA. The second approach uses RFID tags to establish communication between the PDAs and the exhibits and the third which uses Bluetooth to establish communication with the exhibits and deliver content. The forth and most common approach uses IrDA technology to estimate the position of the visitor in space. Usually, IrDA tags are placed near every exhibit or in the entrance of each exhibition room and Wi-Fi derives the information to the PDA from a server Also, many different additional devices are built and integrated into these systems like screens (as a standalone devices or as interacting devices with the PDAs, where the user has the opportunity to transmit sequentially her interaction with the system from the PDA to a Screen). Regarding the *location*, all the studied systems use a topological approach to identify the position of a PDA, which informs approximately the system about the user's location. However, in the case of a museum with densely place exhibits, a more precise Cartesian approach can yield accurate user localization.

Domain context concerns aspects related to the situated interaction that takes place in the specific domain. Often in museum applications there is a lack of information about user profiles and characteristics. It is however important to consider that each visitor in a museum has different expectations, and is interested in different aspects regarding the exhibits. In the studied systems only in those that allow interaction of the users with servers there is a possibility for personalized interaction. Most of the systems require from the user to login, answer some specific questions, in

order to build a model of the user and present the information in her PDA according to her language, her expertise level and her physical needs (i.e., bigger fonts for those with sight impediments). When domain context is absent from the design process the system operates as a tool suited for the needs of a single hypothetical 'ideal' user. In such an environment this 'ideal' user will likely represent the needs and expectations of a small fraction of real visitors.

The system may push information to the user or it may wait until the user decides to pull it from the system. In the first case, special consideration should be taken to the user's specific activity and objective. Questions related to situated domain context are the following: Does the system propose any relevant information based on the history of users interaction? Does it adapt to actions repeatedly made by the user? Does it present content in different ways? For example, the "ImogI" system rearranges the order of the icons putting in front the mostly used ones. Also, in PEACH and in 'Points of Departure' the user can change the interaction medium from PDAs to Screens, in order to see more detailed information.

The *physical* context lays in the relation of the system with the physical environment and in problems concerning the physical nature of the devices. However, in the studied systems there is not a single mechanism of identifying the physical conditions. For example, in a room full with people, where a lot of noise exists, it would be appropriate if the system could automatically switch from an audio to a text presentation.

From the survey of the mobile guides applications presented here it seems that efficient design approaches could be achieved by augmenting physical space with information exchanges, by allowing collaboration and communication, by enhancing interactivity with the museum exhibits and by seamlessly integrating instantly available information delivered in various forms. However, the synergy between technology and pedagogy is not straightforward especially if we take into account the need to tackle issues such as efficient context integration, transparent usage of the PDA, and novel pedagogical approaches to exploit the capabilities of mobile devices. As a result, after discussing in detail usages of a mobile device as a mean of museum guidance, in the following, we attempt to discuss explicit educational activities mediated by mobile devices and a specific example of a new Mobile Learning environment.

DESIGNING MUSEUM MOBILE EDUCATIONAL ACTIVITIES

The level of exploitation of mobile devices in a museum setting is increasing and part of this use may have educational value. In this section we will focus on the added value of integrating educational mobile applications in museums. We will start our analysis by posing two questions that we consider central to this issue: (a) what is changing in the learning process taking place in a museum when mediated by mobile technology and (b) why these changes might be of educational or pedagogical interest? We will attempt to address these questions by focusing on three aspects related not only to the characteristics of mobile technology but also to the results of its integration in a museum. Specifically we will discuss: (a) the types of interaction between the visitor and the learning environment (e.g., the museum), (b) the learning activities that these interactions can support and (c) the role of context and motion in learning.

One facet of the learning process when mediated by mobile technology in museum visits involves the tangibility of museum artifacts: distant museum exhibits that were out there for the visitors allowing them just to observe now can be virtually touched, opened, turned and decomposed. In this case, technology provides to the user the key to open up the exhibit, explore it and construct an experience out of it. The tra-

ditional reading of information and observation of the exhibit is considered as one-dimensional "information flow" from the exhibit to the user. Mobile technology facilitates the transformation of the one dimensional relationship to a dialectic relationship between the user and the exhibit. Furthermore, this relationship can now include another important component (apart of the exhibits) of the museum environment: the other visitors. By providing a record of user–exhibit interaction for other visitors to see, reflect upon and transform technology can support social activities of communication, co-construction, and so forth between the visitors. To sum up, mobile technology mediates three types of interaction between the learner and the learning environment of a museum: (a) "exhibit–user" interaction (b) "user –exhibit" interaction and (c) "between the users" interaction about "a" and "b."

The enrichment of interaction between the learner and the museum might result in more or different learning opportunities (Cobb, 2002) the characteristics of which are outlined here. Specifically, the dialectic relationship between the user and the museum artifacts, mediated by mobile devices, might offer chances for analysis of the exhibit, experimentation with it, hypothesis formulation and testing, construction of interpretation, information processing and organization, reflection and many more, according to the educational activity designed. Collaboration and communication about the exhibits and information processing about them makes possible socio-constructive learning activities. By comparing these elements of the learning process to the reading or hearing of information about the exhibits (which is a the starting point for a non technology mediated museum visit) we realize that mobile technology has the potential to offer an active role to the learner: she can choose the information she wants to see, open up and de-construct an exhibit if she is interested in it, see how other visitors have interacted with a certain exhibit, discuss about it with them, exchange information, store information for further processing and use and so on.

Up until now, we described the role of mobile technology in learning with respect to two characteristics of the museum as learning environment: the exhibits and the other visitors. Another characteristic of the museum, which differentiates it from other learning environments (e.g., classroom) is that learning in a museum takes place while the learner moves. Learning while moving, quite often takes place very effectively without the support of technology. However there are cases that further processing with appropriate equipment is needed or some structuring of this "mobile learning experience" is proved to be useful. Mobile technologies can find in museums an important area of implementation not only because museum visits are structured around motion but because we have to support visitors *during* and not just after or before the visit (Patten, Arnedillo Sanchez et al., 2006). But why is it important to support learning during the visit? The answer here comes from the theory of situated learning (Lave & Wenger, 1991) which underlines the role of context in learning. Specifically, context facilitates knowledge construction by offering the practices, the tools, and the relevant background along with the objectives towards which learning is directed and has a specific meaning or a special function (knowledge is used for something). Finally, the use of mobile devices provides a new and very attractive way of interacting with the museum content especially for young children (Hall & Bannon, 2006).

As mentioned previously a large number of mobile applications have been developed during previous years for use in the museums (Raptis et al., 2005). All these mobile applications can add educational value to a museum visit in various ways. A survey of mobile educational applications for use inside the museum, led us to a categorization according to the educational approach followed in every occasion. The first category includes applications that mainly deliver

information to the visitor and concerns the vast majority of applications created for museums. Mobile devices take the place of the museums' docents and offer predetermined guided tours based upon certain thematic criteria. The aforementioned applications offer the museum visitor an enhanced experience which can support the learning process through a behaviorist approach. Enhancement is succeeded by supplying multimedia and context-related content.

The second category of applications, suitable for educational use in museums, consists of applications which provide tools that can support the learning process in a more profound way. Compared to the first category, they provide information about the exhibits of a museum but furthermore they include a series of functions that increase the interactivity with the user. Such an example is the Sotto Voce System (Grinter et al., 2002), which includes an electronic guide with audio content and the ability of synchronized sharing of this content between visitors. Thus, the users can either use individually the guide or "eavesdrop" to the information that another visitor listens.

Another example is the applications developed for the Exploratorium, a science museum in San Francisco (Fleck et al., 2002). In this museum, the visitor has the possibility to manipulate and experiment with the exhibits. Also, an electronic guidance was designed to provide information about the exhibits and the phenomena related with them, posing relative questions to provide deeper visitors' engagement. These applications are closer to social-cultural learning theories as they provide the user with tools to organize and control the provided information.

The third category of educational applications presents a specific educational scenario. Usually, game-based activities where the users, mostly children aged 5-15, are challenged to act a role and complete carefully designed pedagogical tasks. Such an example is the MUSEX application (Yatani, Sugimot & Kusunoki, 2004), deployed in the National Museum of Emerging Science and Innovation in Japan. MUSEX is a typical drill and practice educational system in which children work in pairs and are challenged to answer a number of questions. Children select an exhibit with their RFID reader equipped PDA and a question is presented in the screen with four possible answers. The activity is completed when each pair collects twelve correct answers. Children may collaborate and communicate either physically or via transceivers and monitor each group progress through a shared screen. After the completion of the activity the participators have the possibility to visit a Website and track their path inside the museum. The users can deeply interact with the exhibits, review the progress of her partner or ask for help (Yatani et al., 2004).

DinoHunter project includes several applications for the transmission of knowledge through game-based and mixed reality activities in the Senckenberg museum, Frankfurt, Germany. Three of these applications, namely DinoExplorer, DinoPick and DinoQuiz, are being supported by mobile technologies (Feix, Gobel, & Zumack, 2004). DinoExplorer delivers information to the users as an electronic guide, DinoPick allows the users to pick one part of the body of a dinosaur and get more multimedia information about this specific part and DinoQuiz provides a set of questions for further exploration of the exhibits of the museum.

Mystery at the Museum is another mobile, game-based, educational activity created for the Boston Museum of Science. It engages visitors in exploring and thinking in depth about the exhibits, thus making connections across them and encourages collaboration (Klopfer, Perry, Squire et al., 2005). High School students and their parents are called to solve a crime mystery where a band of thieves has stolen one of the exhibits. The users try to locate the criminals by using a PDA and a walkie-talkie. The participants must select upon the role of a technologist, a biologist or a detective. Depending on the chosen role they can interview

virtual characters, pick up and examine virtual objects by using virtual equipment (e.g., microscope), collect virtual samples via infrared tags or exchange objects and interviews through the walkie-talkies. A study confirmed deep engagement of the participants and extensive collaboration due to the roles set.

Another similar approach is presented through the Scavenger Hunt Game activity used in the Chicago Historical Society Museum (Kwak, 2004). In this case, the children are challenged to answer a series of questions related to the exhibits and the local history. They undertake the role of a historical researcher and they are called to answer 10 multiple choice questions while examining the exhibits. Each user is individually engaged into the activity and her progress is evaluated in a way similar to electronic games. The Cicero Project implemented in the Marble Museum of Carrara introduces a variety of games to the visitors (Laurillau & Paternò, 2004). The games vary from finding the missing parts of a puzzle to answering questions about the exhibits. Its main characteristic is the support it provides to the visitors to socially interact and collaboratively participate in activities concerning the exhibits of the museum, through peer-awareness mechanisms.

A series of mobile educational activities was also carried out in the frame of the Handscape Project in the Johnson Museum (Thom-Santelli, Toma, Boehner et al., 2005). The "Museum Detective" engage students in role-playing activities. Children working in pairs are called to locate an object described by one clue and learn as much as possible for it. A series of multiple-choice questions is presented for further exploration of the exhibit. Four types of interactive element are also provided for the exhibits: a painting, a drawing activity and a building activity and a multimedia narrative. The multiple-choice questions and the building activity were drill and practice activities and the rest were activities allowing children to make their own creations.

The systems of the latter category present coherent learning experiences comprised of planned and organized pedagogic activities, where an intervention has been purposefully designed to result a positive impact on children's cognitive and affective development. With respect to the contextual and interaction issues presented in the previous sections, we attempt to present in the next section an integrated application that involves children as role-playing characters by exploring the museum using a PDA.

AN EXAMPLE OF MOBILE ACTIVITY DESIGN FOR INDOOR MUSEUM VISIT

The "Inheritance" activity discussed here, is designed to support learning in the context of a cultural/historical museum visit. The application involves role-playing, information retrieval, data collecting and collaboration educational activities, suitable for children aged 10 or above working in teams of two or three members each. The activity scenario describes an imaginary story where the students are asked to help the Museum in finding the will of a deceased historian, worked for years in it. This will is hidden behind the historians' favorite exhibit. Clues to locate the document are scattered among the descriptions of some exhibits. If the children manage to find the will, all of the property of the historian will be inherited by the museum and not by his "greedy relatives." The scenario urges the students to read the description of the exhibits, find the clues and collaboratively locate the specific one.

During the design process of the activity we had to study the *museum context*, the *mobile technology* used and the *learning approach* to be followed in order to achieve the desired pedagogical outcome. The survey discussed in the previous section led us to adopt the following interaction design decisions. A PDA with wireless network capability is used and an RFID reader is attached

to it to 'scan' the RFID tags used to identify the exhibits. Wi-Fi infrastructure is being used to deliver data and establish communication between the visitors. When an exhibit is scanned, the PDA sends a request for information to the server which delivers the appropriate content presented in the form requested by the user. Data exchange between two users is accomplished through alignment of their devices while pointing one to the other, which mimics the exhibit scanning procedure. We also opted for small chunks of text since reading at low resolution screens reduces reading comprehension significantly.

The educational design of the activity was inspired by the social and cultural perspective of constructivism. It was structured around a set of learning objectives relevant to the thematic focus of the museum, to the exhibits' information, to the age and previous knowledge of the students, and to the fact that involves a school visit (as opposed to individual museum visits). The basic elements which shaped the activity were:

a. **Engagement of interest:** Engagement and interest hold an important role in the learning process. Student interest in a museum should not be taken for granted, especially because a visit arranged by the school is not usually based on the fact that some students might be interested to the theme of the museum. In the inheritance activity we considered to trigger student interest by engaging them in a game. The setting, the rules and the goal of the game were presented in the context of a story.

b. **Building on previous knowledge:** The focus of the activity was selected with respect to the history courses that students were taught in school. They had a general idea about the specific period of the Greek history and the activity offered complementary information about certain issues of this period. Building on previous knowledge was expected to support students in problem solving and hypothesis formulation and testing.

c. **Selecting–processing–combining pieces of information:** The scenario is structured around the idea that students read the offered information, select what is relevant to their inquiry and combine it with other pieces of information that have selected and stored earlier. Thus the students are expected to visit and re-visit the relevant exhibits, go through the information that involves them as many times as they think necessary and not just retrieve that information but combine it and use it in order to find the favorite exhibit which is the end point of the game

Figure 1. Screenshots of the "Inheritance" application: (a) Dialogue for RFID tags reading (b) information for a selected exhibit (c) clue selection (d) the notepad screen.

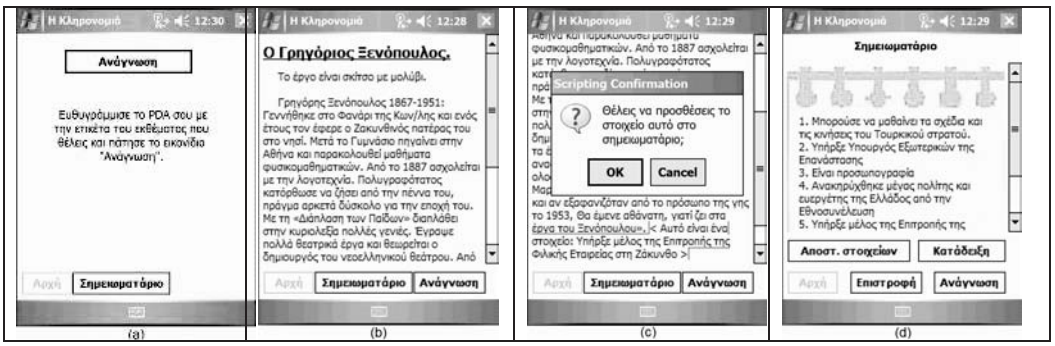

Figure 2. Children engaged in the activity

d. **Hypothesis formulation and testing:** When students have selected enough information from the exhibits around one room of the museum they can attempt to use some of the clues they have selected in order to find the favorite exhibit. If they fail they can go around the room to collect more information and try again.
e. **Communication and collaboration:** The activity is designed to facilitate inter and intra-group collaboration. Specifically, two groups of students are expected to collaborate to determine which exhibit they will interact with, to exchange clues using their PDA and to discuss their ideas about the favorite exhibit.

During the activity, the participating teams are free to explore any exhibit. Each team is provided with a PDA to extract information related to the exhibits by reading the tags attached to each of the exhibits (Figure 1). Only some of the exhibits contain 'clues,' which give information about the favourite exhibit to be found. Children must locate them, store them in the PDAs notepad and after collecting all or most of the clues the teams are able to beam their clues to each other. After collecting all six clues the students are challenged to locate the favorite exhibit. When both teams agree that one exhibit is the favorite one, they can check the correctness of their choice by reading with both PDAs the RFID tag of the chosen exhibit.

After the development of a prototype application, a case study was conducted inside the museum in order to validate the design choices. Seventeen students, aged 11, participated in the study (Figure 2). Data concerning all involving elements were collected to study the activity in depth. The activity was videotaped, PDA screen recording has been used and voice recorders were used to record dialogues among the participants.

The goal of the data analysis was twofold. First, to identify problems children encountered during the process in relation to each of the activity's elements. Then, to identify the nature of the interactions occurred during the procedure. Our analysis is based on the Activity Theory, concerning mainly human practices from the perspective of consciousness and personal development. It takes into account both individual and collaborative activities, the asymmetrical relation between people and things, and the role of artifacts in everyday life. The activity is seen as a system of human processes where a subject works on an object in order to obtain a desired outcome. In order to accomplish a goal, the subject employs tools, either conceptual or embodiments. Activity

Figure 3. Description according to the activity theory model

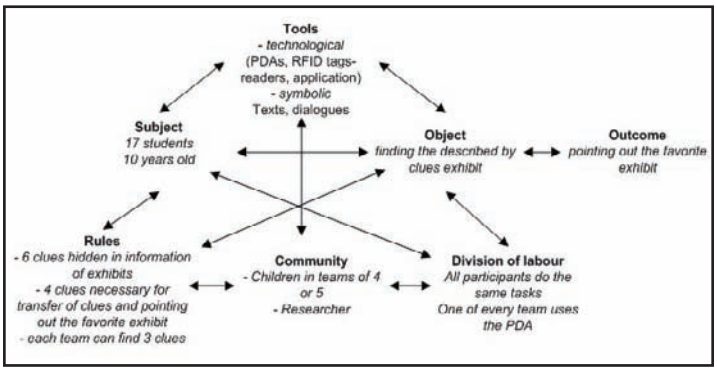

Table 2. An extract of the data analysis presenting action of the 'reading and searching for clues' class

Time	Actor	Tool	Events
00 : 08 : 50	Group1	PDA	Selection of "read"
00 : 08 : 52	Group1	texts	Information D. Stefanou
00 : 09 : 21	Group1	PDA	scrolling
00 : 09 : 33	Group1	PDA	scrolling
00 : 09 : 38	Group1	PDA	scrolling
00 : 09 : 42	Group1	PDA	scrolling
00 : 09 : 45	Group1	PDA	scrolling
00 : 09 : 49	Group1	PDA	scrolling
00 : 09 : 57	Group1	PDA	scrolling
00 : 10 : 02	Group1	PDA	scrolling
00 : 10 : 03	Group1	Dialogue	It doesn't have any (clues) here

is consisted by different components which are (Figure 3): (a) *subject*, (the persons engaged in the activity), (b) *object* (scope of the activity), (c) its *outcome* (c) *tools* used by the subjects (d) *rules-roles* that define the activity process, (e)*community* (context of the activity) and (f)*division of labour* (tasks division among the participants, Kuuti, 1995; Zurita & Nussbaum, 2004).

Activity Theory is of fundamental importance to deeper understand learning with mobile devices while visiting a museum, since in this case knowledge construction is mediated by cultural tools in a social context. The data collected were analyzed with the use of the Collaboration Analysis Tool (ColAT) environment which supports a multilevel description and interpretation of collaborative activities through fusion of multiple data (Avouris, Komis, Fiotakis et al., 2004).

In our analysis, an activity is a procedure during which objects become knowledge through three different levels-steps. Operation is the lower level where routine processes facilitate the completion of goal-oriented actions which in turn constitute the activity. Dialogues, user operations in the application and observations derived from the videos were transcribed in this first level of analysis. The actors, the operations and the mediating tools were noted in this level. Actors were the two participating teams and the researcher. The mediating tools were the dia-

logue among children and the researcher, texts of information (symbolic) and the application (technological). Some examples of operations in our case are text scrolling, RFID tag reading and transition from one screen to another. Analysis of these user operations led us to the identification of a problem in the use of the application. For example, due to data transfer delay from the server to the PDA, users in some occasions were frustrated and selected repeatedly an action due to lack of timely feedback.

In the second level, the different actions presented among the structural components of the activity are being studied. In order to identify and categorize the actions, a series of typologies were introduced. Typologies were set according to the goal and the mediating tool of each action. For example when children used the PDA to read the text information (mediating tools) their goal was not always the same. Three different typologies were used to describe the situation when the children read carefully the information provided ("Reading of information"), when they were reading the information and searched for clues also ("Reading and searching for clues"), and finally when they were "Searching for clues only." A "Reading and searching for clues" action example is presented in Table 2. Children scroll down the text and one of them states in the end of this action that they were unable to find a clue. When children search only for clues without paying attention to the information we observe rapid scrolling. A clear indication that they have already found all the clues is when children read only the information.

Other actions defined in our study were related to the dialogue between the children and the researcher aimed to overcome difficulties in using the application or understanding the rules-roles of the activity. Typologies where also introduced to describe the interaction between children related to the next step in the procedure (…"*Should we go there? …ok")* and the exchange of thoughts about the solution of the activity (…*"Well, tell me, the first clue is? …He could spy the Turkish army"…).* In the third level of analysis, patterns identified concerning the evolution of the procedure.

Clearly, the basic goals of the activity as described previously in this section have been fulfilled. Data analysis indicated that children were highly motivated by the activity and collaborated in order to achieve their goal. As derived from the analysis, the teams adopted different strategies to accomplish the task. Collaboration was observed mainly while making the choice of the next exhibit to be examined. After completing the task of finding the clues, the two teams collaborated more closely. They divided the work needed to find the exhibit described by the clues and looked in different parts of the room while collaborating and sharing their thoughts and suppositions. They used the clues as information filters thus eliminating the ones that did not match. Additionally, the learning result of this activity, as derived from subsequent students' essays describing the visit experience, was a deeper understanding of the historical role of the persons represented in the exhibits and their interrelations.

CONCLUSION AND FUTURE WORK

This chapter attempted to present current design approaches for mobile learning applications in the context of a museum visit. In addition, thorough study of similar approaches took place, which lead to useful design patterns and guidelines. As discussed, design of mobile learning systems, is not a straightforward process. In addition to the challenge of integrating the concept of context into the design process and independently from context conceptualization, a comprehension of pedagogical goals, desired learning transfers, user typical needs and objectives should take place. We argue that proper design decisions should take into account a solid theoretical cognitive framework, as well as the special characteristics of the mobile devices used and the challenges

of such an informal learning setting. A suitable activity should be properly supported by adequate interaction models, deeper understanding of the tasks involved to carry out the activity as a whole and their expectations while carrying out specific actions. For this reason, further validation of our proposed activity, took place in the actual museum. The activity was enjoyed by the students and enhanced their motivation to learn more about the cultural and historical context represented by the exhibits. The latter challenge has been better illustrated while discussing our experience of designing a collaborative learning activity in a cultural history museum and a case study validating its usefulness.

Clearly, the future of learning technology in museums lies in the blending, not the separation, of the virtual and the real world. That is because learning in a museum context could be conceived as the integration, over time, of personal, socio-cultural, and physical contexts. The physical setting of the museum in which learning takes place mediates the personal and socio-cultural setting. The so called 'interface transparency' should be treated as an effort to seamlessly integrate the computational device to our natural environment. This goal could be achieved by augmenting physical space with information exchanges, allowing collaboration and communication, enhancing interactivity with the museum exhibits and by seamless integrating instantly available information delivered in various forms. However, the synergy between technology and pedagogy is not straightforward, especially if we take into account the need to tackle issues such as efficient context integration, transparent usage of PDA, and novel pedagogical approaches to exploit the capabilities of the mobile devices. Therefore, further research effort should take place to experience established methods and practices.

KEY TERMS

Activity Theory: Is a psychological framework, with its roots in Vygotsky's cultural-historical psychology. Its goal is to explain the mental capabilities of a single human being. However, it rejects the isolated human being as an adequate unit of analysis, focusing instead on cultural and technical mediation of human activity.

Context: Context is any information that can be used to characterize the situation of an entity. An entity is a person, place, or object that is considered relevant to the interaction between a user and an application, including the user and applications themselves (Dey, 2001).

Context-Aware: The ability to sense context.

Interaction Design: Interaction design is a sub-discipline of the design notion which aims to examine the role of embedded behaviors and intelligence in physical and virtual spaces as well as the convergence of physical and digital products. In particular, interaction design is concerned with a user experience flow through time and is typically informed by user research design with an emphasis on behavior as well as form. Interaction design is evaluated in terms of functionality, usability and emotional factors.

Mobile Device: A device which is typically characterized by mobility, small form factor and communication functionality and focuses on handling a particular type of information and related tasks. Typical devices could be a Smartphone or a PDA. Mobile devices may overlap in definition or are sometimes referred to as information appliances, wireless devices, handhelds or handheld devices.

Mobile Learning: Is the delivery of learning to students who are not keeping a fixed location or through the use of mobile or portable technology.

Museum Learning: A kind of informal learning which is not teacher mediated. It refers to how well a visit inspires and stimulates people into wanting to know more, as well as changing how they see themselves and their world both as an individual and as part of a community. It is a wide concept that can include not only the design and implementation of special events and teaching sessions, but also the planning and production of exhibitions and any other activity of the museum which can play an educational role.

This work was previously published in Handbook of Research on User Interface Design and Evaluation for Mobile Technology, edited by J. Lumsden, pp. 253-269, copyright 2008 by Information Science Reference, formerly known as Idea Group Reference (an imprint of IGI Global).

Chapter 8.7
Component Agent Systems:
Building a Mobile Agent Architecture That You Can Reuse

Paulo Marques
University of Coimbra, Portugal

Luís Silva
University of Coimbra, Portugal

ABSTRACT

One central problem preventing widespread adoption of mobile agents as a code structuring primitive is that current mainstream middleware implementations do not convey it simply as such. In fact, they force all the development to be centered on mobile agents, which has serious consequences in terms of software structuring and, in fact, technology adoption. This chapter discusses the main limitations of the traditional platform-based approach, proposing an alternative: component-based mobile agent systems. Two case studies are discussed: the JAMES platform, a traditional mobile agent platform specially tailored for network management, and M&M, a component-based system for agent-enabling applications. Finally, a bird's eye perspective on the last 15 years of mobile agent systems research is presented along with an outlook on the future of the technology. The authors hope that this chapter brings some enlightenment on the pearls and pitfalls surrounding this interesting technology and ways for avoiding them in the future.

INTRODUCTION

A mobile agent (Chess et al., 1994; White, 1996) is a simple, natural and logical extension of the remote distributed object concept. It is an object with an active thread of execution that is capable of migrating between different hosts and applications. By using mobile agents, the programmer is no longer confined to have static objects and perform remote invocations but can program the objects to move directly between applications. In itself, a mobile agent is just a programming

abstraction: an active object that can move when needed. It is a structuring primitive, similar to the notion of class, remote object, or thread.

Two possible approaches for the deployment of mobile agents in distributed applications are:

a. To use a middleware platform that provides all the mechanisms and support for the execution of mobile agents. The basic characteristic of platform-based systems is that there is an infrastructure where all agents execute. This infrastructure typically corresponds to a daemon or service on top of which the agents are run. All agents coexist on the same infrastructure. When the programmer develops an application, he is in fact modeling different mobile agents, which execute on the platform. Typically, this is done by extending a `MobileAgent` class or a similar construct. In fact, some of the mobile agents may not even be mobile but just static service agents interfacing with other functionalities of the system. Examples include, among others, the SOMA platform (Bellavista, Corradi, & Stefanelli, 1999), D'Agents (Kotz et al., 1997), Ajanta (Tripathi et al., 2002), Aglets (Aglets Project Homepage, 2006; Lange & Oshima, 1998), and JAMES (Silva et al., 1999). This is by far the most common approach.
b. An alternative approach is to provide the support for mobile agents as software components that can be more easily integrated in the development of applications. This approach is followed by the M&M project (Marques, 2003), described in this chapter.

In this chapter, we present the results of two major projects that have been conducted in our research group: JAMES and M&M.

The **JAMES** platform was developed in collaboration with SIEMENS and consisted of a traditional mobile agent platform especially optimized for network management applications. Our industrial partners used this platform to develop some mobile agent-based applications that were integrated into commercial products. These applications used mobile agents to perform management tasks (accounting, performance management, system monitoring, and detailed user profiling) that deal with very large amounts of data distributed over the nodes of GSM networks. With this project, we learned that this technology, when appropriately used, provides significant competitive advantages to distributed management applications.

The main motivation for the second project, M&M, was to facilitate the development process and the integration of mobile objects within ordinary applications. M&M abandoned the classic concept of mobile agent platforms as extensions of the operating system. Instead, this middleware is able to provide for agent mobility within application boundaries, rather than within system boundaries. Its objective was to demonstrate that it is possible to create an infrastructure such that the mobile agent concept can be leveraged into existing object-oriented languages in a simple and transparent way, without interfering in the manner in which the applications are normally structured. In order to achieve this goal, a component-oriented framework was devised and implemented, allowing programmers to use mobile agents as needed. Applications can still be developed using current object-oriented techniques but, by including certain components, they gain the ability to send, receive, and interact with agents. The component palette was implemented using the JavaBeans technology and was, furthermore, integrated with ActiveX (Box, 1997; Denning, 1997), allowing programmers from any programming language that supports COM/ActiveX to take advantage of this paradigm. To validate the soundness of the approach, a large number of applications have been implemented using M&M. Two application domains were of particular interest: agent-enabling web servers (Marques, Fonseca, Simões, Silva,

& Silva, 2002a) and disconnected computing (Marques, Santos, Silva, & Silva, 2002b).

The rest of the chapter is organized as follows:

- In the **Background** section, a general introduction to platform-based systems for mobile agents is presented, followed by a case study: the JAMES platform;
- Then, in the **Component-Based Mobile Agent Systems** section, an alternative model is discussed, based on binary software components. In particular, it addresses some of limitations of the platform-based approach, presenting the M&M case study and its implications;
- The next section gives a **Bird's Eye Perspective** on the state of mobile agent technology;
- Finally, the last section presents the **Conclusion** and an outlook on the future of mobile agent technology.

BACKGROUND

Mobile Agent Platforms

The foundation for most platform-based systems is a server that sits on top of the operating system and where all agents execute. The platform is responsible for housing the agents and for providing every single feature needed by them and their surrounding environment (Delamaro, 2002; Marques, Simões, Silva, Boavida, & Gabriel, 2001). It provides functionalities like migration support, naming, security, inter-agent communication, agent tracking, persistence, external application gateways, platform management, and fault-tolerance. In fact, the agent platform plays the role of the "operating system of agents."

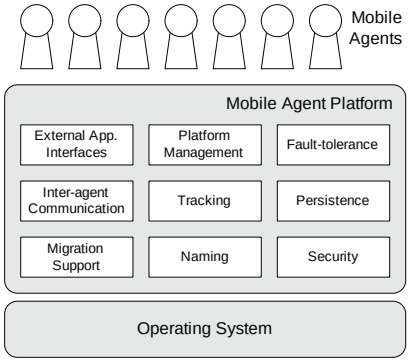
This list of supported features in an agent platform is by no means complete. Many application-specific domains have specific requirements. This leads to domain-specific implementations, having special features to address domain-specific requirements. Examples include: the JAMES platform (Silva et al., 1999), for telecommunication applications; aZIMAS (Arumugam, Helal, & Nalla, 2002) for supporting mobile agents in web servers; SOMA (Bellavista, 1999) for interoperability and integration with CORBA.

Figure 1 presents the typical architecture of such a system. As said, the operating system sits on the bottom. In the middle, there is the agent platform where all the agents execute. On the top, there are the agents belonging to all applications. This last point is especially important. Since all agents execute on top of the platform, usually all the agents from all applications can see each other. Although agents/applications can be divided into namespaces, as it happens in some platforms, and security permissions can be configured for proper access, in most cases the notion of application is quite weak or even inexistent.

In terms of programming model, in most platforms, the only support provided for application development is around the concept of mobile agent. Everything becomes a mobile agent, even entities that are conceptually services or gateways. Typically, inter-agent communication mechanisms are used to allow interactions between the different parts of the system. Some authors even refer to the concept of "whole application as a mobile agent" as the *fat-agent model* (Simões, Reis, Silva, & Boavida, 1999).

In Figure 2, this concept is illustrated. The developers have implemented two different applications, A and B, which in practice are just a set of mobile agents. True mobile agents are represented as white pawns. Black pawns represent static entities that are programmed as mobile agents due to the lack of proper infrastructure for application development. The interactions are fully based on inter-agent communication mechanisms. The concept of application is largely based on conventions about which agents communicate with what. Interestingly, many times there is even the

Figure 1. The mainstream mobile agent platform architecture



need to set up agents with special interfaces (and permissions) that are able to communicate with external applications via inter process communication (IPC) mechanisms. As strange as it seems, it is not uncommon for the only IPC mechanism available to provide integration with external entities to be a socket connection. It is also common for the agent platform to mediate all the access to operating system resources, especially if support for security is provided by the platform.

Developing distributed applications based on mobile agent systems has important advantages over the traditional client-server type of interactions. Mobile agents allow, among other things (Lange & Oshima, 1999), for: *reduced network traffic*, *easy software upgrading on-demand*, *easy introduction of new services in the network*, *higher robustness for the applications*, *support for disconnected computing*, *higher scalability*, *easy integration of vendor-proprietary systems*, and *higher responsiveness in the interactions with other systems.*

The JAMES Platform

In 1998, realizing the importance and advantages of using mobile agents in distributed systems, a consortium was setup for developing a mobile agent platform oriented for the development of applications in the field of telecommunication and network management. The project was called JAMES, and its partners were the University of Coimbra (Portugal), SIEMENS S.A. (Portugal), and SIEMENS AG (Germany); the being was implemented under the umbrella of a European Eureka Program (Σ!1921).

The JAMES platform provides the running environment for mobile agents. There is a distinc-

Figure 2. Applications on a standard agent platform are implemented as different mobile agents that map all the required functionality

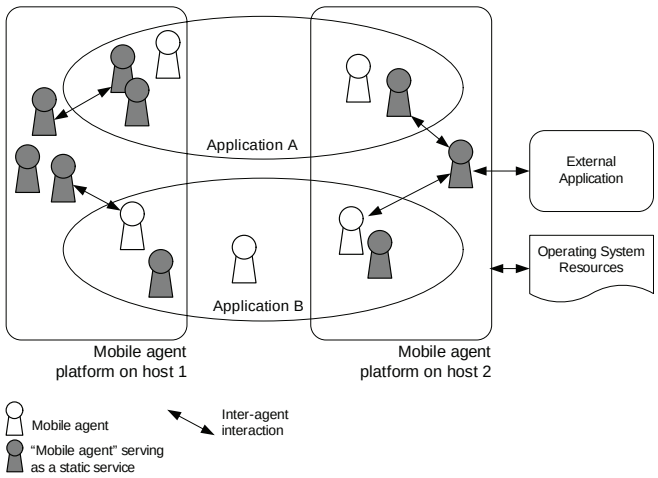


Figure 3. An overview of the JAMES platform

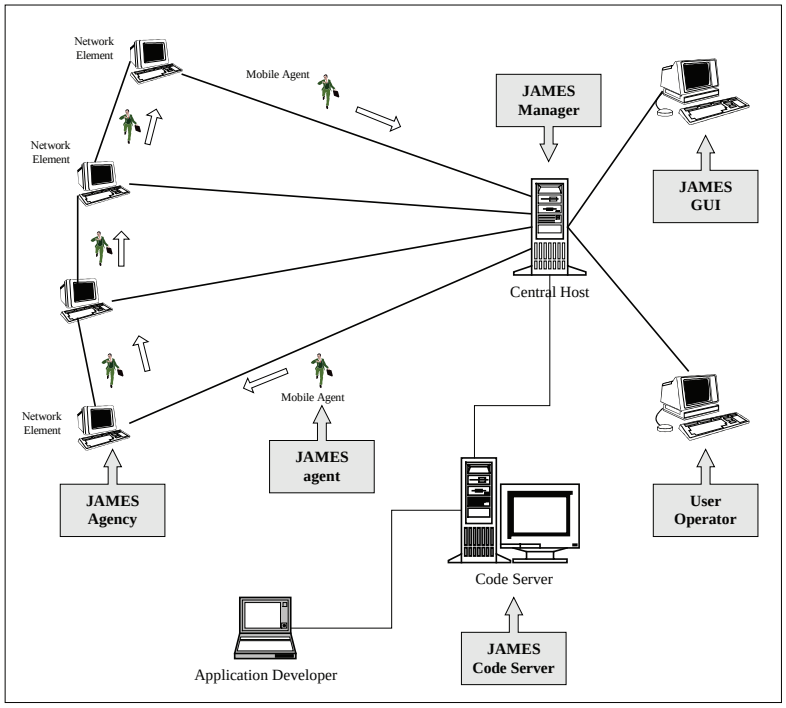


tion between the software environment that runs in the manager host and the software that executes in the network elements (NEs): the central host executes the JAMES manager while the nodes in the network run a JAMES agency. The agents are written by application programmers and execute on top of that platform. The JAMES system provides a programming interface that allows the full manipulation of mobile agents. Figure 3 presents a global snapshot of the system, with a special description of a possible scenario where the mobile agents will be used.

Every NE runs a Java virtual machine and executes a JAMES agency that enables the execution of the mobile agents. The JAMES agents will migrate through these machines of the network to access some data, execute some tasks, and produce reports that will be sent back to the JAMES manager. There is mechanism of authentication in the JAMES agencies to control the execution of agents and to avoid the intrusion of non-official agents. The communication between the different machines is done through stream sockets. A special protocol was developed to transfer the agents across the machines in a robust way and is atomic to the occurrence of failures.

The application developer writes the applications that are based on a set of mobile agents. These applications are written in Java and should use the JAMES API for the control of mobility. After writing an application, the programmer should create a JAR with all the classes that make part of the mobile agent. This JAR file is placed in a JAMES code server. This server can be a different machine or in the same machine where the JAMES manager is executing. In both cases, it maintains a code directory with all the JAR files

available and the mapping to the corresponding mobile agents.

The host machine that runs the JAMES manager is responsible for the whole management of the mobile agent system. It provides the interface to the end-user, together with a graphical user for the remote control and monitoring of agents, places, and applications. The JAMES GUI is the main tool for management and administration of the platform. With this interface, the user can manage all the agents and agencies in the system.

For lack of space we will not describe the inner details of the JAMES platform. However, in the following list we present the key features of our mobile agent system:

- Portability of the applications, through the use of the Java language;
- High-performance in mobility through the use of caching and prefetching techniques;
- Security mechanisms for code authentication;
- Resource control service to manage the use of underlying resources;
- An overview of the JAMES Platform (CPU, memory, disk and operating system resources);
- System monitoring;
- Fault-tolerance through the use of checkpointing and reconfiguration;
- Easy-to-use programming interface;
- Scalable execution of mobile agents, through the use of decentralized protocols;
- Easy customization of the software;
- "On-the-fly" software upgrading;
- Interoperation with classical network management protocols, like SNMP;
- Distributed management and easy configuration of the network;

The result of this platform was further exploited by the industrial partners that have developed some applications for performance management in telecommunications networks using mobile-agent technology and the JAMES platform.

COMPONENT-BASED MOBILE AGENT SYSTEMS

Introduction

Having completed the JAMES project, several important lessons were learned. Possibly the most important was that using a *mobile agent platform* as middleware seriously limits the acceptance of mobile agents as a structuring and programming paradigm. The problem is not the mobile agents by themselves but the use of monolithic platform for developing and deploying them. Platforms force the programmer to adopt a completely different development model from the one in mainstream use (object-oriented programming). When using an agent platform, the programmer is forced to center its development, its programming units, and its whole applications on the concept of agent. Although useful and relatively simple to implement, the use of platforms limit the acceptance of mobile agents as simple programming constructs (Kotz, Gray, & Rus, 2002).

In this section, we start by exploring how traditional mobile agent platforms limit the acceptance of mobile agents as a structuring primitive, and then we present M&M, an agent system specifically for overcoming those limitations.

Limitations of the Platform-Based Model

The reasons why the platform architecture limits the acceptance of the mobile agent paradigm can be seen from three perspectives: the programmer, the end-user, and the software infrastructure itself.

The Programmer

One fundamental aspect of the mobile agent paradigm is that, by itself, it does not provide more functionality than what is attainable with the traditional client/server model. One of the major advantages of the mobile agent paradigm is that *logically* (i.e., without considering its physical implementation), its functionalities as a whole and as a structuring primitive—*an active thread of execution that is able to migrate*—are particularly adapted for distributed computing (Papaioannou, 2000). Mobile agent technology, in itself, has no killer application (Chess et al., 1994; Kotz et al., 2002).

Taking this into consideration, a relevant question is: What strong reason can motivate a programmer to consider using mobile agents to develop its applications? After all, everything that can be attained by using mobile agents can be done using client/server. The most important reason, as discussed before, is that a mobile agent is a logical structuring primitive very adapted for distributed computing. Still, for it to be accepted, the price to be paid by the programmer cannot be too high. With traditional agent platforms, typically it is.

The problems include: the mobile agent concept is not readily available at the language level; the applications have to be centered on the mobile agents; and a complicated interface between the agents and the applications and operating system resources must be written. The programmers want to develop their applications as they currently do, by using object-oriented techniques, and by using mainstream APIs. Agents will typically play a small role on the application structuring. Current platforms force exactly the opposite. Instead of being middleware, agents are the *frontware*.

If one looks at history, it is easy to understand that the RPC success is due to its strong integration with structured programming environments. RPCs did not force programmers to abandon their programming languages, environments, and methodologies. On the contrary, RPCs embraced them. Understandably, if the RPC model had required completely different languages and methodologies, it would have failed. Programmers would have continued to use sockets. After all, everything that can be done using an RPC can be done using a socket, granted that it is so with different degrees of difficulty. The argument also applies to RMI and its integration with object-oriented languages. Remote method invocation did not require different languages or environments but instead blended into existing systems. In both cases, developers started to use the new technologies because: (a) they were readily integrated at the language level and into their programming environments; (b) the applications could continue to be developed using the existing methodologies and only use the new technologies as needed; c) no workarounds were necessary for integrating with existing applications.

The point is that mobile agent technology should not necessarily force complete agent-based software design. It should be a complement to traditional object-oriented software development and easily available to use in ordinary distributed applications, along with other technologies.

The End-User

From the viewpoint of the user, if an application is going to make use of mobile agents, it is first necessary to install an agent platform. The security permissions given to the incoming agents must also be configured, and the proper hooks necessary to allow the communication between the agents and the application must be setup. While some of these tasks can be automated by using installation scripts, this entire setup package is too much of a burden.

Usually, the user is not concerned with mobile agents nor wants to configure and manage mobile agent platforms. The user is much more concerned with the applications than with the middleware they are using in the background. In

the currently available mobile agent systems, the agents are central and widely visible. They are not the background middleware but the foreground applications.

Also, the term *mobile code* has very strong negative connotations, which makes the dissemination of mobile agent technology difficult. The user is afraid of installing a platform capable of receiving and executing code without its permission. This happens even though the existence of mobile code is present in technologies like Java, in particular in Applets, RMI, and JINI. The fundamental difference is that in those cases, the user is shielded from the middleware being used. In many cases, using mobile agents does not pose an increased security threat, especially if proper authentication and authorization mechanisms are in place. However, because the current agent platforms do not hide the middleware from the user, the risk associated with the technology is perceived as being higher than it is. This causes users to back away from applications that make use of mobile agents.

The Software Infrastructure

One final limitation of the platform-based approach lies in the architecture itself. Generally speaking, there are very few platforms that provide means for extensibility. Typically, the platform is a monolithic entity with a fixed set of functionalities. If it is necessary to provide new functionality, for instance, a new inter-agent communication mechanism, that functionality is directly coded into the platform. What this means is that if there are new requirements or features to be supported, it is necessary to recompile the whole platform and deploy it in the distributed infrastructure. This lack of support for system extensibility has several important consequences.

The first important consequence is management costs. As the name indicates, the *platform* is a software infrastructure that must be managed and attended at all times. Currently, when an operator deploys an agent-based application, it does not gain just one new application to administrate. Besides the application, it gains a full-blown agent platform to manage. This type of cost is not negligible. For instance, it is curious to observe how sensitive the network management and telecommunications communities are to management costs, even though they are amongst the ones that can most benefit from the use of this technology (Picco, 1998; Simões, Rodrigues, Silva, & Boavida, 2002).

Another facet of the monolithic structure of the agent platform problem has to do with changing requirements. It is well known in the software industry that the requirements of applications are constantly changing. In fact, this knowledge has motivated a whole series of software methodologies that take this into account, as rapid development (McConnell, 1996) and eXtreme programming (Beck, 1999). In most of the current agent platforms, each time a feature is added or an error corrected, the software is recompiled, originating a new version. Although it is quite simple to upgrade an application based on mobile agents—it may be as simple as to kill the agents and send out new ones—the same does not happen to the agent infrastructure. When there is a new version of the agent infrastructure, it is necessary to manually redeploy it across the distributed environment.

Even though it is easy to devise code-on-demand solutions for the complete upgrade of agent platforms or to use server-initiated upgrades, as in the case of JAMES (Silva et al., 1999), most existing platforms do not provide for it. In many cases, the cost of redeploying the software across the infrastructure may be unacceptable. This is a second type of management cost that must be paid. In terms of deployment, it would be much more appealing to have an infrastructure where parts could be plugged in, plugged out, and reconfigured as necessary. Voyager (Glass, 1997), MOA (Milojicic, Chauhan, & la Forge, 1998), and gypsy (Lugmayr, 1999) provided the first experi-

ments in this area, though, due to the monolithic architecture of most platforms, this type of solution is not readily available for them.

The M&M Agent System

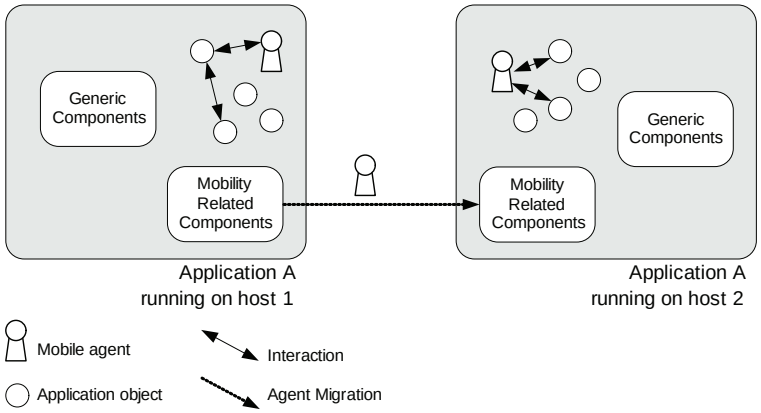
The most distinctive characteristic of M&M is that there are no agent platforms. Instead, the agents arrive and depart directly from the applications they are part of. The agents exist and interact with the applications from the inside, along with the other application objects.

The applications become agent-enabled by incorporating well-defined binary software components into their code. These components give them the capability of sending, receiving, and interacting with mobile agents. The applications themselves are developed using the current best-practice software methods and become agent-enabled by integrating these "mobility components," that is, M&M framework components. We call this approach ACMAS—*application centric mobile agent systems*—since the applications are central and mobile agents are just part of the system playing specific roles.

The key idea is that the different functionality typically found on a monolithic agent platform is factored out as independent pluggable components that can be added or removed from the applications. No underlying agent platform is involved. In Figure 4, the approach is shown. Here, an application is being run on two different hosts. This application was built by using object-oriented programming and by incorporating generic components, like the ones that provide easy database connectivity or graphics toolkits, and mobility-related components, as the ones that provide migration support and agent tracking. Agents are able to migrate between applications by using the mobility-related components.

Comparing this model with the platform-based architecture, it is quite clear that the applications are no longer a set of agents. In this approach, when inside an application, an agent is just another object that has an associated thread of execution. The agents are just like any other objects of the application. Different applications incorporate the specific components necessary for their operation, executing them side-by-side. Another advantage of this approach is that agents can be specific to their applications, not having all the agents from all the applications coexisting together.

Figure 4. The applications become agent-enabled by incorporating well-defined binary components



The M&M Component Palette

When developing an application by using the ACMAS approach, three different types of components are involved: generic third-party off-the-shelf components; application-specific components; and mobile agent-related components (see Figure 5):

- **Third-party off-the-shelf components** are components that are commercially available from software makers. Currently, there is a large variety of components available for the most different things, like accessing databases, designing graphical user interfaces, messaging, and others. All these components can be used for building the applications without having to re-implement the required functionalities.
- **Domain-specific components** are modules that must be written in the context of the application domain being considered, providing functionalities not readily available off-the-shelf. For instance, while implementing a particular application, it may be necessary to write special parsers for extracting information from files or to write supporting services for allowing agents to monitor the hardware of a machine. These modules can be coded as components and incorporated into the application.
- **Mobile agent-related components** provide the basic needs in terms of mobile-agent infrastructure. These components provide the functionalities typically found in agent platforms: mobility support, inter-agent communication mechanisms, agent tracking, security, and others. The M&M component palette fits into this category.

When writing an application, the programmer assembles the necessary components and interconnects them by using programmatic glue. The application logic that mandates the execution of the program can be a separate module or be embedded in the wiring of the components. Typi-

Figure 5. Applications are created by assembling the necessary components

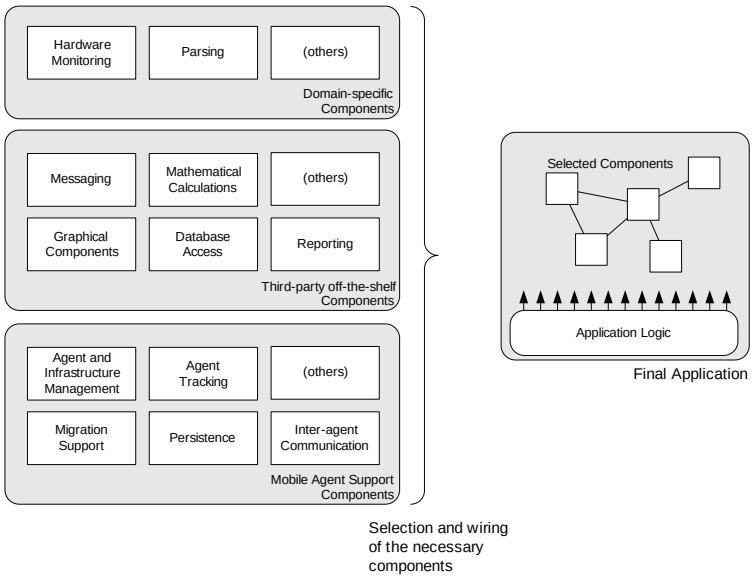


Table 1. Available components in the M&M component palette

Component(s)	Functionality
Mobility component	Provides the basic support for agent mobility, agent control, and monitoring. It incorporates an extensibility mechanism that allows other components to interact with the mobile agents.
Management components	Allows agents and the instantiated components to be monitored and controlled locally and remotely by applications and by administrative agents.
Agent tracking components	Allows the agents, local, and external applications to know the location of each agent in the distributed application.
Security component	Allows agents to safely execute inside the applications and for the applications to safely execute the agents. It is responsible for the provision of authentication and authorization services, and of monitoring and controlling what operations each agent is allowed to perform.
Local communication components	Supports message exchange between agents and applications or other agents, in the context of a single running application, using several paradigms (message passing and publisher-subscriber, both synchronously and asynchronously).
Global communication components	Allows the agents and the applications to exchange messages using several paradigms (message passing and publisher-subscriber, both synchronously and asynchronously), in the global context of a distributed application.
Disconnected computing components	Provides support for disconnected computing, allowing agents to be saved into persistent storage if they are not able to migrate to a disconnected device, and to migrate when the device comes back online. Persistent storage is also implemented as a separate component.
Web publishing components	Allows agents that migrate to a Web server to publish information and act as Web resources.

cal examples of the former are backend database and transaction processing applications; examples of the latter are form-based applications for data entering and querying. The final application is the combination of components, wiring glue, and backend application logic.

When considering a component palette for supporting mobile agents, two different aspects must be considered. On the one hand, there are components that are integrated into the application, giving it special abilities in terms of interacting with mobile agents. One example of this is a component that gives the application the ability to track the agents whenever they migrate.

On the other hand, when programming the mobile agents themselves, there are components that can be used for building them, for instance, a component that when included in a mobile agent gives it the ability to communicate with other mobile agents. Currently, the M&M framework supports both types.

Thus, when discussing the component palette of M&M, presented in Table 1, it is important to realize that there are components for including

into the applications and components for including into agents. In fact, some of the components can even be used for both purposes (e.g., the client components of inter-agent communication).

Another important point is that sometimes the components do not implement the full functionality of a service and serve only as access points to certain functionalities. For instance, the client component for agent tracking connects to a network server that holds and updates the location of the agents. It should be noted that the M&M component list is by no means static or fixed. The M&M framework has well-defined interfaces that allow third-party developers to create new components and add them to the system and to upgrade existing components. In fact, M&M somewhat resembles a Lego system where new pieces can be created and fitted into the existing ones.

Figure 6 shows an application being created in a visual development tool and being agent-enabled by using M&M. On the left it is possible to see that the mobility component has been included; on the right, the properties of this component are shown; on the top, the M&M component palette is visible.

A detailed account of the M&M system and its implementation can be found in Marques (2003).

Consequences of Using a Component-Based Approach

Using a component-based approach for developing applications that use mobile agents has several important consequences. Some of these consequences are directly related to the characteristics of component technology, others are a product of the way M&M was designed. Some of the most important aspects are:

- **The users do not see agents or manage agent platforms:** As agents are sent back into the middleware instead of being "frontware," what the users ultimately see are applications and their interface. The adoption of a certain application is once again based on its perceived added value, not on the technology that it is using. Also, because users do not have to manage agents nor platforms, applications become conceptually simpler. No middleware infrastructure is explicitly visible to install and maintain. Although there are still distributed applications to install and manage, this is much easier than managing a separate infrastructure shared by a large number of distributed applications with different policies and requirements.
- **Tight integration with the end applications:** Since the agents can migrate from end-applications to end-applications, interacting with them from the inside, development becomes much more straightforward. There is no need to set up service agents, configure their policies, and devise workarounds based on IPCs. Once inside an application, a mobile agent is just a thread of execution that can access all the objects of that application, under proper security concerns. This contributes to better performance and scalability since the interaction with the applications does not have to go through the middlemen—the service agents.
- **Tight integration with existing programming environments:** For supporting mobile agents in an application, all the developer has to do is to include some of the components into the application and interconnect them. The applications can continue to be developed using object-oriented methodologies, having the necessary support for active migrating objects. By using M&M components in the applications, developers do not have to center all the development on the agents. Agents become just "one more" powerful distributed programming construct, as once advocated by Papaioannou (Papaioannou, 2000). What this means is that the develop-

ment model is well integrated with current software development practices and environments. The path to using mobile agents in the applications becomes as smooth as using, for instance, remote method invocation.

- **Possibility of using visual development tools:** Software components are normally designed so that they can be manipulated visually. Instead of focusing on an API approach, components emphasize on well-defined visual entities with properties and interconnections that the programmer can configure visually. This can result in a large increase in productivity, a smoother learning curve, and a wider acceptance of a technology. By using a component-based approach, M&M takes benefit of all these characteristics.
- **Support for any programming language:** It is possible to use a JavaBeans/ActiveX bridge to encapsulate JavaBeans components as ActiveX ones. Thus, in the Windows platform it is possible to use a JavaBeans component from any programming environment, as long as it supports COM/ActiveX. This was the approach taken in the M&M framework. By using such a bridge, it was possible to have applications written in several languages—Visual Basic, Visual C++, Java, and so forth—sending and receiving agents between them. Even though, from a research point of view, this might not seem so important, from an integration and acceptance point of view it is quite important: It is directly related to whether a technology gets to be used or not.
- **Security can be integrated into the application:** One of the valuable lessons learned when designing the Internet was the importance of the end-to-end argument in system design (Saltzer, Reed, & Clark, 1984). There is a fragile balance between what can be offered generically by an infrastructure and what should be left to the application design on the endpoints. In terms of security, this is especially important. In many cases, it is only at the end applications, and integrated with the application security policies and its enforcement, that it is possible to take sensible security decisions. By using components directly integrated into the applications, the security of the mobile agents of an application becomes integrated with the security policies of the application itself.
- **Only the necessary components are included in each application:** Because the developer is implementing its application and only using the necessary features of mobile code, only the required components that implement such features need to be included. What this means is that it is not necessary to have a gigantic platform that implements every possibly conceivable feature, because in the end many of these features are not used in most applications. By using specific components it is possible to build a software infrastructure that is much more adapted to the needs of each specific application.
- **Extensibility and constant evolution:** In the last section it was discussed how "changing requirements" are an important problem and how monolithic platforms are ill-equipped to deal with new features, new releases, and redeployment. By using a component-based approach, it is possible to continually implement new components, with new features and characteristics, without implying the rebuilding of a new version of "the platform." The component palette can always be augmented.
- **Reusability and robustness:** One of the acclaimed benefits of using components is their tendency to become more robust over time. As a component is more and more reused in different applications, more errors are discovered and corrected, leading

to new and more robust versions. Because components are black boxes with well defined interfaces and functionalities, they are also easier to debug and correct. By using a component-based approach to implement a mobile agent framework, it is also possible to benefit from these advantages.

Overall many applications have been implemented using M&M accessing its usefulness, easy of use, and close integration with programming environments and software. In this context, two application domains were of particular interest: agent-enabling web servers and supporting disconnected computing.

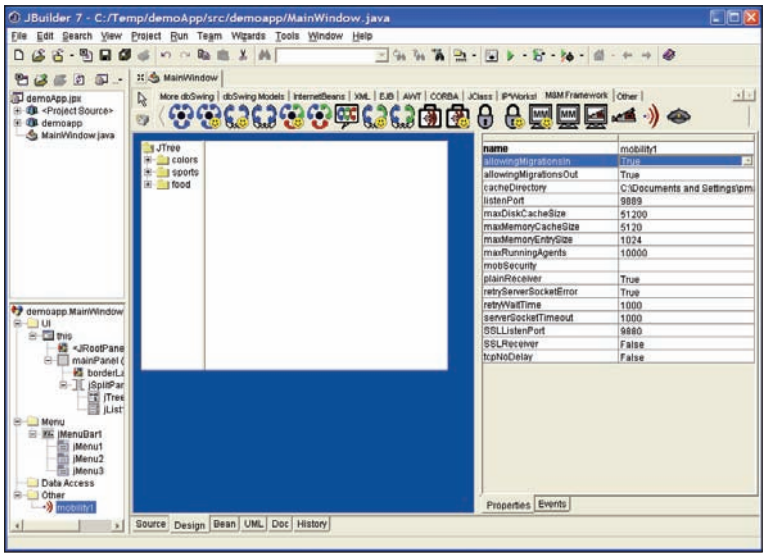
- The M&M component framework allows any Web server that supports the *servlet specification* to send, receive, and use mobile agents. M&M provides a clean integration, requiring neither a custom-made Web server nor a special purpose agent platform. A full account of this exploration can be found in Marques et al. (2002a).
- Finally, supporting disconnected computing has allowed us to understand the current limitations of the framework in supporting very low-level operations. This account can be found in Marques et al. (2002b).

A BIRD'S EYE PERSPECTIVE

Over the years, there has been a huge proliferation of mobile agent platforms. In fact, already in 1999 there were 72 known platforms. Nevertheless, the technology is still far from common use by mainstream programmer and, oddly as it seems, there now seems to exist more agent platforms than mobile agent-based applications.

In the previous sections, we have discussed how the agent platform architecture seriously impairs the actual leverage of the mobile agent paradigm into real applications, by real programmers, to real users. The paradigm does not bring a "one order of magnitude" increase in functionality, and at the same time, the agent platform architecture imposes a too-high price

Figure 6. Screen capture of the M&M component palette being used for developing a demonstration application



to developers, users, systems administrators, and institutions that could make use of the technology. The road imposed by the platform architecture is not one of integration with existing tools and environments but one of complete conversion to a new architecture. This conversion is asked for without giving anything substantial enough in return, and imposing many limitations on what can be implemented and how.

About the Proliferation of Mobile Agent Platforms

In our view, the huge proliferation of mobile agent platforms is directly connected with two factors: (a) the monolithic nature of agent platforms; (b) the advent of the Java language.

When considering different application fields, each one has its specific requirements. For instance, in the network management area, an important requirement is integration with SNMP. In other domains, there are others. Because in most cases it is not possible to extend a generic agent platform to take into account the needs of a certain application domain, what has happened is that researchers, and in fact the industry, have developed many new agent platforms that try to address specific domains. The Java language made it extremely easy to develop basic infrastructures for object and thread mobility, and thus to experiment in this area. In most cases, these platforms were developed from scratch.

The problems with these platforms are: they are not reusable across domains (many times not even across problems in a single domain); they do not take into account results in research (e.g., how to properly implement agent tracking or fault-tolerance); and, because in many cases they are quite experimental, they lack the robustness needed to be usable in the real world. The result is the current huge number of platforms that are not used by anyone and a large disappointment with the mobile agent paradigm.

The Mobile Agent Community

Another important problem is that the mobile agent community is too biased on the platform architecture, and little concerned with its integration with existing systems and infrastructures. This strong bias is easy to observe in practice. For instance, when looking at standards for mobile agents systems such as MASIF (OMG, 2000), from the Object Management Group, and FIPA (FIPA, 2000; FIPA, 2002), from the Foundation for Intelligent Physical Agents, it can be seen that the standardization effort was done around the concept of "agent platform", the platform on top of which all agents *should* execute. Neither alternative execution models nor any provisioning for integration with existing programming environments were considered.

Curiously, two of the most respected researchers in the area of intelligent agents—Nick Jennings and Michael Wooldridge—have long been arguing about the dangers of trying to leverage agents into the market. In the classic article *Software Engineering with Agents: Pitfalls and Pratfalls* (Wooldridge & Jennings, 1999), they examine what has been happening in the intelligent agent community. But, in fact, the observations also apply to the mobile agent community. Some of the key lessons from their experience are: "*You oversell agents*," "*You ignore related technology*," "*You ignore legacy*," "*You obsess on infrastructure*," and "*You see agents everywhere*". These are all relevant points if one wants to bring the mobile agent paradigm into real-world programming environments.

This view is somewhat supported by the success of Voyager (Glass, 1997) when compared with other agent infrastructures. Voyager is not a mobile agent platform but an ORB that, among other things, is also able to send and receive agents. Voyager does not force everything to be centered on agents, nor forces the applications to be agents. Applications are developed using ordinary methods and can use Voyager as an ordinary ORB. In

practice, what has happened is that programmers who were using Voyager as a commercial ORB understood that they also had support for sending and receiving "active threads." Not having any prejudice, they started using this facility. Users continued to see applications as they always had, and system administrators did not gain complex agent platforms to manage.

Security

Security is traditionally singled out as the biggest problem facing mobile agents, and that prevented their dissemination as a paradigm. The idea of having arbitrary code that can execute on a host can be a scary one. There is the danger of resource stealing, denial-of-service attacks, data spying, and many other problems (Farmer, Guttman, & Swarup, 1996; Greenberg, Byington, & Harper, 1998).

Even so, although there are still some hard problems to be solved in a practical way, like the malicious host problem (Hohl, 1998) and proper resource control, security is probably one of the most active areas of research in mobile agent systems (e.g., Loureiro, 2001, contains an extensive survey on existing research on the topic).

When developing mobile agent applications, two different scenarios have to be considered. The first scenario consists of deploying an application that uses mobile agents in a closed environment. What this means is that it is possible to identify a central authority that controls all the nodes of the network where the agents are deployed. For example, a network operator may deploy an agent platform on its network, for being able to deliver new services in an easy and flexible way. Although different users, with different permissions, may create agents, the key point is that there is a central authority that is able to say who has what permissions and guarantee that nodes do not attack agents.

A completely different scenario is to have agents deployed in an open environment. In this picture, agents migrate to different nodes controlled by different authorities, possibly having very different goals. One classic example of this situation is an e-commerce application on the Internet. Different sites may deploy an agent platform, allowing agents to migrate to their nodes and query about products and prices, and even perform transactions on behalf of their owners. Here the sites will be competing against each other for having the agents making the transactions on their places. There is no central authority, and each site may attack the agents, stealing information from them, or making them do operations that they were not supposed to do.

Although it may appear that deploying applications on closed environments is too restrictive, there is a large number of applications that are worth deploying in such setting. Examples include network management, telecommunication applications, software distribution and upgrading, parallel and distributed processing, and groupware. For such environments, the currently available solutions are well adapted and sufficient. In many cases, it is a matter of proper authentication and authorization mechanisms, associated with a public key infrastructure.

The key argument is that although a lot of research is still necessary for securely deploying agents in open environments, there is a multitude of applications that can be developed securely for existing computing infrastructures in closed environments. On closed environments, besides the psychological effect of having code that is able to migrate between hosts, there is no additional risk when compared with existing technologies. The risks are similar to having *rexec* daemons running on machines, or using code servers in Java RMI.

In our view, the argument that it is security that is preventing the deployment of mobile agent technology is a misguided one. Many applications can be developed securely; and considering distributed systems, there are many technologies that operate without any special security considerations. That lack of security has not prevented

them from being developed or having a large user base. A classical example is SNMP.

Agent Languages: Could They Be the Solution?

Over the years, many researchers came up with new languages that express mobile processes and mobile computations directly (e.g., Visual Obliq, Cardelli, 1995; Jocaml Conchon, & Fessant, 1999; Nomadic Pict & Wojciechowski, 1999). Although these languages integrate the mobile agent paradigm at the language level and are interesting in terms of the lessons learned in expressing new abstractions, they present the same generic problem as the platform architecture.

These languages force the programmers to use completely different programming paradigms and software structuring methodologies. At the same time, because using mobile agents does not bring any large increase in productivity nor enables anything important that cannot be achieved by classical means, programmers are not compelled to try out these new languages. In fact, it does not make much sense to ask developers to abandon proven development techniques and environments in favor of new languages that do not allow anything new or powerful, have not proven themselves, and force all the development to be centered on different abstractions.

The mobile agent technology should be available at the language level, but this means that the middleware should allow the creation, management, and integration with mobile entities directly, probably through an API at the same level than other programming libraries. It means that the programmer should be able to continue to use its current programming environments, languages, and development methodologies. When necessary, and only then, it should be able to create an active thread of execution that would be able to migrate and interact with the objects on different applications. This does not mean that all the development should be centered on the agents or that new languages are really necessary.

CONCLUSION

Mobile agent research is now almost 15 years old. Many valuable lessons have been learned in areas so diverse as persistence, resource allocation and control, tracking, state capture, security, communication, coordination, and languages. Nevertheless, no killer application has emerged, and only a few commercial applications have been developed. Two standardization efforts were made and failed.

Although the mobile agent paradigm has not entered the realm of mainstream programming, the fact is that *mobile code* and *mobile state* are now mainstream programming techniques. This has happened not as most researchers would expect it to have, namely as mobile agents, but in many different and more subtle ways. Java RMI code servers are a standard mechanism in use. Java object serialization and .NET's Remoting mechanism, which are for everyday use, offer state mobility and also code mobility in certain circumstances. Remotely upgradeable software, ActiveX-enabled pages, and other forms of code and state mobility are now so common that we do not even think about them. Even mainstream undergraduate books like Coulouris, Dollimore, and Kindberg (2000) and Tanenbaum and Steen (2002) discuss code and state mobility, and even mobile agents, without any prejudice. Books that are not mobile agent-specific but are related to code mobility are available (Nelson, 1999). Mobile code and mobile state have entered the realm of distributed programming.

It is always hard and error prone to make predictions. But, quoting Kotz et. al., it is also our view that "*The future of mobile agents is not specifically as mobile agents*" (Kotz, 2002). We also do not believe that the future of mobile agents is connected to the use of agent platforms as we

know them today. That belief arises from our experiences with the JAMES and M&M systems, as presented in this chapter.

In our view, the future of mobile agents will be a progressive integration of mobile agent concepts into existing development environments. This integration will be as readily available at the API level as object serialization and remote method invocation have become. The programmer will be able to derive from a base class and with no effort have an object that is able to move between applications. That class and that object will be ordinary ones among the hundreds or thousands used in any particular application. This evolution will probably occur as the development of object serialization APIs becomes more complete, powerful, and easy to use.

ACKNOWLEDGMENT

We would like to thank to all the students and researchers that over the years worked on the JAMES and M&M systems. Also, this investigation was partially supported by the Portuguese Research Agency – FCT, through the CISUC Research Center (R&D Unit 326/97).

Chapter 8.8
Building Applications to Establish Location Awareness:
New Approaches to Design, Implementation, and Evaluation of Mobile and Ubiquitous Interfaces

D. Scott McCrickard

ABSTRACT

An emerging challenge in the design of interfaces for mobile devices is the appropriate use of information about the location of the user. This chapter considers tradeoffs in privacy, computing power, memory capacity, and wireless signal availability that accompany the obtaining and use of location information and other contextual information in the design of interfaces. The increasing ability to integrate location knowledge in our mobile, ubiquitous applications and their accompanying tradeoffs requires that we consider their impact on the development of user interfaces, leading to an agile usability approach to design borne from agile software development and usability engineering. The chapter concludes with three development efforts that make use of location knowledge in mobile interfaces.

INTRODUCTION

A key challenge in the emerging field of ubiquitous computing is in understanding the unique user problems that new mobile, wearable, and embedded technology can address. This chapter focuses on problems related to location determination—different ways to determine location at low cost with off-the-shelf devices and emerging computing environments, and novel methods for integrating location knowledge in the design of

applications. For example, many Web sites use location knowledge from IP addresses to automatically provide the user with relevant weather and traffic information for the current location. There is significant opportunity in the use of location awareness for human-computer interaction (HCI) researchers to explore information-interaction paradigms for the uncertainty and unpredictability that is inherent to many location detection systems—particularly indoor systems that use Wifi signals which can be blocked by roofs, walls, shelves, and even people!

The prior knowledge of location to make such decisions in the presentation of information affords it to be categorized as *context awareness*, the use information that can be used to identify the situation of an entity to appropriately tailor the presentation of and interaction with information to the current situation (Dey, 2001). While context awareness can include a wide variety of information—including knowledge of who is in your surrounding area, events that are happening, and other people in your vicinity—this chapter focuses on the identification and use of location information, perhaps the most cheaply and readily available type of context information. This chapter considers the tradeoffs in privacy, computing power, memory capacity, and wireless (Wifi) signal availability in building interfaces that help users in their everyday tasks. We discuss our own SeeVT system, which uses Wifi signals in location determination (Sampat, Kumar, Prakash, & McCrickard, 2005). The SeeVT system provides the backbone for supplying location information to mobile devices on a university campus. Numerous interfaces built on SeeVT provide timely and appropriate location information to visitors in key areas of the campus.

The increasing ability to integrate location knowledge in our mobile, ubiquitous applications requires that we consider its impact on the development of user interfaces. This chapter describes the merging of agile software development methods from software engineering with the scenario-based design (SBD) methodology from usability engineering to create a rapid iteration design approach that is heavy in client feedback and significant in its level of reusability. Also presented are three interfaces developed using our Agile Usability methodology, focusing on the benefits found in using the Agile Usability approach and the tradeoffs made in establishing location awareness.

BACKGROUND

From the early days, navigation has been central to progress. Explorers who set sail to explore the oceans relied on measurements with respect to the positions of celestial bodies. Mathematical and astronomical techniques were used to locate oneself with respect to relatively stationery objects. The use of radio signals proved to be fairly robust and more accurate, leading to the development of one of the first modern methods of navigation during World War II, called long range navigation (LORAN). LORAN laid the foundation of what we know as the Global Positioning System or GPS (Pace et al., 1995). Primarily commissioned by the United States Department of Defense for military purposes, GPS relies on 24 satellites that revolve around the Earth to provide precision location information in three dimensions. By relying on signals simultaneously received by four satellites, GPS provides much higher precision than previous techniques. GPS navigation is used in a wide range of applications from in-car navigation, to geographic information system (GIS)-mapping, to GPS-guided bombs.

GPS has become the standard for outdoor location-awareness as it provides feedback in a familiar measurement metric. Information systems like in-car navigators have adopted GPS as the standard for obtaining location, since it requires little or no additional infrastructure deployments and operates worldwide. However, GPS has great difficulty in predicting location

in dense urban areas, and indoors, as the signals can be lost when they travel through buildings and other such structures. With an accuracy of about 100 meters (Pace et al., 1995), using GPS for indoor location determination does not carry much value. Along with poor lateral accuracy, GPS cannot make altitude distinctions of three to four meters—the average height of a story in a building—thus making it hard to determine, for example, whether a device is on the first floor or on the second floor. Despite continued progress through technological enhancements, GPS has not yet evolved sufficiently to accommodate the consumer information-technology space. This chapter primarily focuses on technologies making inroads for indoor location determination.

While GPS has clear advantages in outdoor location determination, there have been other efforts focused around the use of sensors and sensing equipment to determine location within buildings and in urban areas. Active Badges was one of the earliest efforts at indoor location determination (Want, Hopper, Falcao, & Gibbons, 1992). Active Badges rely on users carrying badges which actively emit infrared signals that are then picked up by a network of embedded sensors in and around the building. Despite concerns about badge size and sensor deployment costs, this and other early efforts inspired designers to think about the possibilities of information systems that could utilize location-information to infer the context of the user, or simply the context of use. One notable related project is MIT's Cricket location system, which involved easy-to-install motes that acted as beepers instead of as a sensor network (Priyantha, Chakraborty, & Balakrishnan, 2000). The user device would identify location based on the signals received from the motes rather than requiring a broadcast from a personal device. Cricket was meant to be easy to deploy, pervasive, and privacy observant. However, solutions like Cricket require deployment of a dense sensor network—reasonable for some situations, but lacking the ubiquity necessary to be an inexpensive, widely available, easy-to-implement solution.

To provide a more ubiquitous solution, it is necessary to consider the use of existing signals—many of which were created for other purposes but can be used to determine location and context. For example, mobile phone towers, IEEE 802.11 wireless access points (Wifi), and fixed Bluetooth devices (as well as the previously mentioned GPS) all broadcast signals that have identification information associated with them. By using that information, combined with the same sort of triangulation algorithms used with GPS, the location of a device can be estimated. The accuracy of the estimation is relative to the number and strength of the signals that are detected, and since one would expect that more "interesting" places would have more signals, accuracy would be greatest at these places—hence providing best accuracy at the most important places. Place Lab is perhaps the most widespread solution that embraces the use of pre-existing signals to obtain location information (LaMarca et al., 2005). Using the broadcasted signals discussed previously, Place Lab allows the designer to establish location information indoors or outdoors, with the initiative of allowing the user community to contribute to the overall effort by collecting radio environment signatures from around the world to build a central repository of signal vectors. Any client device using Place Lab can download and share the signal vectors for its relevant geography—requiring little or no infrastructure deployment. Place Lab provides a location awareness accuracy of approximately 20 meters.

Our work focuses specifically on the use of Wifi access networks, seeking to categorize the benefits according to the level of access and the amount of information available in the physical space. We propose three categories of indoor location determination techniques: *sniffing* of signals in the environment, *Web-services access* to obtain information specific to the area, and *smart algorithms* that take advantage of other

information available on mobile devices. In the remainder of this chapter, we describe these techniques in more detail, and we discuss how these techniques have been implemented and used in our framework, called SeeVT using our Agile Usability development process.

CATEGORIZING INDOOR LOCATION DETERMINATION TECHNIQUES

When analyzing location awareness, it is clear that the goal is not just to obtain the location itself, but information associated with the location—eventually leading to full context awareness to include people and events in the space, as described in Dey (2001). For example, indoor location awareness attributes such as the name of the building, the floor, surrounding environments, and other specific information attributed with the space are of particular interest to designers. Designers of systems intended to support location awareness benefit not only from location accuracy, but also from the metadata (tailored to the current level of location accuracy) that affords several types of cross-interpretations and interpolations of location and other context as well.

Access to this information can be stored with the program, given sufficient computing power and memory. This approach is reasonable for small areas that change infrequently—a library or a nature walk could be examples. Information about the area can be made accessible within the application with low memory requirements and rapid information lookup. However, changes to the information require updates to the data, a potentially intolerable cost for areas where location-related changes occur frequently. For example, a reconfigurable office building where the purpose and even the structure of cubicles change frequently would not be well served by a standalone application. Instead, some sort of Web-based repository of information would best meet its needs. Taking this model another step, a mobile system could request and gather information from a wide range of sources, integrating it for the user into a complete picture of the location. As an example, a university campus or networked city would benefit from a smart algorithm that integrated indoor and outdoor signals of various types to communicate a maximally complete picture of the user's location.

Of course, each added layer of access comes with additional costs as well. Simple algorithms may sense known signals from the environment (for example, GPS and wireless signals) to determine location without broadcasting presence. However, other solutions described previously might require requesting or broadcasting of information, revealing the location to a server, information source, or rogue presence—potentially resulting in serious violations of privacy and security. The remainder of this section describes the costs and benefits for three types of indoor location determination approaches: sniffing, Web services, and smart algorithms.

Sniffing

As the name suggests, sniffing algorithms sense multiple points of a broadcast environment, using the points to interpret the location of a device. The radio environment is generally comprised of one or more standard protocols that could be used to interpret location—modern environments include radio signals including Wifi, Bluetooth, microwaves, and a host of other mediums—creating interesting possibilities for location interpolation. Sniffing is also desirable because all location interpolation and calculations are performed on the client device, eliminating the need for a third-party service to perform the analysis and produce results. As mentioned previously, there are some benefits and disadvantages to this approach.

Performing the location determination on the client device eliminates the need for potentially slow information exchange over a network. This approach gives designers the flexibility they need

in order to perform quick and responsive changes to the interfaces as well as decision matrices within their applications. For example, a mobile device with a slow processor and limited memory will need a highly efficient implementation to achieve a speedy analysis. A limiting factor for this approach is the caching of previously known radio vectors. Since most analysis algorithms require a large pool of previously recorded radio-signal vectors to interpolate location, it translates into large volumes of data being precached on the client device. A partial solution for this exists already, precaching only for regions that the user is most likely to encounter or visit. Though this is not a complete solution to the resource crunch, it is a reasonable approach for certain situations with periodic updates or fetches when radio-vectors are upgraded or the system encounters an unknown location.

Herecast is an example of a system using the sniffing model (Paciga & Lutfiyya, 2005). It maintains a central database of known radio vectors, which are then published to client devices on a periodic basis. The clients are programmed to cache only a few known locations that the user has encountered, and relies largely on user participation to enter accurate location information when they enter new areas that the system has not encountered before. The accuracy for these systems is generally acceptable, but there is always the worry of not having a cache of an area that the application is about to encounter. The lack of linking to a service also means that other contextual information associated with the location is hard to integrate with this approach due to device caching constraints and metadata volatility.

Web-Services Model

Keeping with the fundamental idea of mobile devices facing a resource crunch, this approach has client devices and applications use a central service for location determination. This means that the client device simply measures or "sees" the radio environment and reports it to the central service. The service then performs the necessary computation to interpolate the user location (potentially including other timely information) and communicates it back to the client. This also allows the client to store a minimal amount of data locally and to perform only the simplest of operations—important for mobile devices that often trade off their small size for minimal resources.

The approach is elegant in many ways, but faces several challenges in its simplistic approach such as the problem of network latency leading to lengthy times to perform the transactions. However, as the speed and pervasiveness of mobile networks is on the rise, as is the capability of silicon integration technologies for mobile platforms, designing large-scale centralized systems based on the Web-services model will be a reasonable approach for many situations. Mobile online applications such as Friend Finders and child tracking services for parents are classic examples of tools that require central services to allow beneficial functionality to the end user.

Our own SeeVT system uses the Web services model by allowing its clients to perform Simple Object Access Protocol (SOAP) Web service calls to a standard Web interface, and submit a radio vector for analysis. It then performs the necessary location determination using a probabilistic algorithm and returns the location to the client. SeeVT provides the interface designer access to functionality on the service end as well. It allows the designers to control sessions and monitor the progress of clients by using a logging feature, and provides handles to integrate other widgets as well. For example, if an application wants to perform a search based on the user's current location, SeeVT allows the designer to add functionality to its modules to perform further server-side computations.

Smart Algorithms

Looking ahead, algorithms that span large and diverse geographic areas will require the integration of many signals, information requests, and additional inputs. Place Lab attempts to address this issue for all radio signals (LaMarca et al., 2005). Currently it can compute location using mobile phone tower signals, Wifi, fixed Bluetooth devices, and GPS. However, we expect that other information will be used for location determination in the near future. For example, the ARDEX project at Virginia Tech seeks to use cameras—quickly becoming commonplace on mobile devices—to create a real-time fiducially-based system for location determination based on augmented reality algorithms (Jacobs, Velez, & Gabbard, 2006). The goal of the system is to integrate it with SeeVT such that anyone at defined hot spots can take a picture of their surrounding area and obtain information about their location. In an interesting twist on this approach, the GumSpots positioning system allows users to take a picture of the gum spots on the ground in urban areas and performs image recognition on them to return user location (Kaufman & Sears, 2006). Other information recording devices could be used in similar ways to help determine or enhance the understanding of our current location.

BUILDING INTERFACES FOR LOCATION-KNOWLEDGEABLE DEVICES

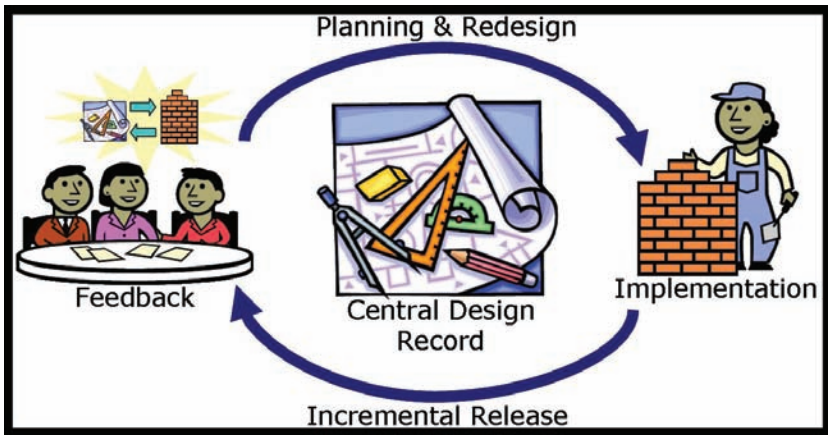
This section begins with a discussion on possible application scenarios that can leverage location knowledge in mobile devices. This section first describes *Agile Usability*, an extension of agile software development methodologies to include key aspects of usability engineering—resulting in an interface building technique that is well suited to ubiquitous and location-knowledgeable computing devices, both from the standpoint of interaction as well as development processes. Next, three case studies illustrate real world applications that have been built using these processes. Each case study describes key aspects of the application, illustrating one of the indoor location determination techniques and highlighting key lessons learned from the use of Agile Usability.

Agile Software Development, Usability Engineering, and Agile Usability

Ubiquitous and pervasive systems are often introduced to augment and support everyday tasks in novel ways using newly developed technology or by using existing technology in different ways. Since end-user needs are often ill-defined for ubiquitous systems, development needs to quickly incorporate stakeholder feedback so the systems can be iteratively improved to address new and changing requirements. This section discusses the use of an agile development methodology to build ubiquitous systems. Based on our own work (Lee et al., 2004; Lee, Chewar, & McCrickard, 2005; Lee & McCrickard, 2007) and on prior investigation of agile development methods (Beck, 1999; Constantine, 2001; Koch, 2004), we present a usability engineering approach for the construction of interfaces for mobile and ubiquitous devices.

Agile software development methodologies have been developed to address continuous requirements and system changes that can occur during the development process. They focus on quick delivery of working software, incremental releases, team communication, collaboration, nd the ability to respond to change (Beck et al., 2001). One stated benefit of agile methods is a flattening of the cost of change curve throughout the development process. This makes agile methods ideally suited to handle the iterative and incremental development process needed to effectively

Figure 1. The agile usability process. The central design record bridges interface design with implementation issues. This enables incremental improvement incorporating feedback from project stakeholders and usability evaluations.

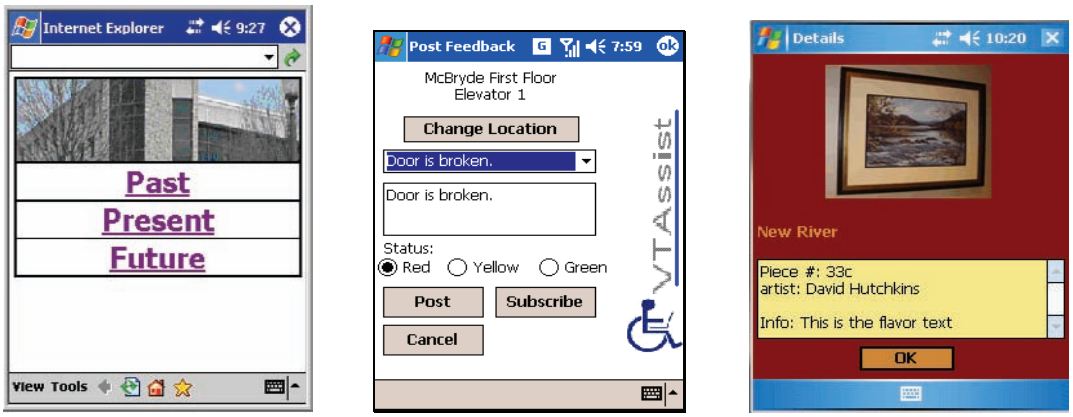


engineer ubiquitous systems. One shortcoming of many agile methods is a lack of consideration for the needs of end users (Constantine, 2001). Current agile development methodologies have on-site clients to help guide the development process and ensure that all required functionality is included. However, many ubiquitous and pervasive systems require continuous usability evaluations involving end-users to ensure that such systems adequately address their needs and explore how they are incorporated in people's daily tasks and affect their behavior. Researchers, including Miller (2005), Constantine (2001), and Beyer, Holtzblatt, and Baker (2004) have developed ways to integrate system and software engineering with usability engineering. We present our approach to agile usability engineering, henceforth referred to as Agile Usability, with the added benefit of usability knowledge capture and reuse.

Our approach combines the software development practices of extreme programming (XP) with the interaction design practices of scenario-based design (SBD) (Beck, 1999; Rosson & Carroll, 2002). The key features of this process are an incremental development process supported by continual light-weight usability evaluations, close contact with project stakeholders, an agile interface architecture model, known as a central design record (CDR), that bridges interface design and system implementation issues, and proactive knowledge capture and reuse of interface design knowledge (Figure 1).

Running a large-scale requirements analysis process for developing ubiquitous systems is not as beneficial as when designing other types of systems as it can be very difficult to envision how a ubiquitous system will be used in a specific situation or how the introduction of that system will affect how people behave or use it. In this type of development process, portions of the system are developed and evaluated by end users on a continual basis. This helps developers in uncovering new requirements and dealing with changing user needs as development proceeds. This type of development process requires some amount of discipline and rigor in terms of the types of development practices to follow. Specific details of these XP programming practices are detailed

Figure 2. Screenshots from three applications built on SeeVT. From the left, the alumni tour guide, VTAssist, and SeeVT-ART



in Beck's book on the subject (Beck, 1999). Our use of these practices are elaborated in a technical report (Lee, Wahid, McCrickard, Chewar & Congleton, 2007).

An incremental development process necessitates close collaboration with customers and end users to provide guidance on what features are needed and whether the system is usable. Ideally, representatives from these groups will be onsite with the developers working in the same team. Our customers were not strictly on site, although they were in the same general location as the developers. Regularly scheduled meetings and continual contact through e-mail and IM were essential to maintaining project velocity.

The key design representation is the central design record (CDR), which draws on and makes connections between design artifacts from XP and SBD. Stories that describe individual system features are developed and maintained by the customer with the help of the developers. They are prioritized by the customer and developed incrementally in that order. These include all features needed to develop the system including underlying infrastructure such as databases, networking software, or hardware drivers. Scenarios, which are narratives describing the system in use, are used to communicate interface design features and behaviors between project stakeholders. Claims, which describe the positive and negative psychological effects of interface features in a design, are developed from the scenarios to highlight critical interaction design features. Story identification and development may lead to changes to the scenarios and claims. The reverse may also be true. This coupling between interface design and system implementation is critical for ubiquitous systems as developers must deal with both interactional and technological issues when deploying a system to the population.

In addition to acting as a communication point between stakeholders and highlighting connections between interface design and implementation, the CDR is important as a record of design decisions. As developers iterate on their designs, they often need to revisit previous design decisions. The explicit tradeoffs highlighted in the claims can be used by developers and clients to determine how best to resolve design issues that come up. Perhaps most important, Agile Usability drives developers to explore key development techniques in the development of location-based

interfaces—the techniques used advance the field and can be reused in other situations.

Agile Usability has been applied in numerous situations, three of which are highlighted in this chapter as case studies. Each case study describes how the user tasks were identified, how stakeholder feedback was included, how our agile methodology was employed, and how appropriate location detection technologies were integrated. The discussion portion of this section will compare and contrast the lessons learned in the different case studies—highlighting specific usability engineering lessons and advancements that can be used by others.

Case Study 1: Alumni Tour Guide

The alumni tour guide application was built for visitors to the Virginia Tech (VT) campus. The system notifies users about points-of-interest in the vicinity as and when they move about the VT campus (Nair et al., 2006). This image-intensive system provides easy-to-understand views of the prior and current layout of buildings in the current area. By focusing on an almost exclusively image-based presentation, users spend little time reading text and more time reflecting on their surroundings and reminiscing about past times in the area. See Figure 2 for a screenshot of the guide.

The earliest prototypes of the tour guide proposed a complex set of operations, but task analyses and client discussions performed in the Agile Usability stages indicated that many alumni—particularly those less familiar with handheld and mobile technology—would be unlikely to want to seek out solutions using the technology. Instead, later prototypes and the final product focused on the presentation and contrast of historical and modern images of the current user location. For example, alumni can use the tour guide to note how an area that once housed some administrative offices in old homes has been rebuilt as a multistory technology center for the campus. This pictorial comparison, available at any time with only a few clicks, was well received by our client as an important step in connecting the campus of the past with the exciting innovations of the present and future.

As the target users are alumni returning to campus, most are without access to the wireless network, and the logistics are significant in providing access to the thousands of people who return for reunions, sporting events, and graduations. As such, the Alumni Tour Guide uses the sniffing location detection method to identify current location. This method fits well with the nature of the tasks of interest to alumni: they care most about the general space usage and the historical perspectives of a location that change little over time.

Case Study 2: VTAssist

Building interfaces is often difficult when the target audience has needs and skills different than those of the developer: for example, users with mobility impairments. It often takes many iterations to focus on the most appropriate solutions—a perfect candidate for Agile Usability. A pair of developers used our methodology to build VTAssist, a location-aware application to enable users with mobility impairments, specifically users in wheelchairs, to navigate a campus environment (Bhatia, Dahn, Lee, Sampat, & McCrickard, 2006). VTAssist helps people in wheelchairs navigate in an environment more conducive to those who are not restricted in movement. Unlike typical handhelds and Tablet PC applications (the two platforms for which VTAssist was created), the VTAssist system must attract the user's attention at times of need or danger, guide them to alternate paths, and provide them with a means to obtain personal assistance when necessary. Perhaps most importantly, VTAssist allows users to quickly and easily supply feedback on issues and difficulties at their current location—both helping future visitors and building a sense of community

among those who traverse the campus. See Figure 2 for a screenshot of the VTAssist.

In developing VTAssist using Agile Usability, we found that needs and requirements changed over time requiring that the methodology account for those changes. For example, the original design was intended to help wheelchair users find location accessible resources and locations, but later the need was identified to keep that information constantly updated, resulting in the addition of the collaborative feedback feature. It was this feature that was deemed most important to the system—the feature that would keep the information in VTAssist current, and would enable users to take an active role in maintaining the information, helping others, and helping themselves.

Due to the importance of the feedback feature in maintaining up-to-date information for those in wheelchairs, VTAssist uses the Web services model. Certainly it would be possible to obtain some benefit from the sniffing model, but the client reaction indicated the importance of user feedback in maintaining an accurate database of problems and in providing feedback channels to frustrated users looking for an outlet for their comments. In addition, the server-side computations of location and location information (including comments from users and from facility administrators) results in faster, more up-to-date reports about the facilities.

Case Study 3: Conference Center Guide

The conference center guide, known as SeeVT-ART, addresses the desires of visitors and alumni to our area in coming to, and generally in returning to, our university campus—specifically the campus alumni and conference center (Kelly, Hood, Lee, Sampat, & McCrickard, 2006). SeeVT-ART provides multimodal information through images, text, and audio descriptions of the artwork featured in the center. Users can obtain alerts about interesting regional and university-specific features within the center and they can be guided to related art by the same artist or on the same topic. The alerts were designed to be minimally intrusive, allowing users to obtain more information if they desired it or to maintain their traversal through the center if preferred. See Figure 2 for a screenshot of SeeVT-ART.

Agile Usability was particularly effective in this situation because of the large amount of input from the client, who generated a lot of ideas that, given unlimited time and resources, would have contributed to the interface. Agile Usability forced the developers to prioritize—addressing the most important changes first while creating placeholders illustrating where additional functionality would be added. Prioritization of changes through Agile Usability also highlighted the technological limitations of the underlying SeeVT system, specifically those related to the low accuracy of location detection, and how that influenced the system design. For example, when a user enters certain areas densely populated with artistically interesting objects, SeeVT-ART requires the user to select from a list of the art pieces, as it is impossible to determine with accurate precision where the user is standing or (with any precision) what direction the user is facing. These limitations suggested the need for smart algorithms that use information about the area and that integrate additional location determination methods.

Smart algorithms that store location data over time and use it to improve location detection can be useful in determining data such as the speed at which a user is walking and the direction a user is facing. SeeVT-ART can use this data to identify the piece of art at which a user most likely is looking. Our ongoing work is looking at integrating not only the widely accessible broadcast signals from GPS, cellular technology, and fixed Bluetooth, but also RFID, vision algorithms, and augmented reality (AR) solutions. Our early investigation into a camera-based AR solution combines information about the current location with image processing by a camera mounted on the handheld to identify

the artwork and augment the user's understanding of it with information about the artist, provenance, and so forth. These types of solutions promise a richer and more complete understanding of the importance of a location than any one method could accomplish alone.

CONCLUSION AND FUTURE DIRECTIONS

The three location-knowledgeable SeeVT applications described in this document offer a glimpse into the possibilities for location-knowledgeable mobile devices. The increasing presence of wireless networks, improvements in the power and utility of GPS, and development of other technologies that can be used to determine location portends the ubiquity of location-knowledgeable applications in the not-too-distant future. Delivery of location-appropriate information in a timely and useful manner with minimal unwanted interruption will be the goal of such systems. Our ongoing development efforts seek to meet this goal.

In support of our development efforts, we explore new usability engineering approaches particularly appropriate for location-knowledgeable applications. The use of stories and the knowledge capturing structures of Agile Usability combined with its rapid multiple iterations enable convergence on solutions to the most important issues faced by emerging application areas. We repeatedly found that designers are able to identify issues of importance to the target users, while keeping in perspective the design as a whole. Our ongoing work seeks ways to capture and share the knowledge produced from designing these applications not only within a given design but across designs, leading to the systematic scientific advancement of the field.

In the future, these developing Agile Usability techniques will be supported by specific tools and toolkits for leveraging the location-awareness needs of on-the-go users. An early contribution that can be drawn from this work is the novel methods for supporting location awareness in users—browseable historical images of the current location, rapid feedback methods for reporting problems, new map presentation techniques—all methods that should be captured in a toolkit and reused in other location awareness situations.

KEY TERMS

Agile Usability: Design methodologies that incorporate practices from agile software development methods and usability engineering methods to enable the efficient development of usable software.

Extreme Programming: An agile software development methodology centered on the values of simplicity, communication, feedback, courage, and respect.

Location Awareness: Functionality in mobile devices that allows them to calculate their current geographic location.

Mobile Devices: Handheld, portable computing devices such as smart phones and personal digital assistants.

Scenario-Based Design: Usability engineering methodology that uses descriptions of how people accomplish tasks—scenarios—as the primary design representation to drive the development and analysis of systems.

SeeVT: Location aware system that uses Wifi signals to calculate the position of wireless-enabled mobile devices.

Ubiquitous Computing: Technology embedded in the environment that becomes implicit and tightly integrated into peoples' day to day tasks.

Wifi: Wireless local area networking technology and standards developed to improve the interoperatility of wireless communication devices.

This work was previously published in Ubiquitous Computing: Design, Implementation, and Usability, edited by Y. Theng and H. Duh, pp. 253-265, copyright 2008 by Information Science Reference, formerly known as Idea Group Reference (an imprint of IGI Global).

Chapter 8.9
From Ethnography to Interface Design

Jeni Paay
Aalborg University, Denmark

Benjamin E. Erlandson
Arizona State University, USA

ABSTRACT

This chapter proposes a way of informing creative design of mobile information systems by acknowledging the value of ethnography in HCI and tackling the challenge of transferring that knowledge to interface design. The proposed approach bridges the gap between ethnography and interface design by introducing the activities of field-data informed design sketching, on a high level of abstraction, followed by iterative development of paper-based mock-ups. The outcomes of these two activities can then be used as a starting point for iterative prototype development—in paper or in code. This is particularly useful in situations where mobile HCI designers are faced with challenges of innovation rather than solving well-defined problems and where design must facilitate future rather than current practice. The use of this approach is illustrated through a design case study of a context-aware mobile information system facilitating people socialising in the city.

INTRODUCTION

This chapter looks at the mobile technology design problem of taking an ethnographic-based approach to gathering field data and making this data available to the design process in a form that is easily assimilated by designers to inform user-centred design of mobile technology. Interface design for mobile technologies presents unique and difficult challenges that sometimes render traditional systems design methods inadequate. Ethnography is particularly well-suited to design for mobile technology. Mobile usability is often highly contextual and ethnographic approaches can facilitate richer understandings of mobile use contexts providing insight into the user's perspective of the world. Exploring the huge po-

tential of mobile devices presents designers with a unique opportunity for creativity. In thinking about mobile technology design for *future*, rather than *current* practice, the challenge becomes even greater.

Before this discussion proceeds further it is worth clarifying the use of the term *ethnography*. Traditionally, ethnographic studies within sociology are conducted from a particular theoretical viewpoint and for the purpose of contributing to theory. However, ethnography, as it is understood in HCI research, generally refers to a collection of techniques used for gathering and organizing field materials from observational studies (Dourish, 2006). By its very definition, ethnography is primarily a form of reportage. It provides both empirical observational data, and makes an analytical contribution in the organization of that data. The virtue of ethnography is that it takes place in real-world settings and provides access to the ways people perceive, understand, and do things (Hughes et al., 1997). Ethnographically-oriented field methods can be used in HCI to provide a deeper understanding of an application domain, a holistic understanding of users, their work, and their context, which can then be drawn into the design process at the earliest stages (Millen, 2000). Ethnographic studies involve detailed observations of activities within their natural setting, providing rich descriptions of people, environments and interactions, and acknowledging the situated character of technology use (Millen, 2000). These observations can provide valuable insights into the processes needed for systems requirements specifications (Sommerville et al., 1993).

In the literature, the terms ethnography and ethnomethodology are both used to refer to field studies using ethnographic methods to understand how people perceive their social worlds. Other terms such as technomethodology (Button & Dourish, 1996), rapid ethnography (Millen, 2000) and design ethnography (Diggins & Tolmie, 2003) are also used to distinguish different aspects of the use of ethnography in the design of technology. For the sake of simplicity, this chapter uses the term ethnography to encompass these understandings as being important to the discussion of the relationship between their outputs and the inputs they provide to the design process.

For ethnography to make a worthwhile contribution to the design of mobile technologies, we need to find ways for translating ethnographic findings into forms that are suitable for informing design processes. In the following sections, the historical relationship between ethnography and HCI is discussed, including how it has been incorporated into the process of interface design. The theoretical and methodological background for how to gather and interpret ethnographic data and use this for informing design is described. A design case study is then presented in which an ethnographic approach has been applied to mobile technology design in a real world research project through a structured series of activities. The overall process is described, and the two steps of developing *design sketches* and *paper-based mock-ups* are introduced as a way of bridging the gap between ethnography and interface design. Finally, lessons learned from using design sketches and paper-based mock-ups in the development process are outlined.

BACKGROUND

Ethnography and HCI

The issue of bridging the gap between ethnography and interface design has been a topic of discussion in HCI research for over a decade. Ethnography is now regarded as a common approach to HCI research and design (Dourish, 2006). Yet there is still no overall consensus on how best to incorporate the results of ethnographic fieldwork into the design processes (Diggins & Tolmie, 2003). In the early 90s seminal work by sociologists, such as Suchman, Hughes, Harper, Heath and Luff, inspired the use of ethnography for under-

standing the social aspects of work processes and informing user interface design (Hughes et al., 1995). However, researchers struggled with the challenge of utilizing insights provided by ethnography into the activity of designing. By the mid 90s, ethnography was hailed as a new approach to requirements elicitation for interactive system design, particularly through its application in the development of computer-supported cooperative work (CSCW) systems (Hughes et al., 1995). Even so, some researchers still held reservations about the ability of ethnographic methods to inform design (Hughes et al., 1997) and ethnography was regarded as a relatively untried approach to systems development, despite the fact that it was increasingly being used to inform and critique actual systems (Button & Dourish, 1996). Toward the end of the 90s, researchers were beginning to develop systematic approaches to social analyses for the purpose of influencing design (e.g., Viller & Sommerville, 1999). However, despite many research efforts, bridging the gap between ethnography and design still remains a matter of concern to HCI researchers today (Diggins & Tolmie, 2003).

The turn towards ethnography within HCI was motivated by a growing need to design for complex real world situations. This began with the belief that methods from the social sciences, such as ethnography, could provide means for understanding these contextual issues of technology use better. In the light of today's ubiquitous and mobile networked computing environments, the need to understand contexts of technology use, such as peoples' dynamic work and social practices, is challenging HCI researchers and designers more than ever. Supporting innovation in a world of emerging technologies can be done by submerging designers, who understand emerging technical possibilities, into rich ethnographic field data about potential users' lives and current practices (Holtzblatt, 2005). In this way technology design drives an understanding of the user's situation, which in turn, propels innovation.

Ethnography and Interface Design

The process of transition from field data to prototype design is a difficult one (Cheverst et al., 2005; Ciolfi & Bannon, 2003). A design process involving ethnography generally starts with observations and interviews collected through ethnographic methods. Key findings are then summarized and design ideas are drawn out with a set of features that can be tied back to the findings. The next step involves, "design suggestions" or "design implications," which may evolve into requirements through the development of a low-fidelity prototype. This prototype is then iterated with feedback from users and evolves into the operational system. The data collected by ethnographic methods reflects the richness of the user's situation in a way that is difficult to derive from a limited set of questions or measures as employed in traditional analysis methods (Wixon, 1995). In contrast to traditional systems analysis that looks at data, structures, and processing, ethnography is concerned with participants and interactions (Sommerville et al., 1993). This provides the designer with a rich understanding of the context of use for the artifacts that are being designed (Millen, 2000). In looking at a situation through the user's eyes rather than the designers, ethnography provides a view of the situation that is independent of design preconceptions (Hughes et al., 1997).

Ethnography has much to contribute to interface design—particularly in mobile device design due to the highly contextual nature of mobile usability and use. However, one of the main problems is finding a suitable mechanism for the transference of knowledge between these two fundamentally different disciplines. Ethnographic findings need to be understood and communicated to designers (Hughes et al., 1995). And yet, current mechanisms for incorporating ethnographic findings into the design process still

fail to capture the value of these investigations (Dourish, 2006).

Ethnography deals in "the particular," and software design in "the abstract" (Viller & Sommerville, 1999). While willing to listen to each other, both disciplines speak different languages and use different methodologies. Ethnographers deal in text, notes, reports, and transcriptions, and produce detailed results giving a rich and concrete portrayal of the particulars of everyday practical action in context, presented in a discursive form; software designers and engineers deal in the creation and manipulation of more formal graphical abstractions, notations and description techniques to simplify the complexity of the situation and extract critical features. Ethnographers avoid judgements; designers make them. Where ethnographers take an analytic role, including gathering and interpreting data, software designers have a synthesis role, designing from abstract models of situations (Button & Dourish, 1996; Hughes et al., 1995). In addition to the problems of communication there are also problems of timing. Ethnography is generally conducted over a long period of time; in fact, it is difficult to define an end point for gathering understanding. On the other hand, software designers are often under restricted time pressure to deliver a product.

The problem has been in finding a timely method and a suitable form to present field findings that can be assimilated by and are readily usable for designers (Hughes et al., 1995; Viller & Sommerville, 1999). The needs of the software designer have to be aligned with a representation of the essential "real world" practices of users in context. Simply describing the social events being observed is not sufficient, designers need to be able to model and use this understanding in design.

USING ETHNOGRAPHY IN THE DESIGN PROCESS

Gathering Data

From HCI research it can be seen that using ethnography as a data gathering method requires the development of more structured approaches to conducting and reporting from ethnographic studies that better support the development of design requirements.

One approach is to conduct ethnography concurrently with design and bring ethnographic results into the design process in a more systematic way throughout the development process. This can, for example, be achieved through meetings between ethnographers and the design team (Hughes et al., 1995). This approach results in a change in the way that ethnography is conducted. Rather than extended periods in the field, ethnographers working in cooperation with software designers to create a system design, making short and focused field studies, reporting back to designers, and often taking design questions back into the field to focus their observations and questions to users. To structure the process, the communication of fieldwork to designers can be supported by dedicated software packages (Diggins & Tolmie, 2003; Sommerville et al., 1993). In this situation, the ethnographic record becomes a joint resource with ethnographers regularly reporting their findings in an electronic form, and designers using this content to develop structured design requirements. Constructing these records in a connected manner preserves backward and forward traceability between ethnographic findings and evolving system requirements.

Another approach is to lead into the design process through *rapid ethnography* (Millen, 2000). Rapid ethnography provides the field worker with a broad understanding of the situation which can then be used to sensitize designers to the use situation rather than identifying specific design issues. It is aimed at gaining a reasonable

understanding of users and their activities in the short time available for this in a software development process. Rapid ethnography provides a more structured approach to ethnographic field studies by limiting the scope of the research focus before entering the field. It focuses time spent in the field by using key informants in the real situation and interactive observation techniques. Rapid ethnography also uses multiple observers in the field to ensure several views of the same events and to create a richer representation and understanding of the situation (Millen, 2000).

Interpreting Data

Ethnography is not simply about the collection of data in the field, it is also about reflection on and interpretation of that field data. Effective communication between ethnography and design is at the heart of the matter of bridging the gap between the two disciplines (Hughes et al., 1997). By recognizing the different natures and input and output requirements of ethnography and interface design, integration between the two disciplines can be achieved through enhancing and structuring the communication between them during the interpretation phase.

One approach to interpreting the data collected is to have a cross-discipline team participating in the fieldwork. In this situation designers go into the field with ethnographers to experience themselves how users work. They also contribute to the representation of the gathered data, shaping it into a form that is easier for designers to use (Diggins & Tolmie, 2003). Representing ethnographic findings through pictorial stories, drawings, data models, analogies and metaphors are ways to communicate field learning to cross-discipline teams (Millen, 2000). Videotapes of field observations and design documentaries play a similar role using a more designer-accessible communication mode than a written report (Raijmakers et al., 2006).

Another approach to interpretation is to have both ethnographers and designers involved in the conceptual design process. In this situation, the ethnographer is an ongoing member of the design team, providing grounded insights and interpretations into the abstracted requirements as they evolve and the design emerges. The ethnographer acts as a substitute user during the design process (Viller & Sommerville, 1999). Through their knowledge of the actual situation, they can participate in discussions with the designers, providing insights and access to instances of specific relevant situations.

A third approach is for the designer to play the part of a pseudo-ethnographer. This involves designers going "into the wild" and being exposed to users by watching real work while it is being done, and hence truly experiencing the richness of work (Wixon, 1995). Structured methods such as rapid ethnography and *contextual design* (Beyer & Holtzblatt, 1998) make this possible. In contextual design, the user and the designer explore the design space together using *contextual interview* or *facilitated enactment* of their practices in context (Holtzblatt, 2005). *Affinity diagramming*, from the contextual design method, provides a synthesis of the data into hierarchical classifications where the meaning contained in the data elements can be reflected on in relation to the design question, facilitating understanding and innovation for designers.

Informing Design

After the ethnographically gathered field data has been interpreted, abstracted findings are used to derive design opportunities and design requirements. The designer uses the outputs from the interpretation of the field data as input into the design process. Sometimes the ethnographers are involved in this design process bringing their intimate knowledge of the users and the situation of use, and their deep relationship to the data, to the team (Cheverst et al., 2005). They participate

in the identification of design incentives by drawing attention to general design opportunities, and relevant topics and concerns. Otherwise, the designers must draw understanding entirely from the reports, discussions, diagrams and models, which represent the ethnographic record.

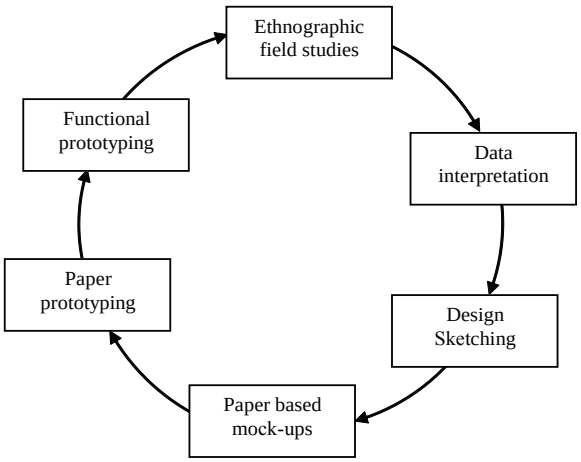
Design is a matter of making, and is used to create and give form to new ideas and new things (Fallman, 2003). A recent approach to informing design and achieving a close connection between the design team and the field data is the use of field observation videos or design documentaries. These videos mediate between ethnographic and design perspectives. As the design team watches them they incorporate interpretation of data into the design process on the fly through discussions drawing design sensitivities and identifying design concerns. Designers become sensitized to relevant issues visible in the real world interactions depicted in the video (e.g., Ciolfi & Bannon, 2003; Raijmakers et al., 2006). This method requires a high level of design experience, and in bridging the gap between ethnography and design, these designers work in an inspirational, ephemeral and creative way. For others this creative leap across the divide is very difficult, and more structured methods are needed to guide the process of envisioning design from ethnographic outputs. In response to new interface design challenges, including mobile technology, HCI researchers are investigating new techniques for guiding designers through this difficult transition – of particular interest to this chapter are the techniques of *design sketching* (Buxton, 2007), *paper-based mock-ups* (Ehn & Kyng, 1991) and *paper prototyping* (Snyder, 2003).

Design sketching is fundamental to the process of design, and can be used by information system designers to bring about the realization of an idea in the way designers think (Fallman, 2003). Sketching is the art of giving form to the unknown; it makes it possible to "see" ideas or envision whole new systems, and is especially critical in the early ideation phase of design (Buxton, 2007). According to Buxton, sketches should be rapid, timely, inexpensive, disposable, plentiful, clear, un-detailed, light, informal representations that practitioners can produce and interact with to suggest and explore ideas. Sketching is not only a way to visualize existing ideas, but it is about shaping new ideas. In making a sketch of something, the visualization talks back to the designer with a new perspective on that idea, providing a link between vision and realization of new ideas.

Paper-based mock-ups are closely related to the notion of design sketching. In this technique from the participatory design tradition, representational artifacts are constructed from paper, cardboard and materials at hand. Informed by studies of practice, mock-ups can play an important mediating role in connecting use requirements and design possibilities in a form recognizable to multi-disciplinary design teams (Ehn & Kyng, 1991). These mock-ups can be used to incorporate materials from the ethnographic study, embody envisioned new technological possibilities, convey design ideas in relation to existing practices and reveal requirements for new practices (Blomberg & Burrell, 2003).

Paper prototyping is a widely used technique for designing, testing and refining user interfaces (Snyder, 2003). This technique helps with the development of interfaces that are useful, intuitive, and efficient, by initiating testing of the interface at a stage when the design is in its formative stages and therefore still open to the input of new ideas. Paper prototyping can be used to reflect on field study findings while developing and refining the design (Holtzblatt, 2005). A collection of interface designs, drawn from ideas generated through design sketching and paper-based mock-ups are given functional and navigational connections through the process of paper prototyping. A paper prototype is a useful vehicle for giving visual form to identified design requirements. It forms the focus for design refinement discussions and cognitive walkthroughs by the design team, and

Figure 1. The overall process of designing the Just-for-Us mobile information system



is in itself part of the design specification for implementation of the system.

A DESIGN CASE STUDY

The project used as a design case study in this chapter involved the development of a context-aware mobile information system, *Just-for-Us*, designed to facilitate people socialising in the city by providing information about people, places, and activities in the user's immediate surroundings. The case study location was a specific city precinct covering an entire city block, Federation Square, Melbourne, Australia. This location was chosen because it is a new, award-winning architectural space providing a variety of activities through restaurants, cafes, bars, a museum, art galleries, cinemas, retail shops, and several public forums spanning an entire city block. The design intention for the civic space was to incorporate digital technologies into the building fabric creating a combination of virtual information space and physical building space for people to experience. Thus, this particular place provided a unique setting for studying people's situated social interactions in a "hybrid" space and for inquiring into the user experience of mobile technology designed to augment such a physical space with a digital layer.

Process

The Just-for-Us mobile information system was designed specifically for Federation Square on the basis of an ethnographic study of people socialising there. The development process involved seven major activities:

- Ethnographic field studies
- Field data interpretation
- Design sketching on a high level of abstraction
- Paper-based mock-up development
- Iterative paper prototyping
- Implementation of a functional prototype
- Field studies of prototype use in-situ

The specific content and outcome of these activities are described in the following subsections.

Figure 2. Ethnographic observations and contextual interviews at Federation Square

Details of the implemented system and findings from the field study of its use are not covered here, but can be found in Kjeldskov and Paay (2006).

As illustrated in Figure 1, data from ethnographic field studies of situated social interactions in public were subjected to data interpretation, using the *grounded theory* approach (Strauss & Corbin, 1990) and affinity diagramming (Beyer & Holtzblatt, 1998). In trying to bridge the gap between our ethnographic data and actual mobile device interface design, outcomes from the interpretation of field data were used to inform a systematic activity of design sketching (Buxton, 2007). The purpose of this activity was to generate design ideas on a high level of abstraction inspired by ethnographic findings but without getting into too much detail about specific look, feel and functionality. On the basis of selected design sketches, we developed a number of paper-based mock-ups (Ehn & Kyng, 2991) of potential design solutions. This forced us to become more specific, but still allowed us to focus on overall functionality and interaction rather than on technical details. After this, we engaged in a number of paper prototyping (Snyder, 2003) iterations with the purpose of developing a detailed set of system requirements and a coherent interface concept prior to writing any program code. Finally, these specifications were implemented in a functional prototype allowing us to introduce new technology into the field and revisit peoples' socialising behavior in the city while using the operational Just-for-Us context-aware mobile information system.

Gathering and Interpreting Data

The aim of our ethnographic field study was to inquire into peoples' social interactions at Federation Square. The field study was guided by a subset of McCullough's typology of everyday situations (McCullough, 2004) for classifying peoples' social activities when out on the town: eating, drinking, talking, gathering, cruising, belonging, shopping, and attending. The study applied a rapid ethnography approach and consisted of a series of contextual interviews (Beyer & Holtzblatt, 1998) and ethnographic field observations (Blomberg & Burrell, 2003) with the designers acting as pseudo-ethnographers and gathering the field data (Figure 2). Three different established social groups participated in the study. Each group consisted of three young urban people, mixed gender, between the ages of 20 and 35, with a shared history of socialising at Federation Square. The groups determined the activities undertaken and the social interactions that they engaged in. Prior to the field visits, each group received a 10-minute introduction to the study followed by a 20-minute interview about their socialising experiences and preferences. This introduction occurred at a place familiar to the group, where they might meet before socialising in the city. This encouraged them to reflect on past social interactions, to relax about the visit, and gave the interviewer insight into the situated interactions that the group typically participated in. One of the members of the group was then taken to Federation Square and asked to arrange to meet up with the other members of the group. The group was then asked to do what they would usually do as a group when socialising out on the town—while "thinking aloud" as they moved around the space, and responding to

Figure 3. Graphical image of inhabited social context at Federation Square

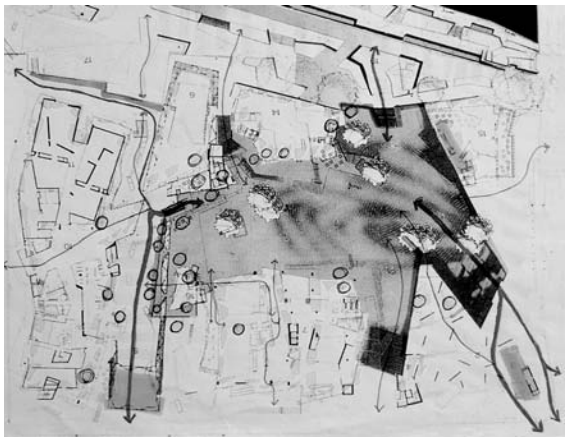


Figure 4. Affinity diagram of situated social interactions at Federation Square

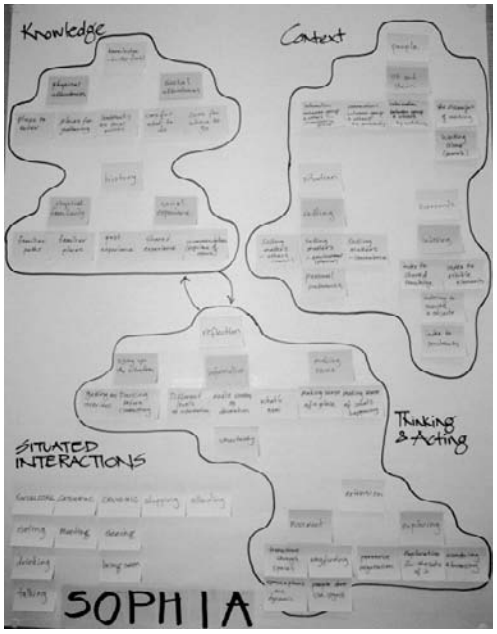


questions from the interviewer. Two researchers were present in the field, providing multiple views on the data collected.

Each field visits lasted approximately three hours and allowed the groups to engage in a number of social activities. The outcome of the ethnographic field studies amounted to eight hours of video and approximately 30 pages of written notes.

In addition to the observational studies of people socialising at Federation Square an architecturally trained observer carried out a single *expert audit* (Lynch, 1960) focusing on the physical space of Federation Square. The expert audit documented architectural elements and their relationships to surrounding context, including the people inhabiting the space through 124 digital photographs and corresponding field notes.

Interpreting data gathered from the ethnographic study involved two phases. Firstly, photographic data and written notes from the expert audit were analyzed using *content analysis* (Millen, 2000) and affinity diagramming (Beyer & Holtzblatt, 1998). Concepts and themes describing the physical space of Federation Square were overlaid onto a map of the precinct to produce a color-coded multi-layered abstraction of the space (Figure 3). This provided an overview of the spatial properties of Federation Square highlighting constraints and enablers for situated social interactions there with traceable links back to specific observations.

Secondly, video data from the contextual interview and observational field study of people socialising at Federation Square was transcribed and then analyzed using open and axial coding adapted from *grounded theory* analysis (Strauss & Corbin, 1990). Identifying key words or events in the transcript, and analyzing the underlying phenomenon created the initial open codes. Analysis of these codes resulted in a collection of categories relating to actions and interactions. After the codes were grouped into categories, higher-level themes were extracted using axial

Figure 5. Design sketching informed by interpreted ethnographic field data. The delineated area corresponds to the paper-based mock-up produced later and highlighted on Figure 6.

coding. Affinity diagramming was then used to draw successively higher levels of abstraction from the data by grouping and sorting the themes until a set of high-level concepts, representing the essence of the data and encompassing all lower level themes, had been formed. The process of affinity diagramming produced a hierarchical conceptual framework containing three overall clusters of themes abstracted from the transcripts (Figure 4). This provided a rich story about how people interact with each other while socialising in public, with traceable links back to specific observations in the field study sessions.

As illustrated in Figures 3 and 4, outcomes from the interpretation of our ethnographic field data were primarily on an abstract level, providing a deeper understanding of peoples' situated social interactions in the physical space of Federation Square. While this is an important part of the foundation for good design, in their current form these outputs did not point towards any particular design ideas. As an example, the analytical outcomes from interpreting the field data included a series of qualitative statements similar to those in the following list (For a detailed account of findings from the ethnographic field studies see Paay and Kjeldskov (2005)).

- Federation Square has four key districts with distinctly different characteristics, each with an associated landmark.
- Federation Square has visible surroundings, general paths, general entrances, focal structures and no clear paths, so people need to use the structures and surrounds in finding their way around the space.
- People socialising at Federation Square like getting an overview of what is happening around them, and want to know about the presence and activities of other people.
- People's past experience with places and people at Federation Square play an important factor in choosing places and activities for socialising.
- People give directions at Federation Square by referring to shared experiences and visible elements, and use their history and physical familiarity with a place to find their way around using familiar paths.

In order to move forward from data interpretation toward an overall design concept as well as actual interface design and system requirements for a context-aware mobile information system for people socialising at Federation Square, the design team engaged in two steps of developing

Figure 6. One of the paper-based mock-ups of possible mobile device screens

design sketches and paper-based mock-ups (as described earlier). Each of these techniques produced interface design artifacts on different levels of detail and abstraction. These two "bridging" steps between ethnography and interface design are described in the following sections.

Design Sketching

The first step in the design of the Just-for-Us mobile information system was to develop a series of conceptual design ideas based on the insight from our data analysis. For this purpose, the design team spent two days generating, discussing, sketching, and refining design ideas on the basis of the abstract models of the architectural space of Federation Square and the clustering of themes in the affinity diagram from the analysis of people socialising there.

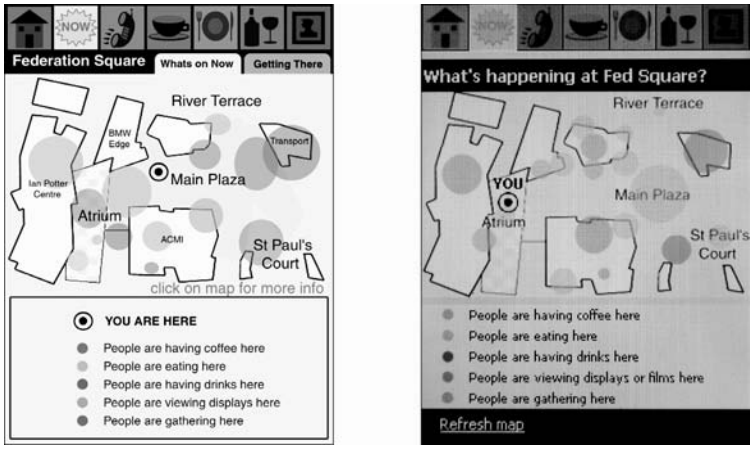
The design sketching activity was done in a dedicated design workspace with sheets of A1 paper lining the walls on which we could sketch and refine design ideas. Each sketch took its origin in a specific finding or observation from the interpreted field data. This field finding would firstly be discussed in more detail to ensure shared understanding among the design team. Secondly, we would start sketching possible design ideas, for example, how to facilitate an observed practice. Hence, we were, in a sense, using collaborative data analysis, as described in the rapid ethnography method, to drive the generation of design ideas.

During the process of sketching, the conceptual outcomes from the data interpretation phase were continually revisited and, in turn, the sketches were continuously annotated with post-it notes referring to the data. For example, a section of the affinity diagram included the themes of "social experience," encompassing "past experience" and "shared experience." A diagram was then sketched to explore the intersections between past and shared experiences in groups of friends. In this way, we ensured a strong link between data and design, and maintained clear traceability between the two. This activity was about sketching the social concepts that came out of the data models, not about generating solutions. In doing this, we were able to explore the field data findings in a graphical form, and to explore derivations from these concepts by generating multiple understandings of them. Design sketching was used as a mechanism to understand the field outcomes, to generate graphical overviews of the design space, and create graphical representations of design opportunities within that space.

The outcome from the two-day design workshop was a collection of design sketches on A1 paper (Figure 5), each describing conceptually a potential design idea or design opportunity, for parts of the Just-for-Us mobile information system, including envisioned general functionality, general ideas for graphical design and user interaction, with clear references back to the empirical data.

The design sketches provided a new visual abstraction to the ethnographically interpreted field data, translating understanding encapsulated in the abstract findings into design parlance.

Figure 7. Detailed paper prototype screen (left) and the corresponding final functional prototype screen (right), designed from the paper-based mock-up highlighted in Figure 6



Engaging in the process of design sketching rather than jumping straight to specifying system requirements, enabled us to see the ethnographic findings from a new perspective and to play with design ideas on a high level of abstraction. This allowed us to distance ourselves from the role of "problem solvers" and to explore instead, on a conceptual level, design ideas facilitating potential future practice in technology use.

Paper-Based Mock-Ups

While useful for generating and working with overall design ideas, conceptual design sketches are far too abstract for informing specific system requirements. Hence, moving directly on to detailed prototype design and implementation is likely to commit designers to specific solutions too early and impede their flexibility to try out new ideas. In an attempt to overcome this problem, the next step of our process from ethnography to interface design was to produce a series of paper-based mock-ups of possible specific design solutions (Figure 6).

The production of paper-based mock-ups took place over several days and facilitated a series of long discussions within the design team leading to an overall concept for the Just-for-Us mobile information system providing functionality such as: an augmentation of the user's physical surroundings; chat capability with friends out on the town; content indexed to the user's physical and social context and history of interactions in the city; a graphical representation of places, people and activities within the user's vicinity; and way-finding information based on indexes to landmarks and familiar places. These design ideas were screen-based solutions to design opportunities identified during design sketching.

Working with each of these ideas in more detail, the paper-based mock-ups gave the design team a medium for trying out and modifying specific design ideas for what the system should be able to do and what it should look like—long before any actual coding was done. Consequently, the mock-ups coming out of this activity had already undergone several iterations of redesign and refinements.

Discussions during the mock-up phase took place on different levels of abstraction: from

screen design, system functionality, privacy issues, problems designing for small screens, what aspects of the user's context to capture in the system, and how to do this. We also had several discussions about whether or not the implementation of the produced mock-ups would be feasible within current mobile technologies, and if not, which enabling technologies would have to be developed. Through these discussions and continued refinements and redesigns, a set of specific design requirements slowly began to take shape—gradually taking us into the "safer ground" of interface design.

Prototyping

Having completed the paper-based mock-up phase, the final steps of our development process were much more straightforward. On the basis of the mock-ups, more detailed paper prototypes were produced using Adobe Photoshop (Figure 7 left). This forced the design team to work within the graphical limitations of the target device and to use the specific graphical user interface elements available in the target browser, for this web based application. Also, the detailed paper prototypes allowed the designers to discuss some of the more dynamic interaction issues such as navigation structure and handling of pushed information. While most design changes were done in Adobe Photoshop at this time, some of the more serious issues, such as how to fit the Internet chat screen(s) into the limited design space, forced the design team back to working with paper-based mock-ups for a short time. After several cognitive walkthroughs, a full paper prototype with a detailed set of requirements was agreed upon and implemented as an operational mobile web site providing context-aware information to users, with very few modifications (Figure 7 right).

The design specified by the paper prototype was implemented as a functional Web-based system accessible through the Web browser of a PDA (personal digital assistant) providing context-related information, dynamic maps and location specific annotated graphics to the user. It also keeps a history of the user's visits to places around the city. The functional prototype uses WLAN or GPRS for wireless Internet access and resolves the user's location and the presence of friends in vicinity by means of Bluetooth beacons potentially embedded into the environment. The implementation of a functional prototype allowed us to close the circle depicted in Figure 1 by returning to Federation Square to do an ethnographic field study of people socialising there—this time facilitated by the Just-for-Us system. For details on this use study see Kjeldskov and Paay (2006).

FUTURE TRENDS

The future trends for bridging between ethnography and interface design for mobile technologies are many. As a part of a drive toward more user centered innovative design for both current and future practice, new techniques are emerging, which respond to the specific challenges of mobile technology design and use. These include, for example, cultural probes, digital ethnography, video diaries, film documentaries, facilitated enactment, acting-out in context, role-playing and body storming. Through these new techniques, the roles of ethnographers, designers, and future users are becoming more interwoven, facilitating a smoother and more effortless transition from ethnography to interface design. Techniques such as these reflect the fact that mobile technology design is not only about designing for existing work practices but also about designing for future practices in peoples' private and social lives and responding to the challenge of innovating for non-work in as yet non-existing use situations. They also respond to issues raised by many researchers that mobile technologies are often used in dynamic and continually changing contexts, offering information directly related to those contexts, and that it can be very difficult

to predict what future user-adaptations of mobile technology might evolve.

The techniques of sketching and mocking-up introduced in this chapter are not new. Both have a long tradition in other design disciplines. However, like many of the above emerging approaches, we have combined existing techniques in a new way that provides designers with a more structured path to follow when making the difficult transition of transferring knowledge from the field into the design process.

CONCLUSION

This chapter addresses the issue of ethnography informing interface design for mobile technologies. It has described how ethnographic studies can be used in HCI design and how such studies can be useful for understanding current practice as well as providing a backdrop for envisioning potential future practice. However, as confirmed in the literature, bridging between ethnography and design is difficult, and techniques are needed that enable designers to better use ethnographic findings in the design process. In response to this, the two steps of conceptual design sketching and creating paper-based mock-ups have been proposed as bridging activities between ethnographic data interpretation and iterative prototype development.

Illustrating how this can be done in practice, this chapter has described a recent project involving the design of a context-aware mobile information system on the basis of a rapid ethnographic field study. In this project, the process of design sketching from analytical data made a useful link between interpretation and design. It provided a means of communicating a conceptual understanding of current practice into the early stages of interface design, and helped "translate" findings from the field data into design parlance. Working with sketches allowed the design team to play with design ideas on a conceptual level rather than moving straight to specifying system requirements. It also allowed them to distance themselves from the role of "problem solvers" and to explore instead potential future practice of technology use.

The process of creating and refining paper-based mock-ups on the basis of selected design sketches gave the design team a medium for being a bit more specific while still maintaining a high level of flexibility. It allowed for drilling down into some specific design ideas and the exploration and modification of ideas for interface design and functionality before doing any coding. It also allowed the team to engage in discussions about possible screen designs, different functionality, privacy, small screens, etc., and to rapidly implement, evaluate, and refine design ideas. By working with paper-based mock-ups, it was possible to generate a strong set of specific design requirements, which provided a solid foundation for subsequent activities of paper and functional prototyping.

Innovative interface design for mobile technologies is both an art and a science. It requires us to be creative and inspired as well as structured and focused. Facilitating creativity and inspiration provides the art. Grounding interface design in empirically informed understanding of people and current practice provides the science. The challenge we are faced with is not just how to perform the art and science of design better individually, but more so how to support a fruitful interplay between the two. For this purpose, techniques such as conceptual design sketching and creation of paper-based mock-ups are valuable tools for researchers and designers on their journey from ethnography to interface design.

KEY TERMS

Affinity Diagramming: One of the techniques of the contextual design process, used during data interpretation sessions to group related individual points together, creating a hierarchical diagram showing the scope of issues in the work domain being studied.

Content Analysis: A qualitative research technique for gathering and analyzing the content of text, where content can be words, meanings, pictures, symbols, ideas, themes, or any message that can be communicated, to reveal messages in the text that are difficult to see through casual observation.

Contextual Design: A collection of techniques supporting a customer-centered design process, created by Beyer and Holtzblatt (1998), for finding out how people work to guide designers to find the optimal redesign for work practices.

Design Sketch: A graphical representation of a concept or design idea on a high level of abstraction. It should be quick, timely, open, disposable, un-detailed, and informal, and is usually hand-drawn on paper.

Expert Audit: A field reconnaissance done by an architecturally trained observer maping the presence of various elements of the physical environment and making subjective categorizations based on the immediate appearance of these elements in the field and their visible contribution to the image of the city.

Ethnography: A collection of techniques used for gathering and organizing field materials from observational studies, involving detailed observations of activities within their natural setting, to providing rich descriptions of people, environments and interactions.

Grounded Theory: A theory based analytical approach, which takes a set of data collected using ethnographic methods and provides a set of specific procedures for generating theory from this data.

Paper Prototype: A paper representation of a system design, able to simulate operation of that system, which is independent of platform and implementation, and can be used for brainstorming, designing, testing and communication of user interface designs and for identifying usability problems at an early stage of the design process.

Paper-Based Mock-Up: A representation of a specific design idea that is built from simple materials such as paper and cardboard, keeping it cheap and understandable, but making it a physical representation of a design idea for a final system, good for envisioning future products in the very early stages of the design process.

Rapid Ethnography: A collection of field methods to provide designers with a reasonable understanding of users and their activities given a limited amount of time spent in the field gathering data.

Chapter 8.10
Mobile e-Learning for Next Generation Communication Environment

Tin-Yu Wu
I-Shou University, Taiwan

Han-Chieh Chao
National Dong Hwa University, Taiwan

ABSTRACT

This article develops an environment for mobile e-learning that includes an interactive course, virtual online labs, an interactive online test, and lab-exercise training platform on the fourth generation mobile communication system. The Next Generation Learning Environment (NeGL) promotes the term "knowledge economy." Internetworking has become one of the most popular technologies in mobile e-learning for the next generation communication environment. This system uses a variety of computer embedded devices to ubiquitously access multimedia information, such as smart phones and PDAs. The most important feature is greater available bandwidth. The learning mode in the future will be an international, immediate, virtual, and interactive classroom that enables learners to learn and interact.

INTRODUCTION

The development of new approaches and technologies to support distance learning are undergoing now. In particular Web-based and mobile asynchronous learning environments and virtual classrooms via the Internet have been adopted widely. Static information as an instructional delivery method is the current trend in e-learning. Learners using these kinds of conventional learning methods are only able to browse through the mass static information. This is passive learning by reading online.

In the last decade, technologies enabling e-learning have increased learning location flexibility. Wireless communication technologies further increase the options for learning location. Advances in wireless communication technologies have provided the opportunity for educators

to create new educational models. With the aid of wireless communication technology, educational practice can be embedded into mobile life without wired-based communication. With the trend in educational media becoming more mobile, portable, and individualized, the learning form is being modified in spectacular ways (Gang & Zongkai, 2005).

In the third generation cellular system (3G) environment (such as Universal Mobile Telecommunications System, UMTS), the data rate reaches 2Mbps while the user is standing and 384Kbps while the user is moving slowly. Multimedia streaming, video conferencing, and online interactive 3D games are expected to attract increasing numbers of users. Such bandwidth is not sufficient for these increasingly popular applications and would be the major challenge for wireless networks. The 3G bandwidth has great problems with interactive teaching (Bos & Leroy, 2001).

In the future, wireless network traffic is expected to be a mix of real-time traffic such as voice, music, multimedia teleconferencing, online games, and data traffic such as Web page browsing, instant messaging, and file transfers. All of these applications will require widely varying and very diverse quality of service (QoS) guarantees for the different types of offered traffic (Dixit, 2001).

For these reasons, a fourth generation improved mobile communication system is necessary. The 4G system can support more bandwidth than other systems. It has advantages like authentication, mobile management, and quality of service (QoS). How to implement future distance learning environments for the fourth generation mobile communication system is the question. In this article, we distinguish four kinds of interactive courses, virtual online labs, interactive online tests, and lab-exercises training platform to deliver over the fourth generation mobile communication system. The fourth generation mobile communication system can use a variety of computer embedded devices to ubiquitously access multimedia information, such as smart phones and PDAs. Most important is that have more bandwidth. Hence, it supply ubiquitous learning environment (Girish & Dennett, 2000).

These new functions can improve the latency and location limits during transmission. Our proposed Next Generation Learning Environment offers learners the opportunities to use all kinds of mobile nodes that can connect to an Internet learning equipment system for access using All-IP communication networks. The Sharable Content Object Reference Model (SCORM) is used to compose information. Hence, as you can imagine, the condition of the learning mode in the future will be an international, immediate, and virtual interactive classroom that enables learners to learn and interact.

The article is organized as follows. We first describe the environments for mobile learning, followed by the virtual online classroom. The 4G testbed system design analyses are dealt with, and then the mobile e-learning results are discussed. The last section concludes the article.

ENVIRONMENTS FOR MOBILE LEARNING

Several investigations have focused on how to support great service for mobile e-learning. How many services will be able to fill the bill? In this session, we are introducing that mobile e-learning environment possesses many unique characteristics as follows (Tony, Sharples, Giasemi, & Lonsdale, 2004).

- Better adaptation to individual needs
- Ubiquitous and responds to urgent learning need
- Flexibility of location and time to learn
- Interactive knowledge acquisition
- Efficiency due both to re-use and feedback
- Situational instructional activities

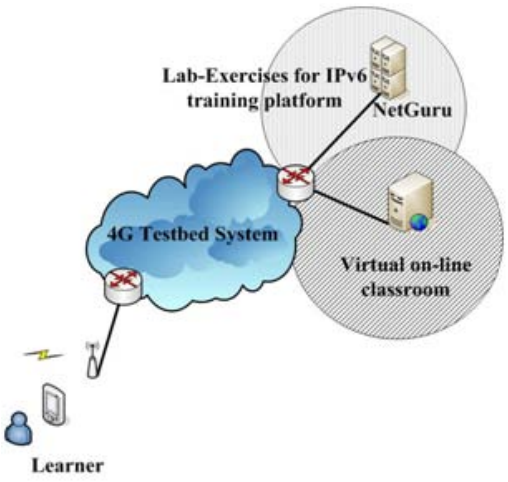
- Integrated instructional context (Chao, Wu, & Kao, 2004)

The mobile e-learning system includes interactive courses, virtual online labs, interactive online tests, and lab-exercises training platform on the fourth generation mobile communication system. As shown in Figure 1 the following sessions will present each part:

- **Interactive course system**: In learning history learners could experience interactive learning only in the classroom. The e-learning systems support only a single way for learning. These ways cannot support learning anytime and anywhere. We therefore developed an interactive course system to do that. Learners can choose which chapter they want to learn in this system. This learning method is not limited by the environment.
- **Virtual online labs system:** Generally speaking, experiments must be conducted in a laboratory. Learners are thereby limited to a specific learning area. To solve this problem special equipment is required. How can this problem be overcome? We simulated an experiment on laboratory all the time by Flash program. This virtual online lab platform supports step-by-step experimentation. Learners are therefore not restricted in the laboratory.
- **Interactive online test system:** An online interactive testing system is used to examine the teaching effect on students. The instructors can know how many learners were impacted via the testing system. Learners can obtain the learning effect on themselves.
- **Lab-exercises training platform:** The learners have more items for experimentation. NetSmooth Inc. developed a complete solution called NetGuru platform to tackle this issue. The learners can access the lab-exercises training platform via pre-arranged authorization.

A communication system is required to transfer the learning data. The most common communication platform used by students is the third generation cellular system. The data rate reaches

Figure 1. The virtual classroom on 4G system



2Mbps while the user is standing and 384Kbps while the user is moving slowly. This kind of system does not have enough bandwidth and no All-IP core network. Therefore, we developed a 4G testbed system that can support high transfer bandwidth.

VIRTUAL ONLINE CLASSROOM

Today there is much work going on in the field of virtual online classrooms around the world. The Web-based virtual classroom via the Internet as an instructional delivery method is a popular trend. Traditional learning methods only allowed the student to browse through mass static information. This is passive learning. In this session, we will introduce an interactive virtual classroom that includes the interactive course, virtual online labs, an interactive online test, and a lab-exercise training platform. For more information, see the virtual online classroom interactive Web site: http://6book.niu.edu.tw/ (6BOOK).

Setting up the Interactive Learning Course Web Site Platform

The Internet has uni-location and unlimited time features. Early online teaching materials included video lessons captured by DV, e-books, poster messages, and so on. These materials were used via the Internet. However, these approaches are single direction learning. These approaches are not good approaches for learning. These ways cannot attain learning anytime and anywhere. Therefore, we developed the interactive course system to do that (see Figure 3). The learners can choose which chapter they want to learn in this system. It can repeat whatever the learners want. The course collocates the interactive online test with interactive capability. The learners can learn anytime and anywhere unlimited by the environment.

Learners can select the chapters that they want to learn or review rapidly. They can study the chapters in order or preview or review any chapters, in any order. They can save all of their previous study processes. During learning, the system supports sliders with hints and oral explanations. Learners can control their learning speed and repeat it at will. Learners can see clearly just like taking the classes live (see Figure 4).

Setting up Virtual Online Lab Exercises

Generally, learner lab exercises must be conducted in a laboratory. They cannot perform experiments without a laboratory. This reduces a lot of opportunity to learn. Therefore, we used FLASH to produce a series of online lab exercises, explaining the lab exercises from the beginning and performing the exercises with detailed background voice and subtitles. There are explanations in great detail for each exercise. These explanations include the experiment goals, steps, and approaches that can help learners understand the background.

Most important, the learners can control the speed at which the lab-exercises proceed by themselves. Relying on online lab exercises, learners can perform lab exercises an unlimited number of times. They can perform experiments anytime from anywhere. The instructors do not have to spent time to prepare lab exercises or setup equipment. If learners have any questions about the exercises, they can use hyperlink to text to the Web site for answers. This teaching platform covers both theory and lab exercises interactively.

Setting up On-Line Exercises

The Virtual online lab exercises and interactive learning Web site platform help learners study efficiently. This system is able to identify the learning effect. We developed online interactive exercises for each chapter. These exercises identify

Figure 2. The interactive virtual online classroom Web site

Figure 3. Interactive learning course Web site platform

the comprehension of each learner for the instructor that uses these teaching materials. The system tutors learners that do not exhibit complete lesson understanding. Learners can also know clearly what areas should be enhanced and the content of each chapter by practicing the exercises.

Lab-Exercises Training Platform

The lab-exercises training platform is set-up using the NetSmooth Inc. test platform. This platform supports another solution with lab exercises for learners. The proposed NetGuru platform helps instructors to conduct network courses easily with Web-based tutorial courseware. It also assists students to strengthen the concepts of network with hands-on lab experiences (Chiang, Liang, Wu, & Chao, 2005).

The pragmatic lab exercises for the IPv6 training platform use a small-sized personal computer. There are some characters as follows (shown in Figure 7):

- All necessary lab hardware equipment is bundled together. No PC is required.
- Large-scale training labs are supported with multiple Netguru sets.
- The default setting is easily restored to initiate another lab work.
- Built-in 3 hosts and 3 hubs. (Each host has 3 NICs)
- Each set of NetGuru supports 3 groups to do Lab work.
- Simply connect monitor, mouse and keyboard with NetGuru to start Lab work instantly.

NetGuru integrates hardware, lab software, and training media into one complementary training set. We equipped the system with common use software to easily implement network services, such as routing, DNS, VPN, DHCP, NAT, Firewall, and so on. With build-in Ethereal tools for packet analyzing, learners will reinforce their conception about the packet structure. Based on the online commands, the environment will restore and default setting to initiate another lab work easily. In past days, while establishing a network environment, we not only needed computers, but also the heavy and complicated equipment configura-

Figure 4. The teaching slides with voice on the platform

Figure 5. The virtual online lab exercises

Figure 6. The online interactive exercises platform

Figure 7. NetGuru platform framework interface

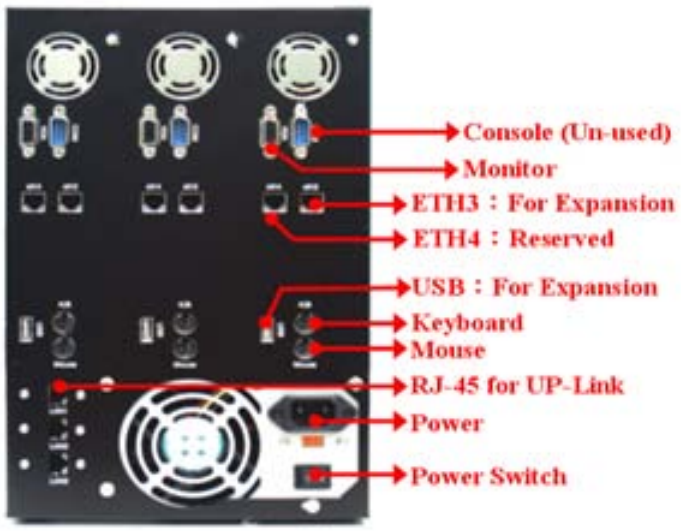


Figure 8. The cross-layer coordination plane

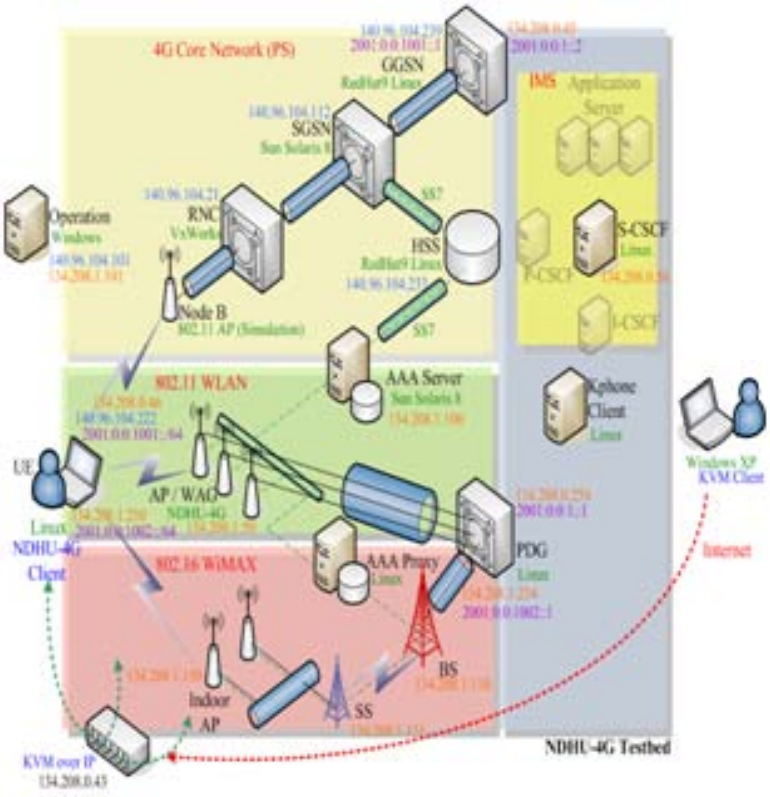

tion. With NetGuru, the TCP/IP lab environment can be easily set-up requiring no PC. We scaled down the size, and the small footprint allows easy relocation. Thus, we can set-up the TCP/IP lab environment anytime and anywhere. As we mentioned before, with multiple sets of NetGuru, large-scale training labs can easily be supported. NetGuru also supports extended network devices. Instructors can design other advanced lab work for use with this system.

4G Testbed System Design Analyses

We propose a fourth generation mobile communication testbed system. The system can support greater bandwidth than other systems. It has advantages like authentication, mobile management, and quality of service (QoS).

This session will introduce our fourth generation communication testbed system. We followed the specification defined in 3GPP to design our system. This system is composed of two main components: RAN (Radio Access Network) and Core-Network. RAN includes RNC and Node B. The Core-Network then includes SGSN (Serving GPRS Support Node), GGSN (Gateway GPRS Support Node), and HSS (Home Subscriber Server), as shown in Figure 8.

At RAN, Node B works like the access point of wireless network, providing the ability for UE (User Equipment) to connect to the core network through radio interface, each RNC can work with single or multiple Node B to form a RNA. RAN is then constituted by these RNS.

At the core network, SGSN is responsible for tasks such as connecting to the core network with single or multiple RAN, access control, location management, routing management etc. GGSN is an interface responsible of connecting core network and outer network, also routing traveling packets. It is also responsible for mobility management (Uskela, 2001).

HSS is a data center responsible for recording the operations of the entire network. HLR is its main component. Its function is to store the user's identity, location, and registered services that are allowed to the user.

Figure 9. The fourth generation mobile communication testbed system

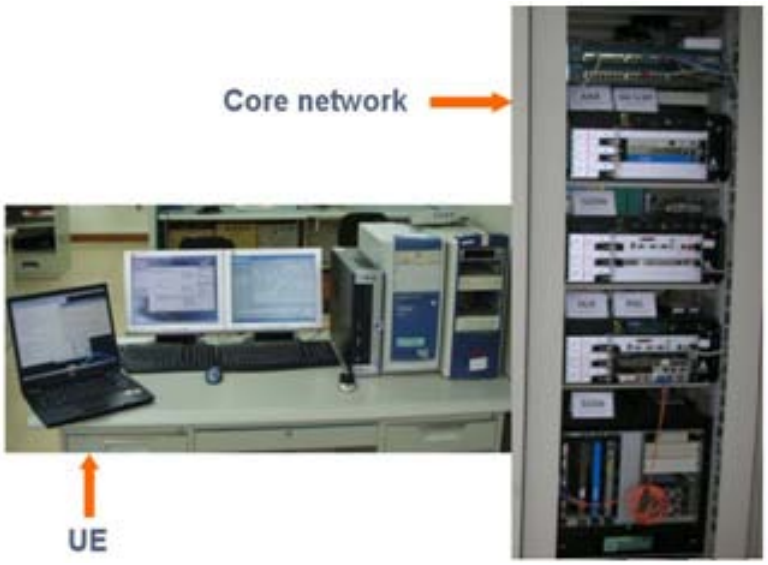

Figure 10. To learn in virtual classroom via PDA

Since the radio frequency used by a 3GPP cell phone is a licensed band, a legal license must be acquired. Therefore we used 802.11g which belongs to the ISM band instead. Through broadcasting UDP packets to simulate the radio network, and because the protocol stack of the simulation program is executed in UE according to the 3GPP standard, all generated packets are identical to packets generated by an actual 3GPP cell phone. UE enables us to acquire the flow chart of packets generated through the data exchange process between UE and the network. Figure 9 shows the entire system (3GPP, 3GPP TS 23.228, 3GPP TS 23.234).

Measurement Results with Mobile e-Learning

Wireless networks and mobile systems will continue to have explosive growth in the future. The traffic is expected to be a mix of real-time traffic such as voice, music and multimedia, and data traffic such as Web page browsing, instant messaging, and file transfers. All of these applications will require widely varying and very diverse quality of service (QoS) guarantees for the different types of offered traffic. Therefore, the mobile e-learning environment will be replacing traditional e-learning. We proposed a fourth generation mobile communication testbed system with advantages such as high transmission rate,

Figure 11. End-to-end delay

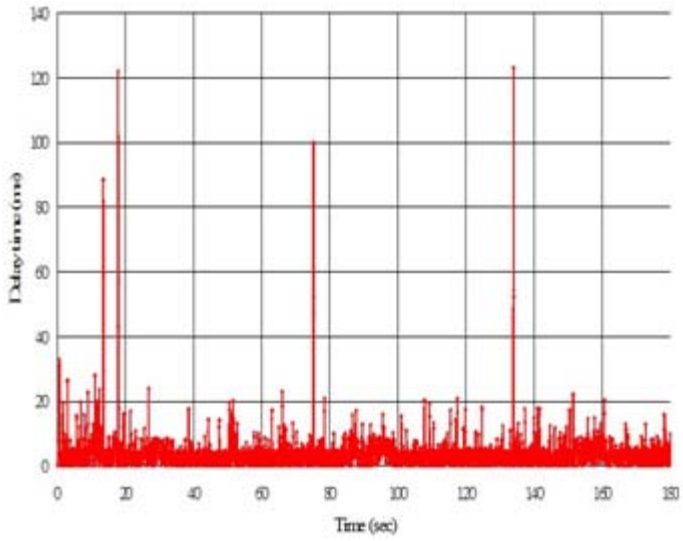

Figure 12. End-to-end bandwidth

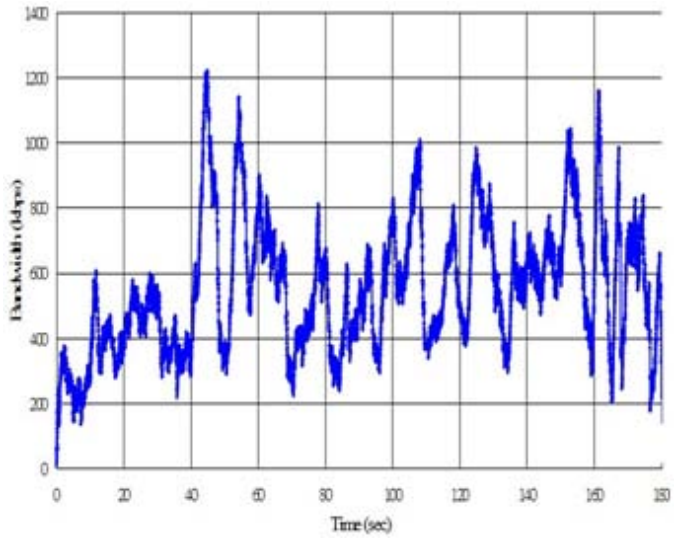

robust wireless QoS control, wide cover area and supply IMS technology. Next generation communication technology can supply a variety of portable devices to ubiquitously access multimedia information, such as smart phones and PDAs. All Learners can use portable devices to log-on to the virtual classroom. Figure 10 shows a portable device surfing the virtual classroom via 4G.

In this session, we measure the mobile e-Learning system results via 4th generation core network. The scenarios are the UEs ability to connect to WLAN. Two scenarios are used for this measurement.

The first scenario is that the UE connects to the core network through WLAN. We measure the end-to-end delay of voice packet delivery. We captured the packets using the Wireshark protocol analyzer. We installed the protocol analyzer at the end of the core network client to capture the packet and decode the voice stream.

End-to-end delay refers to the time cost used for a packet to be transported across a network from the source to destination. For voice packet transmission, we calculate the end-to-end delay according to RFC 3550. Figure 11 shows the end-to-end delay for voice packet delivery in WLAN.

The second scenario is that the UE connects to core network through WLAN. We measure the throughput of video packet delivery. These results show the transported bandwidth in the 4G testbed system, as shown in Figure 12.

CONCLUSION

The explosive development of the Internet and wireless communications has made personal communication more convenient. Mobile computing uses the Next Generation Learning Environment (NeGL) to set up learning systems. We proposed a mobile e-learning system that includes interactive courses, virtual online labs, interactive online testing, and a lab exercise training platform via the fourth generation mobile communication system. It offers learners opportunities to use all kinds of mobile nodes or anything that can

connect to an Internet learning equipment system to be accessed using All-IP communication networks. In order for Content Object Reference Model (SCORM) to compose information, the 4G can use a variety of computer embedded devices to ubiquitously access multimedia information, such as smart phones and PDA. Most important is that more bandwidth is available. As you can imagine, the condition of the learning mode in the future will be an international, immediate and virtual interactive classroom that enables learners to learn and interact.

INTRODUCTION

Morse code has been shown to be a valuable tool in assistive technology, augmentative and alternative communication, and rehabilitation for some people with various conditions, such as spinal cord injuries, non-vocal quadriplegics, and visual or hearing impairments. In this article, a mobile phone human-interface system using Morse code input device is designed and implemented for the person with disabilities to send/receive SMS (simple message service) messages or make/respond to a phone call. The proposed system is divided into three parts: input module, control module, and display module. The data format of the signal transmission between the proposed system and the communication devices is the PDU (protocol description unit) mode. Experimental results revealed that three participants with disabilities were able to operate the mobile phone through this human interface after four weeks' practice.

BACKGROUND

A current trend in high technology production is to develop adaptive tools for persons with disabilities to assist them with self-learning and personal development, and lead more independent lives. Among the various technological adaptive tools available, many are based on the adaptation of computer hardware and software. The areas of application for computers and these tools include training, teaching, learning, rehabilitation, communication, and adaptive design (Enders, 1990;

McCormick, 1994; Bower et al., 1998; King, 1999).

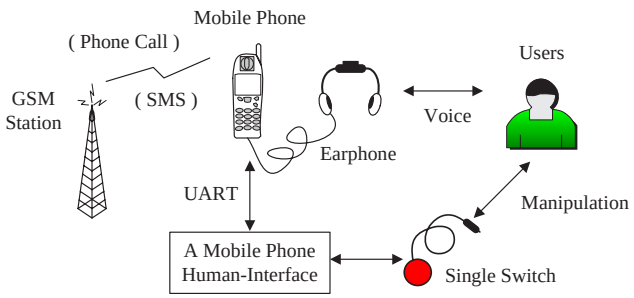
Many adapted and alternative input methods now have been developed to allow users with physical disabilities to use a computer. These include modified direct selections (via mouth stick, head stick, splinted hand, etc.), scanning methods (row-column, linear, circular) and other ways of controlling a sequentially stepping selection cursor in an organized information matrix via a single switch (Anson, 1997). However, they were not designed for mobile phone devices. Computer input systems, which use Morse code via special software programs, hardware devices, and switches, are invaluable assets in assistive technology (AT), augmentative-alternative communication (AAC), rehabilitation, and education (Caves, 2000; Leonard et al., 1995; Shannon et al., 1981; Thomas, 1981; French et al., 1986; Russel & Rego, 1998; Wyler & Ray, 1994). To date, more than 30 manufactures/developers of Morse code input hardware or software for use in AAC and AT have been identified (Anson, 1997; http://www.uwec.edu/Academic/Outreach/Mores2000/morse2000.html; Yang, 2000; Yang, 2001; Yang et al., 2002; Yang et al., 2003a; Yang et al., 2003b). In this article, we adopt Morse code to be the communication method and present a human interface for persons with physical disabilities.

The technology employed in assistive devices has often lagged behind mainstream products. This is partly because the shelf life of an assistive device is considerably longer then mainstream products such as mobile phones. In this study, we designed and implemented an easily operated mobile phone human interface device by using Morse code as a communication adaptive device for users with physical disabilities. Experimental results showed that three participants with disabilities were able to operate the mobile phone through this human interface after four weeks' practice.

SYSTEM DESIGN

Morse code is a simple, fast, and low-cost communication method composed of a series of dots, dashes, and intervals in which each character entered can be translated into a predefined sequence of dots and dashes (the elements of Morse code). A dot is represented as a period ".", while a dash is represented as a hyphen, or minus sign, "-". Each element, dot or dash, is transmitted by sending a signal for a standard length of time. According to the definition of Morse code, the tone ratio for dot to dash must be 1:3. That means that if the duration of a dot is taken to be one unit, then that of a dash must be three units. In addition, the silent ratio for dot-dash space to character-space also has to be 1:3. In other words, the space between the elements of one character is one unit while

Figure 1. System schematics of the mobile phone human-interface



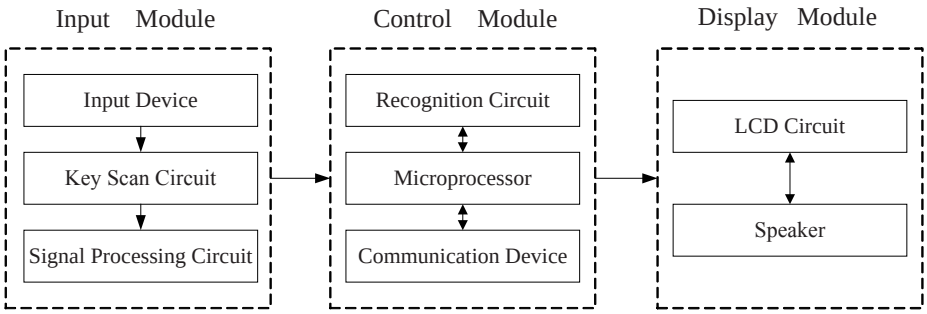
the space between characters is three units (Yang et al., 2002).

In this article, the mobile phone human interface system using Morse code input device is schematically shown in Figure 1. When a user presses the Morse code input device, the signal is transmitted to the key scan circuit, which translates the incoming analog data into digital data. The digital data are then sent into the microprocessor, an 8051 single chip, for further processing. In this study, an ATMEL series 89C51 single chip has been adopted to handle the communication between the press-button processing and the communication devices. Even though the I/O memory capacity of the chip is small compared to a typical PC, it is sufficient to control the device. The 89C51 chip's internal serial communication function is used for data transmission and reception (Mackenzie, 1998). To achieve the data communication at both ends, the two pins, TxD and RxD, are connected to the TxD and RxD pins of a RS-232 connector. Then the two pins are connected to the RxD and TxD of an UART (Universal Asynchronous Receiver Transmitter) controller on the mobile phone device. Then, persons with physical disabilities can use this proposed communication aid system to connect their mobile communication equipment, such as mobile phones or GSM (global system for mobile communications) modems, and receive or send their messages (SMS, simple message service). If they wear an earphone, they might be able to dial or answer the phone. SMS is a protocol (GSM 03.40 and GSM 03.38), which was established by the ETSI (the European Telecommunications Standards Institute) organization. The transmission model is divided into two models: text and PDU (protocol description unit). In this system, we use the PDU model to transmit and receive SMS information through the AT command of the application program (Pettersson, 2000). Structurally the mobile phone human-interface system is divided into three modules: the input module, the control module, and the display module. The interface framework is graphically shown in Figure 2. A detailed explanation is given below.

INPUT MODULE

A user's input will be digitized first, and then the converted results will be sent to the micro controller. From the signal processing circuit can monitor all input from the input device, the Morse code. The results will be entered into the input data stream. When the user presses the input key, the micro-operating system detects new input data in the data stream, and then sends the corresponding characters to the display module. Some commands and/or keys, such as *OK, Cancel, Answer, Response, Send, Receive, Menu, Exit,*

Figure 2. Interface framework of mobile phone for persons with physical disablities



and so forth, have been customized and perform several new functions in order to accommodate the Morse code system. These key modifications facilitate the human interface use for a person with disabilities.

CONTROL MODULE

The proposed recognition method is divided into three modules (see Figure 3): space recognition, adjustment processing, and character translation. Initially, the input data stream is sent individually to separate tone code buffer and space recognition processes, which are based on key-press (Morse code element) or key-release (space element). In the space recognition module, the space element value is recognized as a dot-dash space or a character space. The dot-dash space and character space represent the spaces existing between individual characters and within isolated elements of a character respectively. If a character space is identified, then the value(s) in the code buffer is (are) sent to character translation. To account for varying release speeds, the space element value has to be adjusted. The silent element value is sent into the silent base adjustment process. Afterwards, the character is identified in the character translation process.

A Morse code character, x_i, is represented as follows:

$$m_1(x_i), b_1(x_i), \ldots, m_j(x_i), b_j(x_i), \ldots, m_n(x_i), b_n(x_i)$$

where

$b_j(x_i)$: jth silent duration in the character x_i.

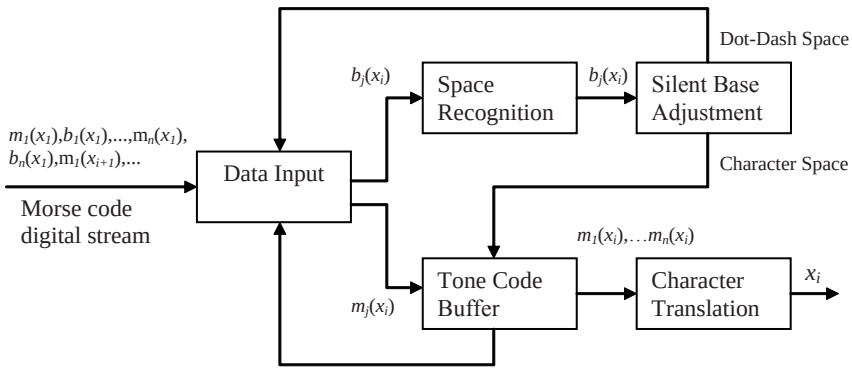
n: the total number of Morse code elements in the character x_i.

$m_j(x_i)$: the jth Morse code element of the input character x_i.

DISPLAY MODULE

Since users with disabilities have, in order to increase the convenience of user operations, more requirements for system interfaces than a normal person, the developed system shows selected items and system condition information on an electronic circuit platform, which is based on LCD (liquid crystal display). The characteristics

Figure 3. Block diagram of the Morse code recognition system



of the proposed system can be summarized as follows: (1) easy operation for users with physical disabilities with Morse code input system, (2) multiple operations due to the selection of different modes, (3) highly tolerant capability from adaptive algorithm recognition, and (4) system extension for customized functions.

RESULTS AND DISCUSSIONS

This system provides two easily operated modes, the phone panel and LCD panel control mode, which allow a user with disabilities easy manipulation. The following shows how the proposed system sends/receives simple message service (SMS) message or make /respond to a phone call.

SMS Receiving Operation

First, when users receive a message notification and want to look at the content, this system will provide "phone panel" and "LCD panel" control modes to choose from. In the phone panel mode, users can directly key-in Morse code "…" (as character 'S'). The interface system will go through the message recognition process, then exchange the message into AT command "AT+CKPD='S', 1", to execute the "confirm" action of the mobile phone. The purpose of this process is the same as users keying-in "yes" on the mobile phone keyboard, then keying-in Morse code ". - - ." (as key '↓'). The system will recognize the message, then automatically send the "AT+CKPD='↓', 1" instruction. The message cursor of the mobile phone is moved to the next line, or key-in Morse code ". - . -" (as key '↑') for moving it to the previous data line. Finally, if users want to exit and return to the previous screen, they only need to key-in Morse code ". . - ." (as character 'F'), and start the c key function on the mobile phone keyboard. If LCD panel mode is selected, one can directly follow the selected items on the LCD crystal, to execute the reception and message reading process.

SMS Transmitting Operation

Message transmission services are provided in two modes: phone panel and LCD panel. In the phone panel mode, continually type two times the Morse code ". - . - ." (as key '→'). The system will be converted into AT Command and transferred into mobile phone to show the selection screen of the message functions. Then continuing to key-in three times the Morse code ". . ." (as character 'S'), one can get into the editing screen of message content, and wait for users to input the message text data and receiver's phone number. The phone book function can be used to directly save the receiver's phone number. After the input, press the "yes" key to confirm that the message sending process has been completed. In addition, if the LCD panel mode is selected, one can follow the LCD selection prompt input the service selection of all the action integrated in the LCD panel. Then go through the interface and translate to a series of AT command orders, and batch transfer these into the mobile phone to achieve the control purpose.

The selection command "Answer a phone," displays on the menu of the LCD screen, and can be constructed using Morse code. The participants could press and release the switch, and input the number code ". - - - -" (as character '1') or hot key ". -" (as character 'A'). The mobile phone is then answered automatically. Problems with this training, according to participants, are that the end result is limited typing speed and users must remember all the Morse code set of commands.

Three test participants were chosen to investigate the efficiency of the proposed system after practicing on this system for four weeks. Participant 1 (P1) was a 14-year-old male adolescent who has been diagnosed with cerebral palsy. Participant 2 (P2) was a 14-year-old female adolescent with cerebral palsy, athetoid type, who experiences in-

voluntary movements of all her limbs. Participant 3 (P3) was a 40-year-old male adult, with a spinal cord injury and incomplete quadriparalysis due to an accident. These three test participants with physical impairments were able to make/respond to phone calls or send/receive SMS messages after practice with the proposed system.

FUTURE TRENDS

In the future, Morse code input device could be adapted to several environmental control devices, which would facilitate the use of everyday appliances for people with physical disabilities considerably.

CONCLUSION

To help some persons with disabilities such as amyotrophic lateral sclerosis, multiple sclerosis, muscular dystrophy, and other conditions that worsen with time and cause the user's abilities to write, type, and speak to be progressively lost, it requires an assistive tool for purposes of augmentative and alternative communication in their daily lives. This article presents a human interface for mobile phone devices using Morse code as an adapted access communication tool. This system provides phone panel and LCD panel control modes to help users with a disability with operation. Experimental results revealed that three physically impaired users were able to make/respond to phone calls or send/receive SMS messages after only four weeks' practice with the proposed system.

KEY TERMS

Adaptive Signal Processing: Adaptive signal processing is the processing, amplification and interpretation of signals that change over time through a process that adapts to a change in the input signal.

Assistive Technology (AT): A generic term for a device that helps a person accomplishes a task. It includes assistive, adaptive and rehabilitative devices, and grants a greater degree of independence people with disabilities by letting them perform tasks they would otherwise be unable of performing.

Augmentative and Alternative Communication (AAC): Support for and/or replacement of natural speaking, writing, typing, and telecommunications capabilities that do not fully meet communicator's needs. AAC, a subset of AT (see below), is a field of academic study and clinical practice, combining the expertise of many professions. AAC may include unaided and aided approaches.

Global System for Mobile Communications (GSM): GSM is the most popular standard for global mobile phone communication. Both its signal and speech channels are digital and it is therefore considered a 2nd generation mobile phone system.

Morse Code: Morse code is a transmission method, implemented by using just a single switch. The tone ratio (dot to dash) in Morse code has to be 1:3 per definition. This means that the duration of a dash is required to be three times that of a dot. In addition, the silent ratio (dot-space to character-space) also has to be 1:3.

Simple Message Service (SMS): A service available on digital mobile phones, which permits the sending of simple messages between mobile phones.

Chapter 8.12
A Mobile Computing Framework for Passive RFID Detection System in Health Care

Masoud Mohammadian
University of Canberra, Australia

Ric Jentzsch
Compucat Research Pty Limited, Australia

INTRODUCTION

The cost of health care continues to be a world wide issue. Research continues into ways and how the utilization of evolving technologies can be applied to reduce costs and improve patient care, while maintaining patient's lives. To achieve these needs requires accurate, near real time data acquisition and analysis. At the same time there exists a need to acquire a profile on a patient and update that profile as fast and as possible. All types of confidentiality need to be addressed no matter which technology and application is used. One possible way to achieve this is to use a passive detection system that employs wireless radio frequency identification (RFID) technology. This detection system can integrate wireless networks for fast data acquisition and transmission, while maintaining the privacy issue. Once this data is obtained, then up to date profiling can be integrated into the patient care system. This article discussed the use and need for a passive RFID system for patient data acquisition in health care facilities such as a hospital. The development of profile data is assisted by a profiling intelligent software agent that is responsible for processing the raw data obtained through RFID and database and invoking the creation and update of the patient profile.

BACKGROUND

Health is on everyone's agenda whether they are old or young. Millions of hours of lost time is recorded each week by employers' whose staff are in need of health care. It is and has been known that more research into applications and

innovative architectures is needed. To this end the use of Radio Frequency Identification (RFID), a relatively new technology and is showing itself to be a viable and promising technology as an aid to health care (Finkenzeller, 1999; Glover & Bhatt, 2006; Hedgepeth, 2007; Lahiri, 2005; Schuster, Allen, & Brock, 2007; Shepard, 2005). This technology has the capability to penetrate and add value to nearly every area of health care. It can be used to lower the cost of some services as well as improving service to individuals and the health care provider. Although many organizations are developing and testing the possible use of RFIDs, the real value of RFID is achieved in conjunction with the use of intelligent software agents. Thus the issue becomes the integration of these two great technologies for the benefit of assisting health care services.

To begin with, let us look at data collection. In health care, we can collect data on the patients, doctors, nurses, institution itself, drugs and prescriptions, diagnosis, and many other areas. It would not be feasible to do all of these nor would all of these be able to effectively use RFID. Thus for our perspective we will concentrate on a subset with the understanding that all areas could, directly or indirectly, benefit from the use of RFID and intelligent software agents in a health care and hospital environment.

In this research, we begin to look at the architecture of integrating intelligent software agents technology with RFID technology, in particular in managing patients' health care data in a hospital environment.

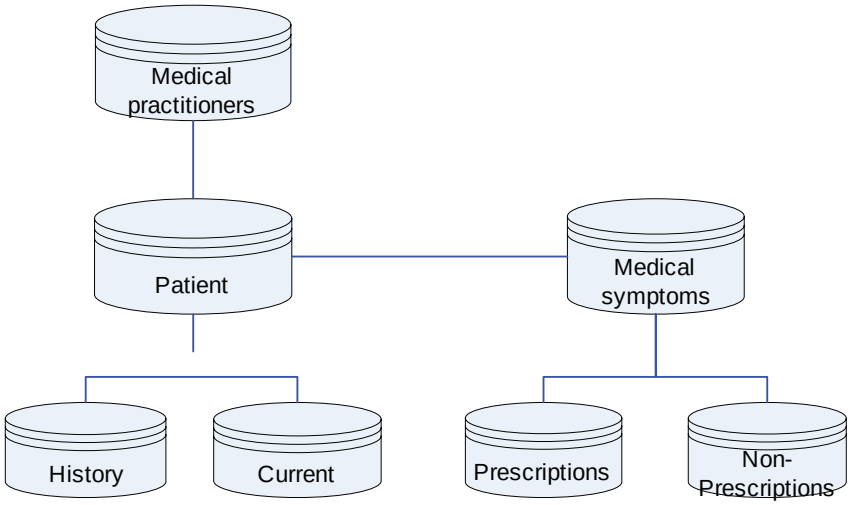
An intelligent software agent can continuously profile a patient based on their medical history, current illness, and on going diagnostics. The RFID provides the passive vehicle to obtain the data via its monitoring capabilities. The intelligent software agent provides the active vehicle in the interpretation profiling of the data and reporting capacity. There are certain data that is stored about each patient in a hospital. The investigation of this data provides an analysis that describes the patient's condition, is able to monitor their status, and cross reflect on why the patient was admitted to the hospital. Using this information an evolving profile of each patient can be constructed and analysed.

Using the data and analysis this will allow us to assist in deciding what kind of care he/she requires, the effects of ongoing care, and how to best care for this patient using available resources (doctors, nurses, beds, etc.) for the patient. The software agent is used to build a profile of each patient as they are admitted to the health care institution. Although not shown in the illustration, an additional profile for each doctor can be developed that practices in the hospital can be developed. If this is done, then the patient and doctor profile can be correlated to obtained the availability of the best doctor to suit the patient. However, this will require an additional data repository, as shown in Figure 1.

The patient profiling is useful in a variety of situations:

- The profile provides a personalized service based on the patient and not on symptoms or illness. to a particular patient. For example, by identifying the services that the patient requires this will allow us to target that which will be directed to speeding up their recovery progress;
- A good profile will assist the medical facilities in trying to prevent the need for the patient to return to the hospital any sooner than necessary;
- Disambiguating patient's diagnostic based on patient profile may help in assisting in matching a doctor's specialization to the right patient;
- When a patient needs to re-enter a hospital, a past profile can make it easier to match the patient's needs to a relevant available doctor;
- Presenting information about the patient on an on-going, continuous basis for the

Figure 1. Data repositories for patient and doctors



doctors means that current up to date information is available rather than information that needs to be searched for and compiled before it is useful; and

- Providing tailored and appropriate care to reduce health care costs.

Profiling is being done in many business operations today. Often profiling is combined with personalization, and user modeling for many e-commerce applications such as those by IBM, ATG Dynamo, BroadVision, Amazon, and Garden (18). However, there is very little in the way of the use of such systems in hospital and very little in health care in this perspective has been reported. It must be remember that there are different definitions of personalization, user modeling, and profiling. In e-commerce the practice of tracking information about consumers' interests by monitoring their movements online is considered profiling or user modeling. This can be done without using any personal information, but simply by analyzing the content, URL's, and other information about a user's browsing path/ click-stream. Many user models try to predict the user's preference in a narrow and specific domain. This works well as long as that domain remains relatively static and, as such, the results of such work may be limited.

In this research, profiling is a technique whereby a set of characteristics of a particular class of person, patient, is inferred from their past and data-holdings are then searched for individuals with a close fit to symptom characteristics. One of the main aims of profiling and user modeling is to provide information recipients with correct and timely response for their needs. This entails an evolving profile to ensure that as the dynamics of that which is being monitored change, the profile and model reflects these updates as appropriate.

There are several ways in which a patient's visit to a hospital can be recorded. A patient's visit may simply be classified as a regular visit.

This may be for a check up, for tests, or at the request of a doctor. A patient might be at the hospital because of an emergency or an ad hoc appointment due to lack of other facilities being available. Of course there are a whole set of patients that visit the hospital for reasons that are less well defined. In each situation, the needs of the patients are different.

The patient's profile can assist the attending doctor in being aware of the particular patient's situation. This provides the attending doctor with information that is needed without waiting for the patient's regular doctor. The regular doctor may be unavailable and therefore the profile of the patient can be matched with the available doctor suitable to the needs of the patient. The patient to doctor assignment is a type of scheduling issue and is not going to be discussed in this article.

However, in an emergency visit, there is no assigned doctor for such a patient. The doctor in emergency section of the hospital will provide information about a patient after examination and a patient profile then can be created. In this case, the intelligent agent can assist the patient by matching the profile of the patient with the doctors suitable to the needs of the patient. Also the doctors can be contacted in a speedier manner as they are identified and their availability is known.

An appointment visit is very similar to a regular visit but it may happen only once and therefore the advantages mentioned for regular patients applies here.

We will endeavor to describe several of these, but will expand on one particular potential use of RFIDs in managing patient health data. First let us provide some background on RFIDs and present some definitions. We will discuss the environment that RFIDs operate in and their relationship to other available wireless technologies such as the IEEE 802.11b, IEEE 802.11g, IEEE 802.11n, and so forth, in order to fulfill their requirements effectively and efficiently.

This research is divided into four main sections. Section two is based on the patient to doctor profiling and intelligent software agents. The third section is a RFID background; this will provide a good description of RFIDs and their components. This section discusses several practical cases of RFID technology in and around hospitals. It will also list three possible applicable cases assisting in managing patients' medical data. The final section discusses the important issue of maintaining patients' data security and integrity and relates that to RFIDs.

PATIENT TO DOCTOR PROFILING

A profile represents the extent to which something exhibits various characteristics. These characteristics are used to develop a linear model based on the consensus of multiple sets of data, generally over some period of time. A patient or doctor profile is a collection of information about a person based on the characteristics of that person. This information can be used in a decision analyze situation between the doctor, domain environment, and patient. The model can be used to provide meaningful information for useful and strategic actions. The profile can be static or dynamic. The static profile is kept in prefixed data fields where the period between data field updates is long such as months or years. The dynamic profile is constantly updated as per evaluation of the situation. The updates may be performed manually or automated. The automated user profile building is especially important in real time decision-making systems. Real time systems are dynamic. These systems often contain data that is critical to the user's decision making process. Manually updated profiles are at the need and discretion of the relevant decision maker.

The profiling of patient doctor model is base on the patient/doctor information. These are:

- The categories and subcategories of doctor specialization and categorization. These categories will assist in information processing and patient/doctor matching.
- Part of the patients profile based on symptoms (past history problems, dietary restrictions, etc.) can assist in prediction of the patient's needs specifically.
- The patients profile can be matched with the available doctor profiles to provide doctors with information about the arrival of patients as well as presentation of the patients profile to a suitable, available doctor.

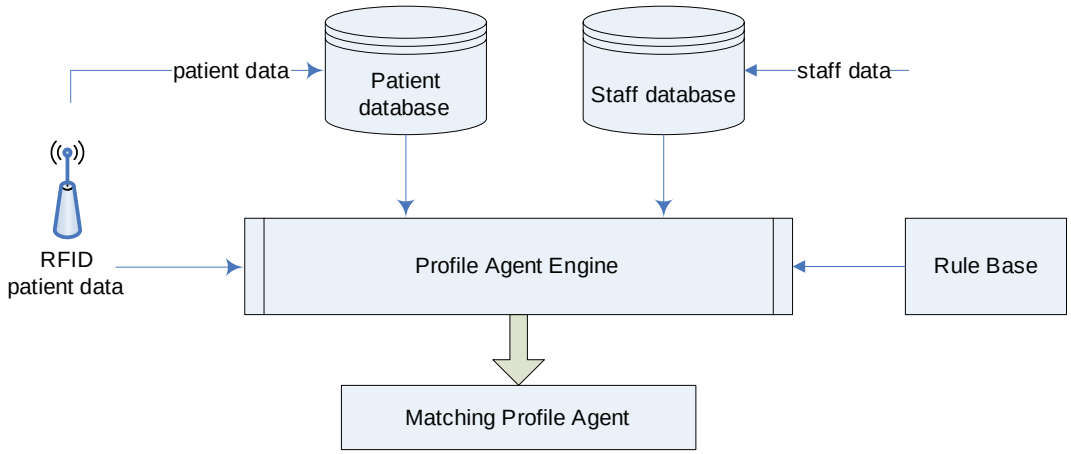
A value denoting the degree of association can be created form the above evaluation of the doctor to patient's profile. The intelligent agent based on the denoting degrees and appropriate, available doctors can be identified and allocated to the patient.

In the patient/doctor profiling, the agent will make distinctions in attribute values of the profiles and match the profiles with highest value. It should be noted that the agent creates the patient and doctor profiles based on data obtained from the doctors and patient namely:

- Explicit profiling occurs based on the data entered by hospital staff about a patient.
- Implicit profiling can fill that gap for the missing data by acquiring knowledge about the patient from its past visit or other relevant databases if any and then combining all these data to fill the missing data. Using legacy data for complementing and updating the user profile seems to be a better choice than implicit profiling. This approach capitalizes on user's personal history (previous data from previous visit to doctor or hospital).

The proposed agent architecture allows user profiling and matching in such a time intensive important application. The architecture of the agent profiling systems using RFID is given in Figure 2.

Figure 2. Agent profiling model using RFID



PROFILE MATCHING

Profile matching done is based on a vector of weighted attributes. To get this vector, a rule based systems can be used to match the patient's attributes (stored in patient's profile) against doctor's attributes (stored in doctor's profile). If there is a partial or full match between them, then the doctor will be informed (based on their availability from the hospital doctor database).

INTEGRATION OF INTELLIGENT SOFTWARE AGENTS AND RFID TECHNOLOGIES

Intelligent software agent technology has been used in order to provide the needed transformation of RIFD passive data collection into an active organizational knowledge assistant (Finkenzeller, 1999; Glover & Bhatt, 2006; Hedgepeth, 2007; Lahiri, 2005; Schuster et al., 2007; Shepard, 2005). Intelligent agent should be able to act on new data and already stored profile/knowledge and thereafter to examine its current actions based on certain assumptions, and inferentially plans its activities. Furthermore, intelligent software agents must be able to *interact* with other agents using symbolic language (Bigus & Bigus, 1998; Wooldridge & Jennings, 1995) and able to substitute for a range of human activities in a situated context. (In our case the activities are medical/patient assignment and the context is a hospital environment)

Context driven Intelligent software agents' activities are also dynamic and under continuous development in an historical time related environment (Bigus & Bigus, 1998; Wooldridge & Jennings, 1995).

Medical and hospital patient applied ontology's describing the applied domain are necessary for the semantic communication and data understanding between RFID inputs and knowledge bases inference engines so that profiling of both patients and doctors can be achieved (Gruber, 1993; Guarino, Carrara, & Giaretta, 1994).

The integration of RFID capabilities and intelligent agent techniques provides promising development in the areas of performance improvements in RFID data collection, inference, knowledge acquisition, and profiling operations.

By using mediated activity theories, an RIFD agent architecture could be modeled according to the following characteristics:

- The ability to use patient/doctor profile in natural language, ACL, or symbolic form as communicative tools mediating agents cooperative activities.
- The ability to use subjective and objective properties required by intelligent software agents to perform bidirectional multiple communication activities.
- The ability to internalize representations of medical/patient profile patterns from agents or humans.
- The ability to externalize internally stored representations of medical assignment patterns to other agents or humans.

The Agent Language Mediated Activity Model (ALMA) agent architecture currently under research is based on the mediated activity framework described and is able to provide RFID with the necessary framework to profile a range of internal and external medical/patient profiling communication activities performed by wireless multi-agents.

RFID DESCRIPTION

RFID or Radio Frequency Identification is a progressive technology that has been said to be easy to use and well suited for collaboration with intelligent software agents. Basically an RFID can:

- Be read-only;
- Volatile read/write; or
- Write once/read many times
- RFID are:
    - Noncontact and
    - Non line-of-sight operations.

Being noncontact and non line-of-sight will make RFIDs able to function under a variety of environmental conditions and while still providing a high level of data integrity (Finkenzeller, 1999; Glover & Bhatt, 2006; Hedgepeth, 2007; Lahiri, 2005; Schuster et al., 2007; Shepard, 2005).

MAIN COMPONENTS

A basic RFID system consists of four components:

1. The RFID tag (sometimes referred to as the transponder);
2. A coiled antenna;
3. A radio frequency transceiver; and
4. Some type of reader for the data collection.

Basically there are three components as often components are combined such as the transponder or transceiver or the antenna.

Transponders

The reader emits radio waves in ranges of anywhere from 2.54 centimeters to 33 meters. Depending upon the reader's power output and the radio frequency used and if a booster is added that distance can be somewhat increased. When RFID tags (transponders) pass through a specifically created electromagnetic zone, they detect the reader's activation signal. Transponders can be online or off-line and electronically programmed with unique information for a specific application or purpose. A reader decodes the data encoded on the tag's integrated circuit and passes the data to a server for data storage or further processing.

Coiled Antenna

The coiled antenna is used to emit radio signals to activate the tag and read or write data to it. Antennas are the conduits between the tag and the transceiver that controls the system's data acquisition and communication. RFID antennas are available in many shapes and sizes. They can be built into a doorframe, book binding, DVD case, mounted on a tollbooth, embedded into a manufactured item such as a shaver or software case (just about anything) so that the receiver tags the data from things passing through its zone (Finkenzeller, 1999; Glover & Bhatt, 2006; Hedgepeth, 2007; Lahiri, 2005; Schuster et al., 2007; Shepard, 2005).

Transceiver

Often the antenna is packaged with the transceiver and decoder to become a reader. The decoder device can be configured either as a handheld or a fixed-mounted device. In large complex, often chaotic environments, portable or handheld transceivers would prove valuable.

TYPES OF RFID TRANSPONDERS

RFID tags can be categorized as active, semi-active, or passive. Each has and is being used in a variety of inventory management and data collection applications today. The condition of the application, place and use determines the required tag type.

Active Tags

Active RFID tags are powered by an internal battery and are typically read / write. Tag data can be rewritten and/or modified as the need dictates. An active tag's memory size varies according to manufacturing specifications and application requirements; some tags operate with up to 5 megabyte of memory. For a typical read/write RFID work-in-process system, a tag might give a machine a set of instructions, and the machine would then report its performance to the tag. This encoded data would then become part of the tagged part's history. The battery-supplied power of an active tag generally gives it a longer read range. The trade off is greater size, greater cost, and a limited operational life that has been estimated to be a maximum of 10 years, depending upon operating temperatures and battery type (Finkenzeller, 1999; Glover & Bhatt, 2006).

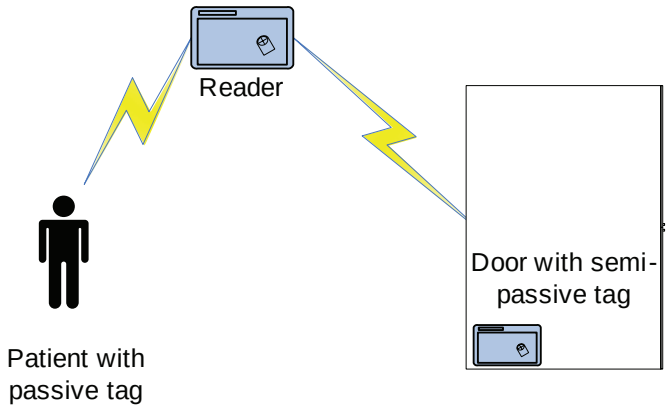
Semi-Active Tags

The semi-active tag comes with a battery. The battery is used to power the tags circuitry and not to communicate with the reader. This makes the semi-active tag more independent than the passive tag, and it can operate in more adverse conditions. The semi-active tag also has a longer range and more capabilities than a passive tag (Shepard, 2005). Linear barcodes that reference a database to get product specifications and pricing are also data devices that act is a very similar way. Semi-passive tags are preprogrammed, but can allow for slight modifications of their instructions via the reader/interrogator. However, it is bigger, weighs more, and is more complete than a passive tag. A reader is still needed for data collection.

Passive Tags

Passive RFID tags operate without a separate external power source and obtain operating power generated from the reader. Passive tags,

Figure 3. Semi-passive tag



since they have no power source embedded, are consequently much lighter than active tags, less expensive, and offer a virtually unlimited operational lifetime. However, the trade off is that they have shorter read ranges, than active tags, and require a higher-powered reader.

Read-only tags are typically passive and are programmed with a unique set of data (usually 32 to 128 bits) that cannot be modified. Read-only tags most often operate as a data device that utilizes a database for all data storage (Finkenzeller, 1999; Shepard, 2005).

Range

RFID systems can be distinguished by their deployment and frequency range. RFID tags generally operate in two different types of frequencies that make them adaptable for nearly any application. These frequency ranges are:

Low Frequency Range (Short Range)

Low-frequency (30 KHz to 500 KHz) systems have short reading ranges and lower system costs. They are most commonly used in security access, asset tracking, and animal identification applications (Glover & Bhatt, 2006; Hedgepeth, 2007; Lahiri, 2005).

High Frequency Range (Long Range)

High-frequency (850 MHz to 950 MHz and Industry, Science and Medical - 2.4 GHz to 2.5 GHz) systems, offer longer reading ranges (greater than 33 meters) and high reading speeds. These systems are generally used for such applications as railroad car tracking, container dock and transport management, and automated toll collection. However, the higher performance of high-frequency RFID systems incurs higher system operating costs (Glover & Bhatt, 2006; Schuster et al., 2007).

Hospital Environment

In hospitals, systems need to use rules and domain knowledge that is appropriate to the situation. One of the more promising capabilities of intelligent software agents is their ability to coordinate information between the various resources.

In a hospital environment, in order to manage patient medical data we need both types; fixed and handheld transceivers. Also, transceivers can be assembled in ceilings, walls, or doorframes to collect and disseminate data. Hospitals have become large complex environments.

In a hospital, nurses and physicians can retrieve the patient's medical data stored in transponders (RFID tags) before they stand beside a patient's bed or as they are entering a ward.

Given the descriptions of the two types and their potential use in hospital patient data management we suggest that:

- It would be most useful to embed a passive RFID transponder into a patient's hospital wrist band;
- It would be most useful to embed a passive RFID transponder into a patient's medical file (there are several versions and perspectives that we can take no this).

Doctors should have PDAs equipped with RFID or some type of personal area network device. Either would enable them to retrieve some patient's information whenever they are near the patient, instead of waiting until the medical data is pushed to them through the hospital server (there are several versions and perspectives that we can take no this):

- *Active RFID tags* are more appropriate for the continuous collection of the patient's medical data. Since the patient's medical data needs to be continuously recorded to an active RFID tag and an associated

reader needs to be employed. Using an active RFID means that the tag will be a bit bulky because of the needed battery for the write process and there is a concern with radio frequency admissions. Thus, it is felt that an active tag would not be a good candidate for the patient wrist band. However, if the patient's condition is to be continuously monitored, the collection of the data at the source is essential. The inclusion of the tag in the wrist band is the only way to recorder the medical data on a real-time base using the RFID technology. As more organizations get into the business of manufacturing RFIDs and the life and size of batteries decrease, the tag size will decrease and this may be a real possible use.

- *Passive RFID tags* can be also used as well. These passive tags can be embedded in the doctors PDA, which is needed for determining their locations whenever the medical staff requires them. Also, passive tags can be used in patients' wrist bands for storage of limited amount of data- on off-line bases, for example, date of hospital admission, medical record number, and so forth.

After examining both ranges, we can suggest the following:

- *Low frequency range tags* are suitable for the patients' band wrist RFID tags. Since we expect that the patients' bed will not be too far from a RFID reader. The reader might be fixed over the patient's bed, in the bed itself, or over the door-frame. The doctor using his/her PDA would be aiming to read the patient's data directly and within a relatively short distance.
- *High frequency range tags* are suitable for the physician's tag implanted in their PDAs. As physicians use to move from one location to another in the hospital, data on their patients could be continuously being updated.

One final point in regards to the range of RFIDs: until 2002, the permissible radio frequency range was not regulated, that is, it still operated in some low frequency ranges (30- 500 KHz) and in the free 2.45 GHz ISM band of frequency. The IEEE's 802.11b and IEEE's 802.11g (WiFi) wireless networks also operate in the same range (actually there are many other wireless application that operate in that range). This band of frequency is crowded. Where equipment in a hospital is often in the ISM band of frequency, there may be some speed of transmission degradation. The IEEE 802.11n builds upon previous 802.11 standards by adding MIMO (multiple-input multiple-output). MIMO uses multiple transmitter and receiver antennas to allow for increased data throughput via spatial multiplexing and increased range by exploiting the spatial diversity. Note that 802.11n draft 2.0 has been released but the certification of products is still in progress. What this means is that even though 802.11n has greater benefits then previous standards, it is still a draft. The full version is not expected until 2008; thus; products may take several years to be compliant and incorporate that into RFIDs (Hedgepeth, 2007).

Shapes of RFID Tags

RFID tags come in a wide variety of shapes and sizes. Animal tracking tags that are inserted beneath the animal's skin can be as small as a pencil lead in diameter and about one centimeter in length. Tags can be screw-shaped to identify trees or wooden items, or credit card shaped for use in access applications. The antitheft hard plastic tags attached to merchandise in stores are RFID tags (Glover & Bhatt, 2006). Manufacturers can create the shape that is best for the application, including flexible shaped tags that

act like and resemble human skin. RFID tags can be flexible and do not have to be rigid.

Transceivers

The transceivers/interrogators can differ quite considerably in complexity, depending upon the type of tags being supported and the application. T\he overall function of the application is to provide the means of communicating with the tags and facilitating data transfer. Functions performed by the reader may include quite sophisticated signal conditioning, parity error checking, and correction. Once the signal from a transponder has been correctly received and decoded, algorithms may be applied to decide whether the signal is a repeat transmission, and may then instruct the transponder to cease transmitting or temporarily cease asking for data from the transponder. This is known as the "Command Response Protocol" and is used to circumvent the problem of reading multiple tags over a short time frame. Using interrogators in this way is sometimes referred to as "Hands Down Polling." An alternative, more secure, but slower tag polling technique is called "Hands Up Polling." This involves the transceiver looking for tags with specific identities, and interrogating them in turn. A further approach may use multiple transceivers, multiplexed into one interrogator, but with attendant increases in costs (Glover & Bhatt, 2006; Hedgepeth, 2007; Lahiri, 2005; Schuster et al., 2007).

Hospital patient data management deals with sensitive and critical information (patient's medical data). *Hands Down polling* techniques in conjunction with multiple transceivers that are multiplexed with each other, form a wireless network. The reason behind this choice is that, we need high speed for transferring medical data from medical equipment to or from the RFID wrist band tag to the nearest RFID reader, and then through a wireless network or a network of RFID transceivers or LANs to the hospital server. From there it is a short distance to be transmitted to the doctor's PDA, a laptop, or desktop through a WLAN IEEE 802.11b, 802.11g, or 802.11n, or wired LAN which operates at the 5.2 GHz band with a maximum data transfer rate exceeding 104 Mbps.

The "Hand Down Polling" techniques, as previously described, provides the ability to detect all detectable RFID tags at once (i.e., in parallel). Preventing any unwanted delay in transmitting medical data corresponding to each RF tagged patient.

RFID TRANSPONDER PROGRAMMERS

Transponder programmers are the means, by which data is delivered to write once, read many (WORM) and read/write tags. Programming can be carried out off-line or online. For some systems re-programming may be carried out online, particularly if it is being used as an interactive portable data file within a production environment, for example. Data may need to be recorded during each process. Removing the transponder at the end of each process to read the previous process data, and to program the new data, would naturally increase process time and would detract substantially from the intended flexibility of the application. By combining the functions of a transceiver and a programmer, data may be appended or altered in the transponder as required, without compromising the production line.

We conclude from this section that RFID systems differ in type, shape, and range; depending on the type of application, the RFID components shall be chosen. Low frequency range tags are suitable for the patients' band wrist RFID tags. Since we expect that a patients' bed is not too far from the RFID reader, which might be fixed on the room ceiling or door-frame. High frequency range tags are suitable for the physician's PDA

tag. As physicians use to move from on location to another in the hospital, long read ranges are required. On the other hand, transceivers which deal with sensitive and critical information (patient's medical data) need the Hands Down polling techniques. These multiple transceivers should be multiplexed with each other forming a wireless network.

PRACTICAL CASES USING RFID TECHNOLOGY

This section explains in details three possible applications of the RFID technology in three applicable cases. Each case is discussed step-by-step then represented by a flowchart. Those cases cover issues as acquisition of Patient's Medical Data, locating the nearest available doctor to the patients location, and how doctors stimulate the patient's active RFID tag using their PDAs in order to acquire the medical data stored in it.

Case I: Acquisition of Patient's Medical Data

Case one will represent the method of acquisition and transmission of medical data. This process can be described in the following points as follows:

1. A biomedical device equipped with an embedded RFID transceiver and programmer will detect and measure the biological state of a patient. This medical data can be an ECG, EEG, BP, sugar level, temperature or any other biomedical reading.
   After the acquisition of the required medical data, the biomedical device will write-burn this data to the RFID transceiver's EEPROM using the built in RFID programmer. Then the RFID transceiver with its antenna will be used to transmit the stored medical data in the EEPROM to the EEPROM in the patient's transponder (tag) which is around his/her wrist. The data received will be updated periodically once new fresh

Figure 4. Acquisition of patient data

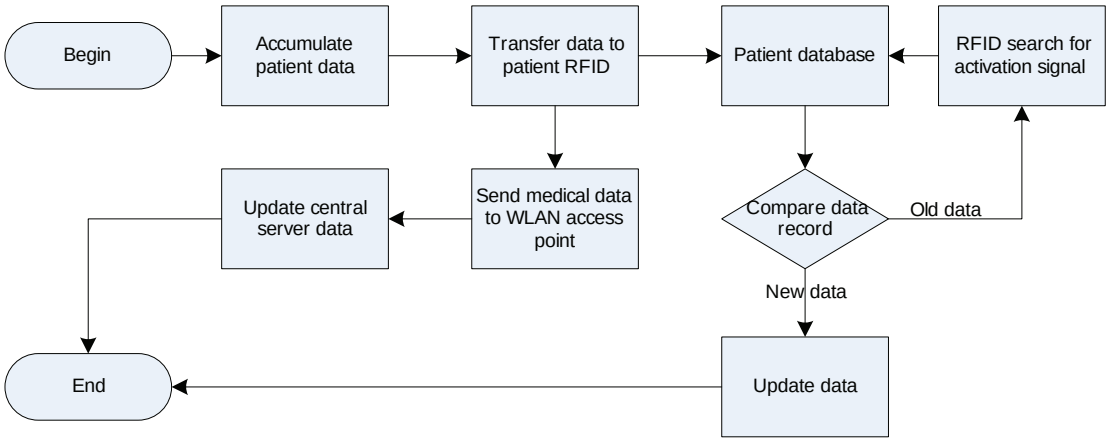


Figure 5. Locating nearest doctor

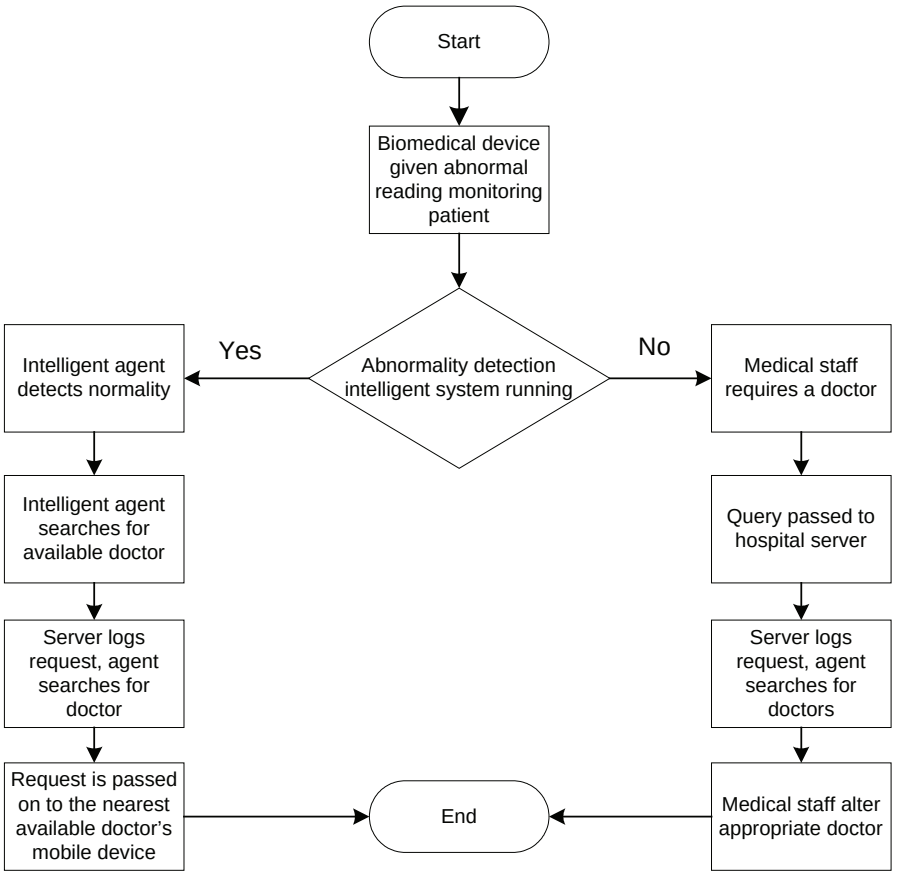


readings are available by the biomedical device. Hence, the newly sent data by the RFID transceiver will be accumulated to the old data in the tag. The purpose of the data stored in the patient's tag is to make it easy for the doctor to obtain medical information regarding the patient directly via the doctor's PDA, tablet PC, or laptop.

2. Similarly, the biomedical device will also transfer the measured medical data wirelessly to the nearest WLAN access point. Since high data rate transfer rate is crucial in transferring medical data, IEEE 802.11b or g is recommended for the transmission purpose.
3. The wirelessly sent data will be routed to the hospitals main server; to be then sent (pushed) to:
   i. Other doctors available throughout the hospital so they can be notified of any newly received medical data.
   ii. To an online patient monitoring unit or a nurse's workstation within the hospital.
   iii. Or the acquired patients' medical data can be fed into an expert (intel-

ligent) software system running on the hospital server. To be then compared with other previously stored abnormal patterns of medical data, and to raise an alarm if any abnormality is discovered.

4. Another option could be using the in-built-embedded RFID transceiver in the biomedical device to send the acquired medical data wirelessly to the nearest RFID transceiver in the room. Then the data will travel simultaneously in a network of RFID transceivers until reaching the hospital server.

Case II: Locating the Nearest Available Doctor to the Patients Location

This case will explain how to locate the nearest doctor who is needed urgently to attend an emergency medical situation. This case can be explained as follows:

1. If a specific surgeon or physician is needed in a specific hospital department, the medical staff in the monitoring unit (e.g., nurses) can query the hospital server for the nearest available doctor to the patient's location. In our framework an intelligent agent can perform this task.
2. The hospital server traces all doctors' locations in the hospital through detecting the presences of their wireless mobile device; for example, PDA, tablet PC, or laptop in the WLAN range.
3. Another method that the hospital's server can use to locate the physicians is making use of the RFID transceivers built-in the doctor's wireless mobile device. Similarly to the access points used in WLAN, RFID transceivers can assist in serving a similar role of locating doctor's location. This can be described in three steps, which are:
   i. The fixed RFID transceivers throughout the hospital will send a stimulation signal to detect other free RFID transceivers—which are in the doctors PDAs, tablets , r laptops, and so forth.
   ii. All free RFID transceivers will receive the stimulation signal and reply back with an acknowledgement signal to the nearest fixed RFID transceiver.
   iii. Finally, each free RFID transceiver cell position would be determined by locating to which fixed RFID transceiver range it belongs to or currently operating in.
4. After the hospital server located positions of all available doctors, it determines the nearest requested physician (pediatrics, neurologist, and so forth) to the patient's location.
5. Once the required physician is located, an alert message will be sent to his\her PDA, tablet PC or laptop indicating the location to be reached immediately. This alert message could show:
   i. The building, floor, and room of the patient (e.g., 3C109).
   ii. Patient's case (e.g., heart stroke, arrhythmia, etc.)
   iii. A brief description of the patient's case.
6. If the hospital is running an intelligent agent as described in the proposed framework on its server, the process of locating and sending an alert message can be automated. This is done through comparing the collected medical data with previously stored abnormal patterns of medical data, then sending an automated message describing the situation. This system could be used instead of the staff in the patient monitoring unit or the nurse's workstation where nurses observe and then send an alert message manually.

Case III: Doctors Stimulate the Patient's Active RFID Tag Using their PDAs in Order to Acquire the Medical Data Stored in it

This method can be used in order to get rid of medical files and records placed in front of the patient's bed. Additionally, it could help in preventing medical errors- reading the wrong file for the wrong patient and could be considered as an important step towards a paperless hospital.

This case can be described in the following steps:

1. The doctor enters into the patient's room or ward. The doctor wants to check the medical status of a certain patient. So instead of picking up the "hard" paper medical file, the doctor interrogates the patient's RFID wrist tag with his RFID transceiver equipped in his\her PDA, tablet PC, or laptop, and so forth.
2. The patient's RFID wrist tag detects the signal of the doctor's RFID transceiver coming from his\her wireless mobile device and replies back with the patient's information and medical data.
3. If there was more than one patient in the ward possessing RFID wrist tags, all tags can respond in parallel using Hands Down polling techniques back to the doctor's wireless mobile device.
4. Another option could be that the doctor retrieving only the patient's number from the *passive* RFID wrist tag. Then through the WLAN the doctor could access the patient's medical record from the hospital's main server.

RFID technology has many potential important applications in hospitals, and the discussed three cases are a real practical example. Two important issues can be concluded from this section: WLAN is preferred for data transfer; given that IEEE's wireless networks have much faster speed and coverage area as compared to RFID transceivers\transponders technology. Yet, RFID technology is the best for data storage and locating positions of medical staff and patients as well.

The other point is that we need a RFID transceiver & programmer embedded in a biomedical device for data acquisition and dissemination, and only a RFID transceiver embedded in the doctor's wireless mobile device for obtaining the medical data. With the progress the RFID technology is currently gaining, it could become a standard as other wireless technologies (Bluetooth, for example), and eventually manufacturers building them in electronic devices; biomedical devices for our case.

MAINTAINING PATIENTS' DATA SECURITY AND INTEGRITY

Once data is transmitted wirelessly, security becomes a crucial issue. Unlike wired transmission, wirelessly transmitted data can be easily sniffed out leaving the transmitted data vulnerable to many types of attacks. For example, wireless data could be easily eavesdropped on using any mobile device equipped with a wireless card. In worst cases wirelessly transmitted data could be intercepted and then possibly tampered with, or in best cases, the patient's security and privacy would be compromised. Hence emerges the need for data to be initially encrypted from the source.

In this section, a discussion on how to apply encryption for the designed wireless framework for hospital is considered. Suggesting exactly where data needs to be encrypted and\or decrypted depending on the case that is being examined does this.

First a definition of the type of encryption that would be used in the design of the security (encryption\decryption) framework is discussed,

followed by a flowchart demonstrating the framework in a step-by-step process.

Layers of Encryption

Two main layers of encryption are recommended. They are:

Physical (Hardware) Layer Encryption

This means encrypting all collected medical data at the source or hardware level before transmitting it. Thus, we insure that the patient's medical data would not be compromised once exposed to the outer world on its way to its destination. So even if a person with a malicious intent and also possessing a wireless mobile device steps into the coverage range of the hospitals' WLAN, this intruder will gain actually nothing since all medical data is encrypted, making all intercepted data worthless.

Application (Software) Layer Encryption

This means encrypting all collected medical data at the destination or application level once receiving it. Application level encryption runs on the doctor's wireless mobile device (e.g., PDA, tablet PC, or laptop) and on the hospital server. Once the medical data is received, it will be protected by a secret pass-phrase (encryption\decryption key) created by the doctor who possesses this device. This type of encryption would prevent any person from accessing patient's medical data if the doctor's wireless mobile device gets lost, or even if a hacker hacks into the hospital server via the Internet, intranet or some other mean.

Framework of Encrypting Patient's Medical Data

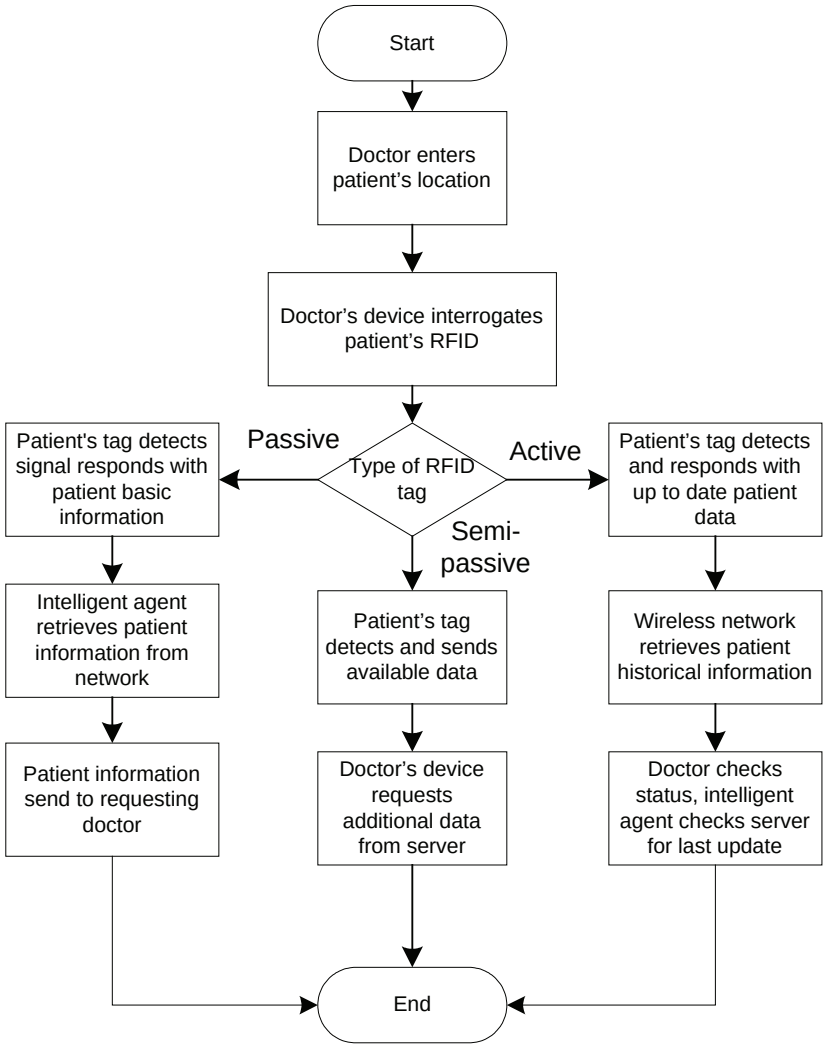
The previous section (Practical Cases using RFID Technology) focused on how to design a wireless framework to reflect how patients' medical data can be managed efficiently and effectively leading to the elimination of errors, delays, and even paperwork. Similarly, this section will focus on the previously discussed framework from a security perspective, attempting to increase security and data integrity.

i. Acquisition of Patients' Medical Data
ii. Doctors stimulating the patient's active RFID tag using their wireless mobile devices in order to acquire the medical data stored in it.

While the third case which was about locating the nearest available doctor to the patients location, is more concerned about locating doctors than transferring patient's data, so it is not discussed here.

The lower part of Figure 6 represents the physical (hardware) encryption layer. This part is divided into two sides. The left side demonstrates the case of a doctor acquiring patient's medical data via a passive RFID tag located in a band around the patient's wrist. The passive RFID tag contains only a very limited amount of information such as the patients name, date of admission to the hospital and above all his/her medical record number (MRN), which will grant access to the medical record containing the acquired medical data and other information regarding the patient's medical condition. This process is implemented in six steps, and involves two pairs of encryption and decryption. The first encryption occurs after the doctor stimulates the RFID passive tag to acquire the patient's MRN, so the tag will encrypt and reply back the MRN to the doctors PDA for example. Then the doctor will decrypt the MRN and use it to access the patient's medical record from the hospital's server. Finally the hospital server will encrypt and reply back the medical record, which will be decrypted once received by the doctors' PDA.

Figure 6. Functional flow



The right side of Figure 6 represents a similar case but this time using an active RF tag. This process involves only one encryption and decryption. The encryption happens after the doctor stimulates the active RFID tag using his PDA which has an in-equipped RFID transceiver, so the tag replies with the medical data encrypted. Then the received data is decrypted through the doctors' PDA.

The upper part of Figure 6 represents the application encryption layer, requiring the doctor to enter a pass-phrase to decrypt and then access the stored medical data. Whenever the doctor wants to access patient's medical data, the doctor simply enters a certain pass-phrase to grant access to either wireless mobile device or a hospital server depend where the medical data actually resides.

CHOOSING LEVEL OF SECURITY FOR THE WIRELESSLY-TRANSMITTED MEDICAL DATA

Securing medial data seems to be uncomplicated, yet the main danger of compromising such data comes from the people managing it, for example, doctors, nurses, and other medical staff. For that, we have seen that even though the transmitted medical data is initially encrypted from the source, doctors have to run application level encryption on their wireless mobile devices in order to protect this important data if the devices gets lost, left behind, robbed, and so forth. Nevertheless, there is a compromise. Increasing security through using multiple layers, and increasing length of encryption keys decreases the encryption\decryption speed and causes unwanted time delays, whether we were using application or hardware level of encryption. As a result, this could delay medical data sent to doctors or online monitoring units.

Figure 6 represents the case of high and low level of security in a flowchart applied to the previously discussed two cases in the last report.

At the end of this section, we conclude that there are two possible levels of encryption, software level (application layer) or hardware level (physical layer), depending on the level of security required. Both physical (hardware) layer and application layer encryption are needed in maintaining collected medical data on hospital servers and doctors wireless mobile devices.

Encrypting medical data makes the process of data transmission slower while sending data unencrypted is faster. We have to have a compromise between speed and security. For our case, medical data has to be sent as fast as possible to medical staff, yet the security issue has the priority.

CONCLUSION

Managing patients' data wirelessly (paperless) can prevent errors, enforce standards, make staff more efficient, simplify record keeping, and improve patient care. In this research report, both passive and active RFID tags were used in acquiring and storage of medical data, and then linked to the hospitals' server via a wireless network Moreover, three practical applicable RFID cases discussed how the RFID technology can be put in use in hospitals, while at the same time maintaining the acquired patients' data security and integrity.

This research in the wireless medical environment introduces some new ideas in conjunction to what is already available in RFID technology and wireless networks. Linking both technologies to achieve the research main goal, delivering patients medical data as fast and secure as possible, to pave the way for future paperless hospitals.

Finally, as reported by Frost and Sullivan, the high cost of radio frequency identification (RFID) technology is a deterrent for health care providers, though RFID has great benefits to hospitals in tracking patients, monitoring patients, assisting in health care administration, and reducing medical costs. With the reduction in cost of radio frequency identification (RFID) technology, increased use of RFID technology in health care in monitoring patients and assisting in health care administration is expected.

Chapter 8.13
Widely Usable User Interfaces on Mobile Devices with RFID

ABSTRACT

Diffusion of radio frequency identification (RFID) promises to boost the added value of assistive technologies for mobile users. Visually impaired people may benefit from RFID-based applications that support users in maintaining "spatial orientation" (Mann, 2004) through provision of information on where they are, and a description of what lies in their surroundings. To investigate this issue, we have integrated our development tool for mobile device, (namely: MADE, Bellotti, Berta, De Gloria, & Margarone, 2003), with a complete support for RFID tag detection, and implemented an RFID-enabled location-aware tour-guide. We have evaluated the guide in an ecological context (fully operational application, real users, real context of use (Abowd & Mynatt, 2000)) during the EuroFlora 2006 international exhibition (EuroFlora). In this chapter, we describe the MADE enhancement to support RFID-based applications, present the main concepts of the interaction modalities we have designed in order to support visually impaired users, and discuss results from our field experience.

INTRODUCTION

Starting from the European Union cofounded E-Tour project, we designed the tourist digital assistant (TDA) concept and developed multimedia

tour guides on mobile devices (PocketPC and Smartphone devices) for a number of European tourist sites, such as the Costa Aquarium of Genoa, "Strada Nuova" architectonical area and the city of Genoa, the Castellon region in Spain, and the city of Uddevalla in Sweden (Bellotti, Berta, De Gloria, & Margarone,, 2002).

The tour guide provides multimedia contents, added-value information, and location-based services to the tourists. Added-value services are implemented by integrating the mobile devices with additional hardware and software tools such as GPS, electronic compasses, wireless connectivity, digital cameras, written text input, databases, and so forth.

See Figure 1 for snapshots of tourist guide applications.

Relying on the argument that "play is a powerful mediator for learning throughout a person's life," we developed the "educational territorial-gaming" concept in VeGame (Bellotti, Berta, De Gloria, Ferretti, & Margarone, 2003), a computer-supported educational wireless team-game played along Venice's narrow streets to discover the art and the history of the city (see Figure 2), and in ScienceGame (Bellotti, Berta, De Gloria, Ferretti, & Margarone, 2004), a sort of treasure-hunt game inviting players to discover the mysteries and the marvels of the science (see Figure 3) during the "Festival della Scienza" exhibition held in Genoa every year.

These applications were developed from scratch. From these first experiences, we identified common needs and came up with a system to support design of multimedia applications

Figure 1. Snapshots from the Aquarium and Strada Nuova tour guides on PocketPC device

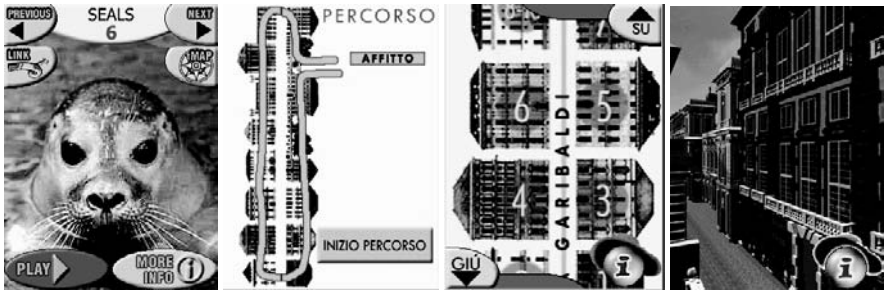

Figure 2. Snapshots from VeGame

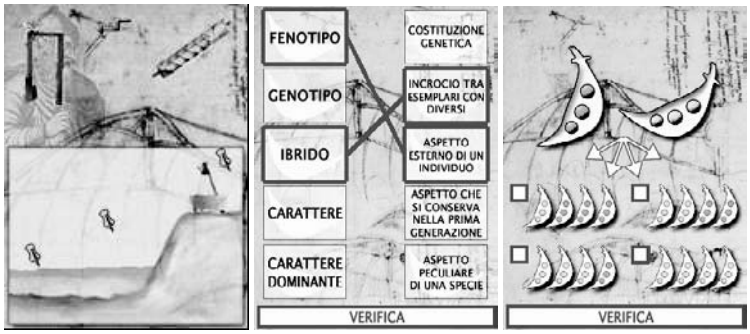
Figure 3. Snapshots from ScienceGame



for mobile devices, called Mobile Applications Development Environment (MADE) (Bellotti et al., 2002).

MADE includes M3P (MicroMultiMedia Player), a network-enabled multimedia player easily programmable through the micromultimedia services language (MSL). MSL provides high-level components encapsulating advanced services (e.g., positioning, database query, path search, etc.) that can be easily integrated in multimedia applications. This allows building modular software programs that provide information-rich services to the general public through a coherent and homogeneous HCI that can be learned with low mental workload. On the other hand, MADE hides the low-level aspects of multimedia and service management, allowing designers to focus on the modalities of presentation of information and on user interaction, reducing learning, development, and code maintenance time.

In this chapter, we describe the latest MADE enhancement: we have integrated it with a complete support for RFID detection to allow development of multimedia mobile applications directly connected with the physical world (Want, Fishkin, Gujar, & Harrison, 1999). All low-level aspects of the hardware tag-detection system that are necessary to identify and locate physical objects with attached small RF tags (Want, 2004) are hidden to MSL programmer by the MADE system.

This chapter will also show the use of MADE with the RFID support in a real context such as EuroFlora 2006 international exhibition. This guide differs from others because it has been ad-hoc developed in order to meet strict usability needs. In particular, the novel interface design assists visually impaired people in maintaining "spatial orientation" (Mann, 2004) through provision of information on where they are, hazards that might be in the way, and a description of what lies in their surroundings.

MADE SUPPORT OF RFID TECHNOLOGY

Location-Aware Computing

Recent research has developed several systems, to determinate physical location, that differ by accuracy, cost, and coverage (Boriello, Chalmers, La Marca, & Nixon, 2005). The global positioning system (GPS), which uses signal from satellite to estimate position (Djuknic & Richton, 2001), is

the most used system, but only for applications in outdoor areas. In indoor areas and urban areas with poor sky visibility, the system does not work properly. Moreover, it has a long start-up time.

To overcome these limitations, the first indoor positioning system was the active badge system (Want, Hopper, Falcão, & Gibbons, 1992), which is based on sensors that receive infrared ID broadcast from tags worn by people. This system gives a poor (room-grained) localization precision. After the active badge system, typical indoor location systems are based on radio frequency and on the estimation of position computed from the measured signal strength. Various technologies can be used: Wi-Fi (Howard, Siddiqi, & Sukhatme, 2003), Bluetooth (Bruno & Delmastro, 2003) and nowadays RFID (Liu, Corner, & Shenoy, 2006).

The first two solutions can give an accuracy of around some meters, but require expensive fixed base stations. RFID tags, instead, are very inexpensive and have the same performance. The literature reports also of many location estimation algorithms based on cellular radio networks (Xu & Jacobsen, 2005). However, there is not a generally agreed solution today, and each algorithm has pros and cons, depending on environmental issues. Finally, some vision-based algorithms (López de Ipiña, Mendonça, & Hopper, 2002) are promising because they do not require infrastructure (like tags, satellite, or base station). However, it is difficult to set up a system to locate a user with a 1-meter precision. In the selection of the best methodology for our system, we have taken into account three major issues: the possibility to have a system for outdoor/indoor spaces (like the EuroFlora 2006 exhibition area), a technology with a low cost for the deployment of the infrastructure, and a likely pervasive availability of the system in the near future. All these requirements are satisfied by the RFID technology.

RFID Application Fields

Major RFID application domains include monitoring physical parameters, such as temperature or acceleration, during fragile or sensitive products delivery, monitoring product integrity from factory to retail locations (Siegemund & Floerkemeier, 2003), utilities for home and office automation (Langheinrich, Mattern, Romer & Vogt,, 2000). Nowadays we have passive or active inexpensive RFID (approaching 35 cents today, with a goal of 5 cents (Quaadgras, 2005)) that makes these kinds of sensors practical for tourist applications. For example, a museum exposition can place tags attached to each point of interest so that tourists can receive information about exposition in the right moment at the right place; when near to the object. The research community has actively explored this possibility at the Exploratorium, the interactive science museum in San Francisco. The HP Laboratories researchers have implemented a system that uses three types of identification technology: infrared beacon, barcodes, and RFIDs (Fleck, Frid, Kindberg, O'Brian-Strain, Rajani, & Spasojevic, 2002). In Goker et al. (Goker, Watt, Myrhaug Whitehead, Yakici, Bierig, et al., 2004), a special tag that can work with mobile devices to provide ambient information to users on the move is described. In the Cooltown project (Kindberg & Barton, 2001), RFIDs are used to attach pointers from everyday objects to entities in the computational world. A full exploitation of RFID potentials requires study and implementation of human–computer interaction (HCI) modalities able to support usability of the enhanced mobile tool by the general public. This implies the necessity to resort to programming methodologies and tools specifically dedicated to support the RFID technology. Thus, we have extended the MADE toolkit to support a link between applications and physical world through RFID sensors.

MADE Architecture

A typical MADE application consists of a set of pages containing multimedia and service objects. The micromultimedia services language (MSL) script specifies pages' layout and objects' appearance, synchronization, and user-interaction modalities. MSL scripts are interpreted at runtime by the M3P player that manages presentation of contents and user interaction according to the instructions specified in the input MSL script.

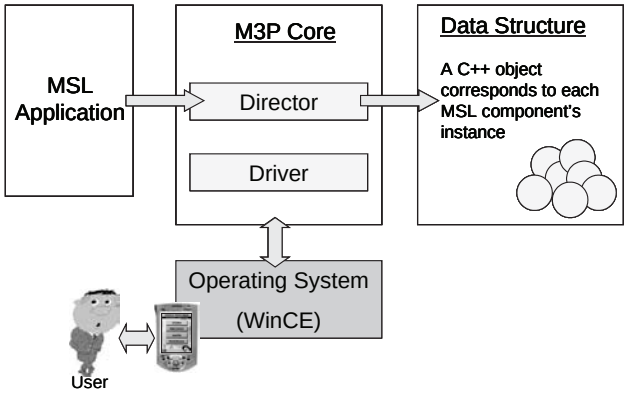
M3P player relies on two-layer architecture (see Figure 4) involving a high-level, platform-independent director and a low-level driver. The director is responsible for creating, initializing, and managing the objects that implement the language functionalities. In order to support incremental development of the player, M3P is composed by a set of modules. In particular, the director has been designed to be independent of the components it manages. According to the object-oriented methodology, this has been achieved by encapsulating the functions of the components in the code of their class, and by structuring the hierarchy so that the director can simply keep a reference to the presentation's pages and convey them events.

According to the instructions specified by the MSL developer in the script, events (either from the system or from user interaction) are conveyed to the director that simply redirects them to the components of the page currently on show, which is the higher-priority choice or, with lower priority, to the other pages of the presentation.

Events are implemented as string messages that are to be interpreted by the target objects. This design choice allows the director's code to be independent of the components and the components to be independent of each other. The basic assumption of this schema is that each component exports a well-defined interface (i.e., a set of messages to which it is able to react) and implements this interface (i.e., implements the reaction to such messages).

Thus, components can be seamlessly added and interchanged (in this last case, as long as they comply with the same interface). Adding a new component (i.e., a new functionality) does not involve any change either in the director's code, or in the other components' code.

Figure 4. MADE architecture



Such a design choice supports easy incremental development, allowing seamless integration of services within a single application framework. This implies that a homogeneous HCI can be applied to an application that hosts several different services that have been developed independently of each other (e.g., intelligent tour planning, interactive maps, positioning, and database access).

MSL relies on a component-based data structure. That is, an MSL file specifies creation of components, attributes of components, and their reaction as a consequence of user interaction. Components are organized in three main libraries: multimedia (e.g., audio, image, video, button), synchronization (utilities like timers that can be used to implement synchronization and scheduling of contents), and services (objects that encapsulate services such as positioning, shortest path search, tour planning, database query, etc).

Every different type of component has its own kind of attributes (fields). The fields record data for specifying the appearance (such as position) and the behaviour (i.e., reactions to events) of the component. In general, components are contained in a special container component, called CARD, that can be thought of as an empty page on which the developer can add components.

The core of M3P involves a platform-independent director and a platform-dependent driver. The director manages the multimedia objects that implement the presentation. Objects are compounded in hierarchical structures. For instance, a CARD (i.e., a multimedia page) may include several images, buttons, and mpeg players. The driver implements the functions to access the hardware, while the director deals with the logic of the multimedia presentation.

Integration of RFID Subsystem

A major feature of MADE consists in the possibility of incrementally adding new hardware and software modules, that are integrated into the HCI framework with no need for modifying the M3P core, since every component's class is responsible for interpreting its receivable messages, independent of the others. MADE can integrate, into a common framework, various hardware modules independently developed to augment the mobile device potentiality. M3P driver's classes, which have to be developed to integrate every new hardware subsystem, manage low-level aspects of the hardware modules, while the MSL interface to the application developer abstracts the services at high level. This implies that a homogeneous HCI can be applied to an application that hosts several different services that have been developed independently of each other (e.g., automatic positioning, intelligent tour planning, and database access can be integrated in an interactive map), and the MSL developer can simply exploit the service modules focusing on the integration of the HCI. Examples of hardware modules already integrated in MADE are a positioning and orientation module that an MSL developer can exploit to get geographical position from a GPS receiver and direction from a digital compass, and the remote communication module able to exploit the hardware available for connection with the external world (e.g., wired/wireless LAN, Bluetooth, GSM/GPRS cellular networks).

In order to enable applications to react to objects in the physical world, our new M3P module, called RFID sensing module (RfidSM), detects presence of RFID tags in the surrounding space and notifies the M3P run-time objects with events implemented as string messages (see Figure 5).

The script interface of the RfidSM is a new MSL component, called RFID, that exposes the fields shown in Table 1.

When the RfidSM component is started, and until it receives a stop event, it scans the surrounding environment to check the presence of tags every "period" of time. The list of detected tags is then sent with the MADE message-exchange modalities to the components specified in the "target" field. In addition, the component has an

Figure 5. Integration (within MADE) of the RFID sensing module (RfidSM)

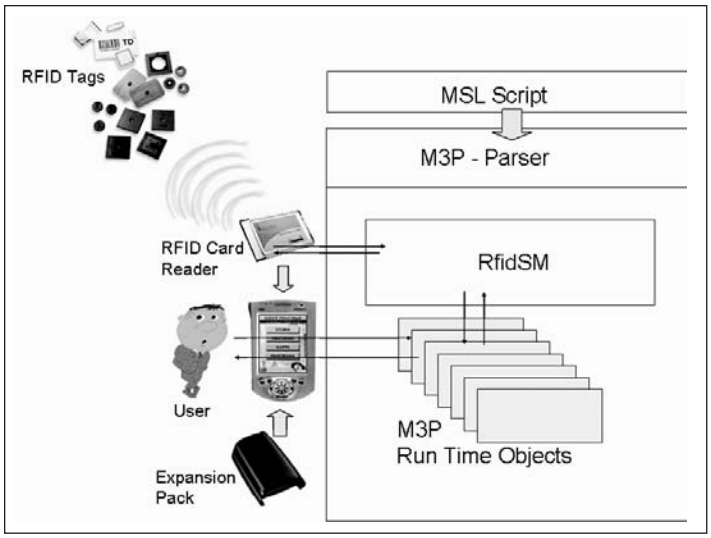


Table 1. RfidSM fields description

Component Field	Description
Target	List of identifiers of the components to which information about identified tags are sent
Period	A time period in milliseconds between two consecutive environmental scans to detect tags
Repetition	A number of tag detection operations executed consecutively on each scanning action
Id	A list of RFID tags that are of interest for the component
Delay	A list of time frames, one for each interesting tag, in which tags are not identified again
dBm	A list of signal strength values, one for each interesting tag, that specify thresholds for tag identifications
onFound	A list of events, one for each interesting tag, that RFID component launch when a tag is identified
Start	If a component launch this event on a RFID component starts the scanning of tags
Stop	If a component launch this event on a RFID component stops the scanning of tags

"id" field to allow programmer expressing interest in a set of tags, and defining (through the field "onFound") the corresponding events list that should be executed. Each interesting tag is also featured with a signal strength threshold (through the field "dBm") that specifies a limit under which the tag is considered in range.

There is the problem of collisions, since the scan results are typically imperfect due to not all tags are detected in every scan. To solve this problem, a tag typically awaits a random number of time slots before it answers the RF pulse sent by the reader. However, the problem still remains and grows as the number of tags in the surrounding

environment grows. The MADE RFID sensing module tackles this issue, allowing the programmer to specify, through the field "repetition," a number of times that the reader should repeat the scanning before returning to the founded tags. The list of founded tags is the collection of all tags observed in each scan. A small value of repetition results in a fast scan with high risk of collision, whereas large repetition value results in a slow scan with few collisions. This trade-off should be resolved by the programmer basing his decision on application constrains: long delays can result in human-computer interaction problems if the application allows a user expectation for immediate reaction to tags. This is the case of applications in which user a voluntarily accosts the mobile device to tagged objects to obtain information. Similar problems arise if the application has a short time frame to detect tags, for example, in applications where the user moves at relatively high speed in the environment, like in territorial games. Instead, others type of applications can gain advantage from precise but slow detections. It is the case of a tourist mobile guide for a naturalistic park in which the user moves along a path with some points of interest largely spaced, like tree species or rare flowers.

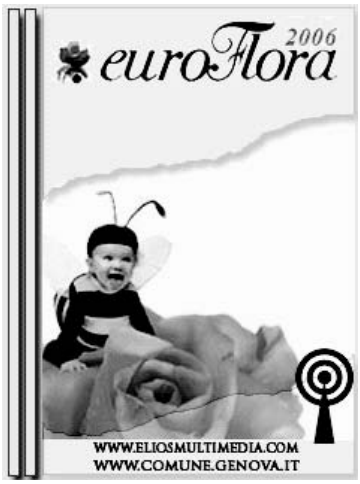
The other problem affecting the RFID technology is the "tag detection flickering" (Römer, Schoch, & Mattern, & Dubendorfer, 2003): due to the collision problem, some tags can appear and disappear from sequential scanning, generating a fast list of tag identifications. The MADE RFID sensing module allows the programmer to decide how to convert scan results into applications events handling this problem. Programmer can specify, through the "delay" field, a time period (for each interesting tag) starting from the detection. During this time, subsequent detection events of the same tag are discarded; also, the exact definition of this delay is application dependent. Applications with events that occur only one time, like tourist guide for museums with linear path, can have delay values set to infinite. Instead, in applications with events generated multiple times closer each other, like territorial games, the delay should be short or zero.

Currently, we have implemented the low-level driver support for the iCARD Identec reader in a PCMCIA card format (IDENTEC). This card can be integrated in handheld, portable, or laptop computers to communicate with the iQ and iD active RFID tags at a distance of up to 100 meters. The RF signal is in the UHF radio band (915 MHz or 868 MHz), providing long-range communication and high-speed transmission rates for reliable data exchange.

THE EUROFLORA GUIDE

In order to assess the possibility of using RFID technology to develop widely usable interfaces, we present a real-world application (see Figure 6) developed through the MADE toolkit and deployed in an ecological environment (fully op-

Figure 6. Snapshot of the cover page of EuroFlora Guide application



erational, reliable, and robust application, used by real users and in a real context of use) at EuroFlora 2006 (the international flower exhibition that is held in Genoa every 5 years). With over 500,000 visitors in 10 days, EuroFlora is one of the most important exhibitions of Europe.

The developed application concerns the research area of assistive technologies for visually impaired people. Such assistive applications have the potential to improve the quality of life of a large portion of population (by 2020, there will be approximately 54 million of blind persons over age 60 worldwide (WHO, 1997)).

In this field, maintaining spatial orientation is a major challenge for people with visual impairment. There is the need of systems in providing blind people with information on where they are, hazards that might be in the way, and a description of what lies in their surroundings (Mann, 2004). The notion of "spatial orientation" refers to the ability to establish awareness of space position relative to landmarks in the surrounding environment (Guth & Rieser, 1997). The goal of our application is to support functional independence to visually impaired people, providing support to indoor awareness of elements in the surroundings (Ross, 2004).

The EuroFlora guide is organized in two parts. One part provides general information about the exhibition, the guide, and their services. The other part provides the description of the selected interest points. While first part is directly accessible by the user at any moment, the second one is event driven. More precisely, every interest point description is associated to an RFID tag, and when a user enters that area (i.e., her/his handheld device recognizes the RFID tag), the software asks the user whether to launch the corresponding description.

We placed 99 RFID sensors on an area of 30,000 mq of exhibition, covering 99 points of interest, services, and major areas (see Figure 7). RFID sensors were IP65 compliant in order to resist to water and dust, and self-powered. Power level of sensors could be set in two levels, low and high.

Design Methodology

The necessity for combining the flexibility and multimedia potential of a mobile device with the extreme simplicity of interaction, required for use by a wide audience (also visually impaired people), involves facing three main HCI issues:

Figure 7. a) The packaging of the multimedia guide in a leather case; b) Snapshots from the tests: users visit EuroFlora 2006 supported by the guide and touch some dedicated plants

- **Usability by general users:** The tourist has little time and willingness to learn how to use the new technological tool, since she or he is there to visit the exhibition and not to learn a tool. Most of the tourists use such a tool for the first time and just for a short time (typically, from 30 to 90 minutes). Thus, the complexity of the platform should be hidden from visitors, making the guide immediately usable, with no effort by users. This implies that the interface is to be as simple and intuitive as possible.
- **Usability by visually impaired people:** Visiting an exhibition is a critical task for the blind, mainly for the combination of several reasons: the site is often crowded and unfamiliar to the visitor, it may be noisy, it is difficult to orientate in a highly dynamic place. In this context, the guide should be not intrusive, with few and very recognizable input interface elements (also with tactile feedback), and should give information in a proactive modality when needed by the user.
- **Presentation of information:** Added-value information (e.g., how the various specimens live in their natural environment) should be synergistic with the direct experience of the visitor at the exhibition. Provision of information has to be structured in order to enhance the direct perception of the visitor, leading to a better and more pleasant comprehension of her/his surrounding environment. For example, the guide should make use of environmental sound (e.g., waterfall) and scent (e.g., flower smell) to connect content information and the objects in the space.

We have tackled such issues resorting to the methodologies of the user-centric design (Carroll, 1997), in an iterative development of the guide involving participatory design (Beck, 1993), definition of usability specifications, and contextual design, as shown in the following:

- Participatory design consisted of the participation of botanists at the design decisions, authors skilled in writing for blind people and visually impaired end-users, together with technical developers. The most significant contribution of the first three categories consisted in the definition of the targets and in the concrete perspective they brought into the project.
- Usability specifications provide explicit and measurable targets to verify the suitability of the work done. Examples of such goals are "90% of the users should be able to operate the guide without asking questions to the personnel," "90% of the users should be able to use the interface with no errors," "90% of the users should be able to understand the meaning of all the touchable controls within 120 seconds." All these objectives were verified in early lab and field tests in order to take the appropriate corrective actions.
- Contextual design involved early field tests with experts and users at the exhibition in the preopening days when the infrastructure of EuroFlora was being built. Field tests have been helpful to highlight problems and shortcomings that had been overlooked or ignored in lab.

Structure of the Interface

The interface of the EuroFlora guide has been designed to support immediate use by the general public, also by visually impaired people. To this end, we used general design principles (we already described them in the introduction) such as overall simplicity, low intrusiveness, and support for natural interaction and knowledge acquisition. Moreover, we added further features in order to meet the specific needs of visually impaired people:

- Tactile feedback in the control interface
- Tutorial stage
- Event-driven interface
- Facilities to support orientation

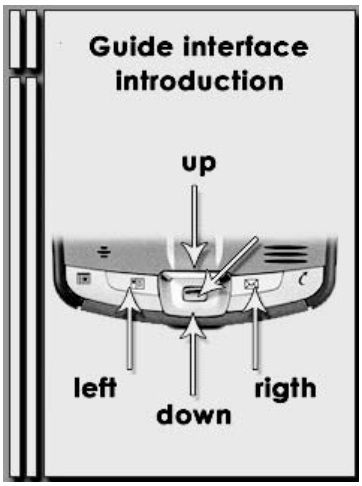
The basic element of the interface is the multimedia card. A multimedia card corresponds to each subject of a presentation (e.g., a flower species). Each multimedia card provides, in an audio format, texts specifically written for visually impaired people (i.e., highlighting olfactive and tactile sensorial information, providing detailed ambient descriptions).

The tactile feedback is necessary to allow impaired people to easily understand the position of the controls and give her/him feedback. Our previous multimedia guides had the interface embedded in the graphic contents, exploiting the touch screen of a pocket-pc device. During the early field tests, visually impaired people pointed out some important shortcomings in these solutions. They felt that the screen was too large and their fingers were lost in a space without roughness. Since most of such users are well acquainted with the common cell phones' relief keyboard, we studied a new solution exclusively based on the hardware buttons (Figure 8).

The hardware buttons of the interface are highlighted. The choice of this area as navigation control allows visually impaired people to have a tactile feedback. The meaning of the button is "up" to accept a content description (which is automatically triggered when the user enters a new cell), "down" to reject it, "right" to exit from a section of the guide, and back to the main menu, "left" to have contextual information about user's current position.

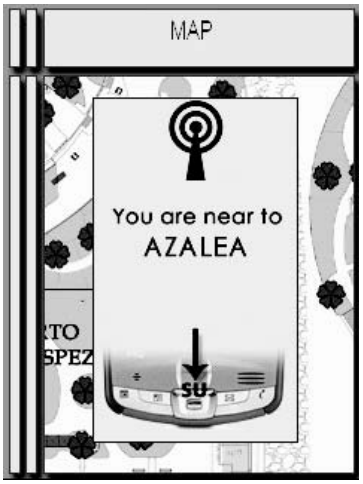
The tutorial stage is an initial guide section in which users could freely experiment withthe interface of the tool in order to allow people to use the guide in an independent way. In this stage, users are invited to freely press buttons. A speech description briefly explains the meaning of each pressed button. This tutorial stage prevents the necessity for providing papers or long explanations when users rent the guide.

Figure 8. Snapshot of the guide instruction



The event-driven interface allows a user to get information about points of interest (POIs) and orientation when they are in the proximity of a POI. For example, in Figure 9, a user near the azalea stand is told about the presence of this flower by a pop-up window (the guide is to be usable by everybody) and a corresponding jingle sound. If she/he wants to listen to this content, she/he can press the "up" hardware button. By default, the system skips the presentation. This operational mode has low intrusiveness (users are asked whether to listen to a content), but it also provides a certain degree of proactivity. Information is not only botanical, as in the example of azalea, but also concerns the positioning of the user. Many tags are placed in the proximity of facilities, such as lavatories, cafés, exits, and intersections. This localization system lowers the mental workload necessary for the tourist to synchronize the physical space of the exhibition with the virtual space of the program.

Figure 9. Snapshot of the event-driven interface



This message (accompanied by a jingle) is shown to the user when she/he has just entered a POI area. The combination of audio and graphics is due to the fact that the guide may be used also by not visually impaired people. In the example in this figure, the user is near to the azalea flower, and if she/he is interested in the description she/he can press the "up" hardware button to access the related content.

One of the main tasks of the guide is to assist the visitor in her/his exploration of the exhibition space. A facility to support orientation (not useful for visually impaired people) is a section with the map that helps the tourist to orient herself /himself in the exhibition. The map (see Figure 10) shows the structure of the EuroFlora, including lavatories, café, exits, and so forth, and the location of the points of interests. In order to enhance user's orientation, the map is centered on the position of the user, as determined by the currently perceived RFID tags.

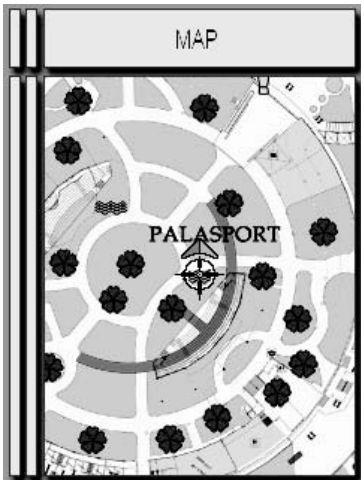
FIELD EVALUATION

Experimental Framework

Real evaluation of advanced mobile device applications and of the impact on their intended population is difficult and costly. Evaluation requires analysis of real users, in a real context of use. In order to adequately evaluate interaction with computation resources, test-people should use a fully operational, reliable, and robust tool, not just a demonstration prototype (Abowd & Mynatt, 2000). Hence, it is important to perform early tests in the authentic context of use in order to verify end-user acceptance and overall usefulness of the system, and to receive feedback to inform future design.

In this chapter, we describe the early stage analysis of acceptance and usefulness of the developed multimedia guide. The tests were performed at EuroFlora 2006, the international flower exhibition that is held in Genoa every 5

Figure 10. Snapshot of the map section of EuroFlora Guide



years. With over 500,000 visitors in 10 days, EuroFlora is one of the most important exhibitions of Europe.

The exhibition area (around 90,000 squared metres) was equipped with an infrastructure of 99 RFID tags. The experimentation involved 120 visually impaired tourists who used the tour guide, and were observed and interviewed by expert of disabilities and HCI designers. Subjects were visually impaired (25%) or blind persons (75%) representing a wide range of age (28% age <30; 32% age between 30 and 50; and age >50 40%). Moreover, the tests involve 64 females and 56 males.

The tour guide consisted of a PocketPC equipped with a special leather package with a lace dropping from the neck for a more comfortable use. Headphones were also used in order to isolate the user from the highly noisy surrounding environment (see Figure 1).

Preexhibition Tests

In an early test session-performed 2 days before the official opening of the exhibition, when some stands were already readyenabling a realistic test-we prepared a prototype software version that was used by five selected visually impaired users visiting 30% of the total exhibition area. We followed and interviewed the users in this phase, in order to understand shortcomings, defects and weaknesses, and strong points of the product. In this phase, we understood and solved some problems on user interface and contents, such as the most suited assignment of buttons to presentation control functionalities and the length of the descriptions. Some test-users found the long silence time between a presentation activation and the next one (i.e., the period of time in which the user is walking through areas not covered by RFID tags) frustrating. We partially tackled this issue by periodically providing a message saying that the user is currently in an area not close to a POI.

Ecological Tests

One hundred and twenty blind people used the guide during the exhibition. Sixty of them (aged from 12 to 78 years old) participated in an ecological test conducted by the authors. We interviewed the users at the return of the guide. We evaluated three main performance factors: usability (including effectiveness, efficiency and pleasantness of use), usefulness, and capability to support spatial orientation (in particular the approach to the POIs). We asked users to give a general comment on the guide and a 1-5 grade for each factor (which was carefully explained and defined by the interviewers). An overall survey of results is reported in Table 2; it clearly shows the high acceptance by the users.

Analyzing the variables' correlations based on the chi-square test, we observed that usability is correlated with the perceived support for spatial orientation (χ=25.3, df (degree of freedom) = 16, 90% confidence), and that perceived utility of the tools is strictly correlated with perceived support for spatial orientation (χ=30.2, df=16, 99.9% confidence). This suggests the importance of our design choice to use mobile technology to support orientation of visually impaired people. Moreover, test results also show that the tool is perceived as useful and usable.

Considering the free comments, the guide was judged as an excellent tool for users to orientate themselves inside the exhibition. Several people expressed a similar concept, which we can synthesize with the words of one visitor: "after always having been guided, for the first time I myself have been able to guide my wife and to explain the exhibition!" Such positive comments were also confirmed by the blind assistance experts, who highlighted the significant degree of independence the blind could reach through the guide.

Shortcomings in the interface were reported by some elderly users, while some people asked for more extended descriptions, though each point of interest included at least one. The high

Table 2. Overall survey results

Issue	Average	Standard Deviation
Usability	4.00	0.64
Usefulness	4.25	0.75
Support for spatial orientation	4.20	0.66
Session length time	201 minutes	30 minutes

performance and reliability of hardware, software, and batteries assured long sessions of use with no troubles for the user.

FUTURE TRENDS AND VISION

The research community is envisaging a new model of a "tagged world" as an intelligent environment that allows providing visually impaired people with information about architectonical barriers, safe paths, points of interest, potential danger areas, and other useful information. A sample scenario description may give an idea of this likely future.

Maria is visually impaired. She is in a foreign city on a business trip. Maria owns a mobile device with a mobility-assistance system (MAS: it is similar to the EuroFlora Guide, but with a much larger action range). The MAS accompanies her in her path to her destination office, and signals pedestrian crossings, traffic lights, safe paths in work-in-progress areas, and so forth. All objects in the world send their signals, but Maria's wearable device has an intelligent reasoning algorithm (based on user preferences and interpretation of the user's current activity) and a suitable human-computer interaction (HCI) in order to provide her only with the needed information. This information is extracted from a mass of data that are continuously received from the close-by RFID tags. Thus, the wearable device notifies Maria about a pedestrian crossing only if it knows that this is useful for her current activity (i.e., going to office). Not useful information will not be provided, in order not to distract Maria. Along her path to her destination, Maria passes by a newsagent. The World Guide scans all the magazines and identifies today's issue of Maria's favourite magazine. It queries Maria's database, which replies that Maria has not purchased this issue yet; so, it notifies her about the opportunity to buy the magazine.

CONCLUSION

The ubiquitous presence of smart tags will offer, in the near future, a critical mass of information, embedded in the world, that will be exploitable to rethink the relationships between people involved in their daily-life activities and the surrounding world.

With MADE we have designed a system that continuously scans the tagged world, interprets the large amount of information coming from the surrounding objects, and provides it to the users through multimedia human-computer interaction. Moreover, the application in the future will filter the raw data coming from the environment (with

artificial intelligence behaviour) taking into account the user needs, preferences, and profile.

The field test at EuroFlora 2006 has demonstrated the feasibility of our vision, by deploying the system in a real-world setting (an exhibition area with indoor and outdoor instrumented environments), and performing extensive field tests with real users. In a longer-term view, with such an application, we intend to investigate the future scenarios that will be enabled by a massive presence of RFID tags in our environments. This "early prototyping" has allowed us to understand, as early as possible, costs, limits, strengths, and benefits of the new technology. We have also obtained a significant positive feedback on user acceptance. Usability results show that the guide is perceived as highly usable and useful, in particular because of its ability to support spatial orientation.

The next step towards a "tagged world" will require integration of data and services, and capability of interpreting a variety of sources according to the specific and dynamic user needs. Achieving these goals will involve a huge research effort that will be successful only if it will lead to the deployment of compelling applications that will be perceived as useful by the users. In a user-centered design view, this implies a rapid prototyping of applications and extensive user testing in the real context of use, which was our inspiring principle in the EuroFlora project.

KEY TERMS

Chi-Square Test: The Chi-square is a test of statistical significance for bivariate tabular analy-

sis (crossbreaks). This test provides the degree of confidence we can have in accepting or rejecting a hypothesis.

Ecological Context: The ecological context is a set of conditions for a user test experiment that gives it a degree of validity. An experiment with real users to possess ecological validity must use methods, materials, and settings that approximate the real-life situation that is under study.

Human-Computer Interaction: Human–computer interaction (HCI), also called man-machine interaction (MMI) or computer–human interaction (CHI), is the research field that is focused on the interaction modalities between users and computers (interface). It is a multidisciplinary subject, relating to computer science and psychology.

Location-Aware Computing: Location-aware computing is a technology that uses the location of people and objects to derive contextual information with which to enhance the application behaviour. There are two ways to acquire information about user context: requiring the user to specify it or by monitoring users and computer activity. Sensor technology, such as RFID, could enable mobile devices to extract information from user position automatically.

Mobile Tourist Guide: A mobile tourist guide is a software application with an intuitive interface, that provides users with multimedia information when and where needed during their visit to museums, city centres, parks, and so forth. Such an application runs on PDA-type terminals or on cellular phones, and could be augmented with GPRS (general packet radio service), GPS (global positioning system), and Bluetooth wireless technology. The guide allows tourists to plan routes according to preferences and ambient conditions (weather, timetables, sites of special interest, etc).

Radio Frequency Identification: Radio frequency identification (RFID) is an automatic identification method based on storing and remotely retrieving data using small and cheap devices called RFID tags or transponders. An RFID tag is an object that can be attached to objects, products, or persons to identification using radio waves. Passive tags (with a few centimeter range of sensitivity) require no internal power source, whereas active tags (with more long range of sensitivity, 100 meters) require a power source.

User-Centric Design: User-centric design is a design process that aims at realizing products that meet users' expectations. The key idea of this design methodology is to start the design strategy taking into account the user's perspective.

ABSTRACT

This chapter describes the use of ontologies for personalized situation-aware information and service supply of mobile users in different application domains. A modular application ontology, composed of upper-level ontologies such as location and time ontologies and of domain-specific ontologies, acts as a semantic reference model for a compatible description of user demands and service offers in a service-oriented information-logistical platform. The authors point out that the practical deployment of the platform proved the viability of the conceptual approach and exhibited the need for a more performant implementation of inference engines in mobile multi-user scenarios. Furthermore, the authors hope that understanding the underlying concepts and domain-specific application constraints will help researchers and practitioners building more sophisticated applications not only in the domains tackled in this chapter but also transferring the concepts to other domains.

INTRODUCTION

Regarding the trend towards ubiquitous computing and ambient intelligence, modern information systems basically have to support mobile users. As a first step towards fulfilling dynamic demands of mobile users, the concept of context-awareness has been introduced to enable filtering of information based on user-specific context information.

To cope with user acceptance, we abstract from context information and use a situation model. Situations are easy to understand for a user and can be derived from a set of context information, including location and time and even user profile information and other sources. They are named cognitive abstractions of context. When such situations are linked with user goals (e.g., get food when hungry), it is evident that different situations imply the need for different information and services to help a user in achieving his goals. User profiles are used for describing personal data, preferences, and interests of individual users, from which user goals can be derived.

Furthermore, we observe a growing demand to cope with dynamic service offers. Service-oriented architectures mainly integrate Web-based services from different providers. One consequence is the need to cope with unavailability of services, for example, due to broken connections or limited scopes of service validity. To enable an automatic replacement of services, that is, service roaming, service profiles are used that provide for a matching with user profiles and context information.

To enable matching of dynamic user demand and service offers on a semantic level, we use semantic technologies. This includes the development of a description model for service semantics and a semantic registry able to cope with such descriptions. The service ontology is modular, based on other ontology modules covering general concepts, situations, and the application domains. As demands from a large number of users are to be matched dynamically with service descriptions provided by a large number of service providers, the application ontology acts as a semantic reference system.

In the following, we start with the discussion of the conceptual background of our approach, followed by an outline of sample application scenarios. In the main part, we discuss the construction and use of the application ontology as a basis for a semantic matching of demand and offers and give an overview of the system architecture supporting this process. A brief summary of practical experiences gained from the deployment of the system as a mobile tourist guide follows. The chapter closes with a look at future trends.

BACKGROUND

Following Dey (2001, p. 5), "context is any information useful to characterize the situation of an entity. An entity is a person, place, or object considered relevant to the interaction between a user and an application, including the user and application themselves." Context-aware applications are able to adapt their functionality based on existing context information towards the user's environment. This includes filtering and provision of information and services being of interest to the user in his specific context, thus making applications more proactive and reducing the need for explicit user interactions. This property is of value especially for mobile applications due to the restricted interaction capabilities of mobile devices. Mobility always has a location aspect that is an important part of almost any context-aware application. In this way, mobile computing and context-awareness are good supplementations in order to provide users with the right information anywhere and anytime.

Research on context-aware applications started in the beginning of the 1990s. One of the first applications was the Active Badge System (Want, Hopper, Falcao, & Gibbons, 1992) from Olivetti Research Lab. It allowed users to locate people

in the office and to redirect incoming calls to the closest phone. This system was later in operation at Olivetti STL, Xerox EuroParc, MIT Media Lab, and Xerox PARC.

The Conference Assistant (Dey, Salber, Abowd, & Futakawa, 1999) was developed at the Georgia Institute of Technology. Its aim was to assist conference attendants. Based on user profiles including a list of research interests, the Conference Assistant displays the timetable with events highlighted that are of interest for the user. When entering a room, the Conference Assistant gives information on the presenter and shows the presentation material. The user can then make notes during the presentation, which are recorded together with additional context information, for example, the time, author, and content information useful for later retrieval.

Another type of popular context-aware applications is location-based tourist guides. There are quite a number of examples available from the mid 1990s. The Cyberguide project (Long et al., 1996) from Georgia Tech was aimed at providing information to a tourist based on his position and orientation. The user could see his position on a map. Selecting points on the map the user could get more information about his environment. A similar guide has been developed by the University of Lancaster and tested between 1996 and 1999 for visitors of the City of Lancaster (Davies, Mitchell, Cheverest, & Blair, 1998). Based on location and user preference, the visitor could get information about points of interest in the region.

Both these tourist guides were restricted to location information. The COMPASS2008 project, which has been realized based on the information-logistical service platform described in this chapter, also aims at assisting tourists in providing suitable information and services dynamically in each situation. In contrast to the previous projects, the COMPASS2008 application is not restricted to the location of the user as a context dimension. Another context dimension is time. Dependent on the current time, different time aspects are inferred, for example, activity of the user, eating time, opening hours of shops, and so forth. In addition, parts of the user profile and even external sources like event calendars are used as context dimensions. Based on the complex context model, a set of situations is derived to provide the basis for a personalized situation-aware filtering of information and services for a user.

Most of the above described applications are prototypes developed in research labs and the academic world. There are not many complex context-aware commercial solutions. However, there are several location-based services offered by mobile communication providers and service providers. Examples are route planning services, city guides, hotel and shopping guides, and location services for nearby gas stations. Most of the commercial and academic applications only use a few context dimensions, mostly location, time, and identity.

APPLICATION SCENARIOS

In this section we describe and analyze scenarios from different application domains, namely tourism and emergency management, regarding their requirements on dynamic information and service supply, ontology support, and relevant context information and user profile data.

Tourism

One application domain for ontology-based service provision is guidance for tourists. Since the behavior of tourists is not predictable and depends on various influencing factors such as personal moods, personal interests, and so forth, an intelligent system should be able to conclude the user's current needs. Furthermore, information relevant for tourists is provided by many different sources.

To be able to decide what information could be relevant for a tourist, it is crucial to detect in

which kind of situation the user currently is in. Context information and user profile information are the basis for that decision. For instance, a user standing in front of a sports stadium in which a sports event is about to start could be there accidentally, could intend to see the event, or could look for tickets. If the user profile indicates no interest in this kind of event, the first option is probably correct, otherwise the user profile could indicate whether the user has a ticket for that event. This information would either lead to provision of, for example, a navigation service to the right entrance and further information about the event (e.g., starting lists), or the system would offer an online booking service.

The COMPASS system (Weißenberg, Voisard, & Gartmann, 2006) being based in the technical infrastructure described in this chapter has recently shown in a field test in Beijing that situation detection is applicable to tourist guide systems and that this is a basis for an intelligent selection of appropriate services, which unburdens the user from searching for desired services among huge offers.

Emergency Response Support

Support for emergency response is a very demanding task. Emergency cases are always different and unpredictable, information needs depend on various parameters, and response times are always critical. A precise efficient demand-specific filtering of information from a huge information offer is needed.

The information needed highly depends on the kind of emergency and a precise recognition of the emergency case is crucial for information selection. Typically, not all relevant parameters are known initially. For instance, fighting a fire in a chemical plant is influenced by the chemical substances stored or processed here. Thus, information about the emergency case is completed gradually, and the system has to refine the provided information accordingly.

An ontology-based service selection, based on situation information such as the type of emergency and context data, is very effective to meet the mentioned requirements. An actual example is the MONA system, the Mobile Emergency Assistant (Holtkamp, Weißenberg, & Speckmann, 2005), developed for the Duisburg fire brigades. This system is fed information about the emergency, such as the location and situation (fire in different levels of escalations, car accident, rescue of jammed persons, and so forth). It has access to all internal information sources of the fire brigades and can additionally access external Web services such as geospatial mapping services to get further information if necessary. That leads to an improved information supply for the officers-in-charge and leads to a more efficient mission processing.

APPLICATION ONTOLOGY

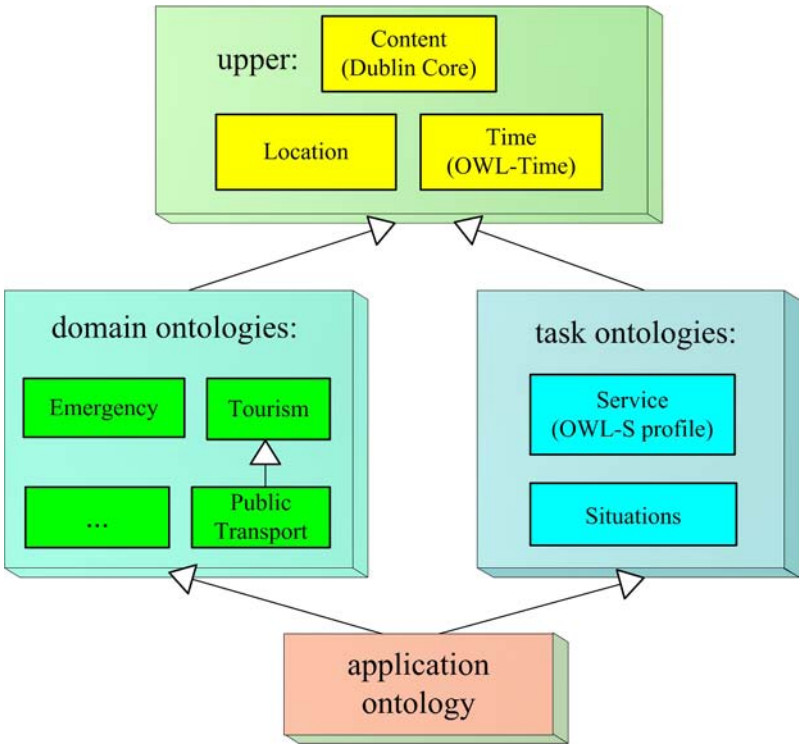
As a basis for semantic matching of dynamic offers with dynamic requests in all scenarios and as a base data model, we use a modular extensible application ontology for the description of both demands and offers. In a first step, the ontology structure is explained. Then dynamic aspects of the ontology are discussed in more detail, such as changes in user profiles, contexts or service sets, and service roaming. Finally, we have a closer look at the implementation side, including performance issues.

Ontology Structure

Following Guarino (1998), an ontology can be structured into different kinds of subontologies as depicted by Figure 1:

- The *upper ontology* is limited to generic and abstract concepts, independent of, and thus addressing a broad range of, application domains. It covers reusable dimensions like

Figure 1. Modular ontology architecture



location, time, and content, which may be refined in other ontologies.

- *Domain ontologies* specify concepts of different application domains and scenarios (e.g., tourism, emergency) and may refine concepts from the upper ontologies. For new application scenarios, mainly new domain ontologies are needed.
- *Task ontologies* code knowledge about the usage of domain ontologies, that is, they characterize computational aspects. They make generic use of domain ontologies, that is, they are independent of special domain ontologies.
- The *application ontology* at the lowest level integrates all other ontologies for the application.

Upper Ontologies

Ontology design has to keep in mind for what the ontology is used. In our case, it is intended for dynamic personalized service provision to a huge amount of concurrent users in scenarios as defined above, that is, for information logistics. Existing upper or top-level ontologies like OpenCyc (Cycorp, 2002) and SUMO (Niles & Pease, 2001) are too large for our scenarios. Hence, we took a more pragmatic approach, concentrating on the main aspects of time, location, and content, which are seen as the main dimensions of information logistics (Deiters, Löffeler, & Pfennigschmidt, 2003).

Location Ontology

For mobile applications, the location aspect is of utmost importance and the use of ontologies for this purpose has been long-praised. Fonseca, Egenhofer, Davis, & Borges (2000) summarize several such approaches. Our location ontology, however, is not a complete geo ontology, but pragmatically provides basic concepts which may be refined in (geo) domain ontologies. There are two layers: the logical or *cognitive* location concepts and their lower-level *geographic extent*, both inheriting from the root concept *Location*. The root concept of the logical layer is *Location-Name,* having subconcepts like *Country, Region*, and *AdministrativeArea,* the latter having subconcepts like *State* and *City*. Multiple inheritance is used to model entities such as *Municipalities*, being a city and a state. A tourism ontology might add concepts like *POI* (point of interest), *Hotel, Shop,* and *Restaurant,* and an emergency ontology might add concepts like *Plant* and its various parts. Instances of the higher-level concepts (i.e., the known locations) are mapped to lower-level concept *GeographicExtent,* having subconcepts like *Point, Box,* and *Polygon*. For example, a *Restaurant* instance is mapped to a *Polygon* instance having some set of points with coordinates (e.g., by using spatial extensions of a database). Using geographic relationships like containment and overlapping at the lower level, corresponding relationship for the higher-level instances can be inferred.

Time Ontology

To define temporal aspects of services and situations, a time ontology is needed. Our time ontology is structured similarly to the location ontology: both have an abstract and a physical layer. The lower physical layer is a subset of OWL-Time (Hobbs & Pustejovsky, 2003), consisting of the *TemporalEntity* subconcepts *Instant* and *Interval*, together with basic relationships (*after, before).* The additional abstract layer with root concept *PeriodicInterval* is mapped to the lower layer by timestamp patterns, which play the role of coordinates. It has subconcepts like *Yearly* and *Daily.* For example, *Yearly* is instantiated by *January*, representing the month occurring every year periodically, not a concrete month as in the lower layer. Instantiations of *Daily* concepts may even be personalized, depending on a user's context (e.g., *Sunrise*) and preferences (e.g., *Lunchtime, Dinnertime,* and *Morning*), or may be object-dependent (e.g., *TradingHours* of a shop). The personalized time *abstraction* method accesses the user profile and yields a set of known logical time concepts for a user for the current time. While the lower level of our time ontology is based on OWL-Time, the higher level is a simplification of concept *CalendarDescription*, found in some versions of OWL-Time. In the OpenCyc upper ontology it is called *RegularlyRepeatedEvent.*

Content Ontology

For the content dimension, Qualified Dublin Core (Kokkelink & Schwänzl, 2002) is often used, which is mainly a refinement of Dublin Core (DCMI, 2004), providing access to information and services at document metadata level.

Domain and Task Ontologies

The modular application ontology is open for different domain ontologies to be added, to support different scenarios. For example, a tourism ontology has different kinds of POIs, restaurants, hotels, and the like, and may use an ontology of public transport. The domain ontologies are mainly used as value pool for different properties in all other ontologies.

There is no separate *user profile ontology*, but it consists of different domain ontologies covering the interests and preferences of users in the application domain. The profile values stemming from a separate system (e.g., from LDAP)

are interpreted using the knowledge of domain ontologies. Additional rules may be meaningful when some profile attributes are to be inferred by others.

Also task ontologies can be added when needed. The main task ontologies in our case are the service ontology and the situation ontology.

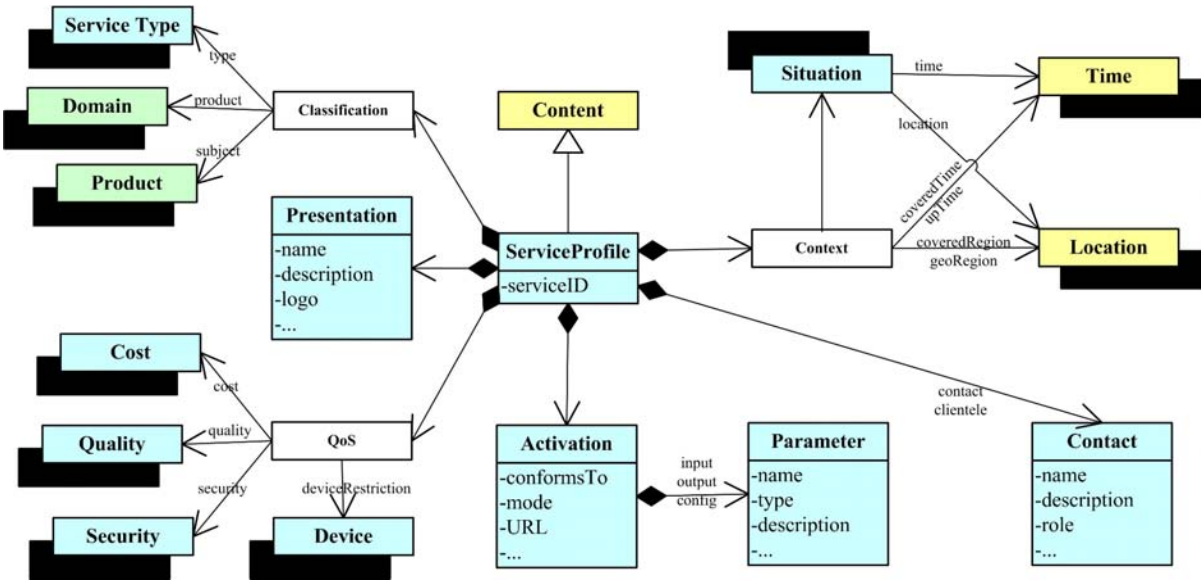
Service Ontology

Service (and information) advertisements and demands are described independently by different user groups (i.e., service provider and user), not knowing exactly the needs of each other. The most flexible way to match demands against offers is to use semantic technologies, that is, ontologies and inference. The *ServiceProfile* is a subconcept of concept *Content* having Qualified Dublin Core properties. Thus, services are special content, having content properties and additionally service-specific properties. Registered services are facts connected by their properties to instances or concepts of other ontologies, which serve as dimensions. The top level ontologies *Location* and *Time* as well as all domain and task ontologies are used as value space for different service properties. This results in a star schema, in which service properties are characterized by subprofiles, which again are characterized by their properties. For example, the *geoRegion* of a specific service may be characterized by a location instance, which itself is characterized by a set of properties and the cost aspect may be characterized by a cost subprofile.

A simplified sample service ontology of this construction is sketched by Figure 2, which is both a relational schema and an ontology, since shadowed boxes indicate the root concepts of subontologies used for a dimension. Only some sample properties are shown here.

Service retrieval is supported by different multivalued classification properties. The values

Figure 2. Modular service ontology schema



are concepts from different domain or task ontologies. Such rather orthogonal classifications together already cover much of the semantics of a service:

- **General classifications** using a service type taxonomy (property *type*), a product taxonomy (for *products* related to the service), and concepts from other domain ontologies used as service subjects (property *subject*).
- **QoS classifications** summarize nonfunctional quality of service aspects, for example, characterizing of main factors of service cost, quality, security, and possible device restrictions in the case of locally installed services (running on PDAs or home gateways).
- **Context** aspects support restricting a service to a multidimensional context and even to detected situations. This includes location and time properties for service validity (service accessibility, that is, *geoRegion*, *upTime*) and service coverage (for its result, that is, *coveredRegion*, *coveredEpoch*). An example is to find services callable *now* (validity is actual context) but delivering information (coverage) for a restaurant or event to visit this evening.
- **Contacts** and **clientele** summarize relational contact data of different parties involved in the service, like service provider and call center, as well as the clientele (for multiclientele ability).

For *presentation and activation* of retrieved services, the following aspects are specified (not necessarily in an ontology but relational, since these aspects are seldom needed for service retrieval):

- **Presentation** covers all information needed to display retrieved service at the user's frontend, and includes multilingual information such as a service name or description and possibly icons. For use of services by programs, this aspect is not relevant.
- **Activation** provides all information needed to call the service, such as an *URI*, the communication standard used (property *conformsTo*), the *mode* (active, passive, etc.) and the parameters. Since we currently do not use a process model for the service, our grounding is simple.
- **Parameter** describes each input, output, and configuration parameter of the services, for example, its name, type, and a brief description, to be used for GUI generation and parameter marshaling.

The service ontology is influenced by standards like OWL-S (Martin et al., 2004), a Web service ontology submitted to the W3C, but we focus on the service profile. However, OWL-S is not the only approach towards Web service ontologies. The Web Service Modeling Ontology (WSMO) has also been submitted to W3C and a third approach is Semantic Web Services Ontology (SWSO). There is a migration process for these approaches. However, they focus on the process model, while their service profile is only basic. In contrast, the service ontology presented here focuses on the service profile, since it is used for demand-based service retrieval primarily.

Situation Ontology

Situation detection requires a modular ontology with subontologies for all context dimensions, all combined in the situation ontology. Thus, the situation ontology extensively depends on its dimension ontologies. It consists of a hierarchy of situation profile concepts, instantiated to characterize different situations. Situations are described by semantic situation profiles, being named sets of characteristic features of situations. Situation descriptions instantiate these concepts by defining a semantic classification of an aggregate of abstracted user context, user profile, and related

information and can be inferred from these. At a given time, a user may be in zero, one, or many situation known by the system.

Ontology Usage

The application ontology is used as follows: Whenever an event occurs that might influence the service set of a user, the set is recalculated by situation detection and service matching (and possibly service roaming). These significant events include:

- **Context changes**: Our application scenarios are mobile, thus location changes occur often. We have developed an algorithm to detect significant location changes based on geographic extents of logical location concepts used in service registrations. This algorithm runs on mobile devices. Any user's GPS locations are only transmitted by his phone or PDA to the context server when a *significant* change has occurred and a new significance specification is returned. The same mechanism can be applied to other context dimensions as well. In this way, frequent context changes of mobile users lead only occasionally to service set recalculations. In a field trial in Beijing discussed in this chapter, only 86 significant context changes were produced by 15 users in approximately 4 hours in total.
- **User profile changes**: Whenever a user entered or modified his user profile, an event is fired, causing the system to react by calculating new situations and an appropriate new service set.
- **Service set changes**: Whenever a new service is provided to the public or whenever a service is changed or removed, an event is fired, causing service set recalculation.
- **Ontology changes:** Our inference engine is RDBMS-based (i.e., inference is directly executed in the relational database management system), thus ontology changes are controlled by the database and valid for the next semantic query, which is triggered.

Situation Detection

Situation detection occurs when context sensors report *significant* context changes. The abstraction and aggregation mechanisms of all dimensions are used to obtain a set of instances of the higher-level situation concepts. For example, not only the location and time may characterize a situation but also whether an action takes place at that location and time, by consulting for example a social event directory service or weather service. The resulting situation request profile is then semantically matched to all situation profiles known to the system, leading to a (possibly empty) set of situations fulfilling the request profile. A user may be in any of these situations or may be interested in being in this situation. For example, if a user is in a filled stadium, situation *Watching Competition* is detected. If it is personal lunchtime, the additional situation *Eating in Stadium* provides corresponding service offers. Only well-defined situations can be detected. If a user is in a situation not known by the system, he will only get situation-independent support.

Service Matching

The service selection process is a semantic matching of an implicitly dynamically constructed service request profile against the profiles of all known services found in the semantic registry. The request profile uses the matching situations determined previously. User profile and context are also used in the request profile, for example, to select only services matching the user's interests at the current location. Some user preferences are mapped to service types or service subjects, which requires fine-grained taxonomies of these kinds, being related to the preferences hierarchy. Other preferences are used for a personalized instantia-

tion of time ontology concepts like *Morning* and *Lunchtime*, which are used to infer situations. The matching evaluates different types of semantic relationships for all profile properties, like subclass, instance, and containment relationships. Different matching strategies can be realized by defining different semantics when using our *ModelAccess* component described below. For example, for a class-valued property (e.g., property *type* or *subject* in our service ontology), it can be defined whether it matches with subclasses, with superclasses, or with both, and to what semantic distance.

Service Roaming

Mostly, services are defined for a certain scope, which could be a geographical area they cover or certain timeframes or situations for which they are useful. Obviously, a service scope can be described based on restrictions defined on context attributes. Service matching regards the actual user context and adds it to the service request profile in order to select only services which scope covers this context. Based on context-specific service selection, service roaming aims at providing certain service functionality to a user constantly during changing contexts. Whenever the actual user context leaves the scope of the used service, a new service instance with similar functionality but with a scope fitting to the new context has to be found and invoked transparently for the user. An example is a service offering parking information for a certain city. Such a service could, for example, be used in a navigation application. If a user leaves one city and enters another, the navigation application is automatically disconnected from the currently used service and connected to the one covering the area of the new city.

Implementation Aspects

Currently, our extensible ontology comprises about 300 concepts with 1900 properties and 900 instances (among them the registered services and locations), divided into several top-level, domain, and task ontologies. It is completely stored in relational database tables, combined with relational data and accessed from all subsystems by our *ModelAccess* component. Multi-user access is controlled by a sophisticated RDBMS. We have done extensive load testing of the new architecture, which proved to scale well with the number of users (concurrent threads), the size of the ontology, and the size of the answer set. The numbers can be summarized as follows: With 100, 000 registered service profiles and about the same number of related entities as above retrieval times of about a second are achieved on a 3.2 GHz, 2 GB RAM PC, of course depending on the complexity of the query.

SYSTEM ARCHITECTURE

To support scenarios like those described, we have developed an information-logistical semantic service platform. We give a gross outline of the system architecture and the interoperation of its subsystems for semantic matching of user demands and registered offers.

Use of Profiles

All subsystems use profiles for describing entities in their interface methods. A profile is a structured set of properties covering different dimensions and characterizing an entity. Each property has a type (range) and may have several values. Samples are user profiles, service profiles, situation profiles, location profiles, and device profiles. They may be used for characterizing offers and also for describing an actual demand of such entities, and are thus a basis for semantic matching of both.

Profiles may be interpreted either directly or semantically. In a semantic profile, the range and values of the attributes are semantic categories

stemming from an ontology, which forms background knowledge for interpreting the syntactic (e.g., relational) data. The ontology can also be used to guide the process of creating or modifying profile properties (e.g., to offer allowed value for properties), and to assure consistency of stored profile properties with the ontology.

Gross Architecture

The information-logistical semantic service platform provides basic functionalities needed for intelligent demand-specific selection and provision of information and services. The key technologies used and combined by the platform are the following:

- **Personalization** is used for the selection of services and information according to a user's profile, preferences, interest, and other user-related information, and for the adaptation of filtered information to the user's needs.
- **Context and situation awareness:** Context information includes any relevant information about the user's state and his environment including the derived situations. It can be used to retrieve the information needed at the location and time or in the situation the user currently is in.
- **Open infrastructure:** The service platform uses and builds on top of existing open and distributed service infrastructures. This enables the dynamic use and selection of already existing information and services.
- **Mobile computing:** A mobile device provides users with information and services everywhere. This allows further integration of the platform in the user's daily life and work processes. The restricted communication and interaction capability of mobile devices, as well as communication costs, reliability, and security aspects have to be considered when selecting suitable presentation forms and delivery strategies.
- **Information-logistical evaluation:** All described key technologies are combined by application-specific evaluation knowledge. The evaluation component of the platform controls the appropriate selection and presentation of services and information. This may even include business processes, being out of scope for this chapter.

Main Components

The logical architecture defines overall system functionality as a cooperation of different subsystems providing specialized tasks related to the key technologies. The subsystems are application-independent and can also be used stand-alone. They all build on services and models of the core layer. As sketched, the platform developed consists of the following main components:

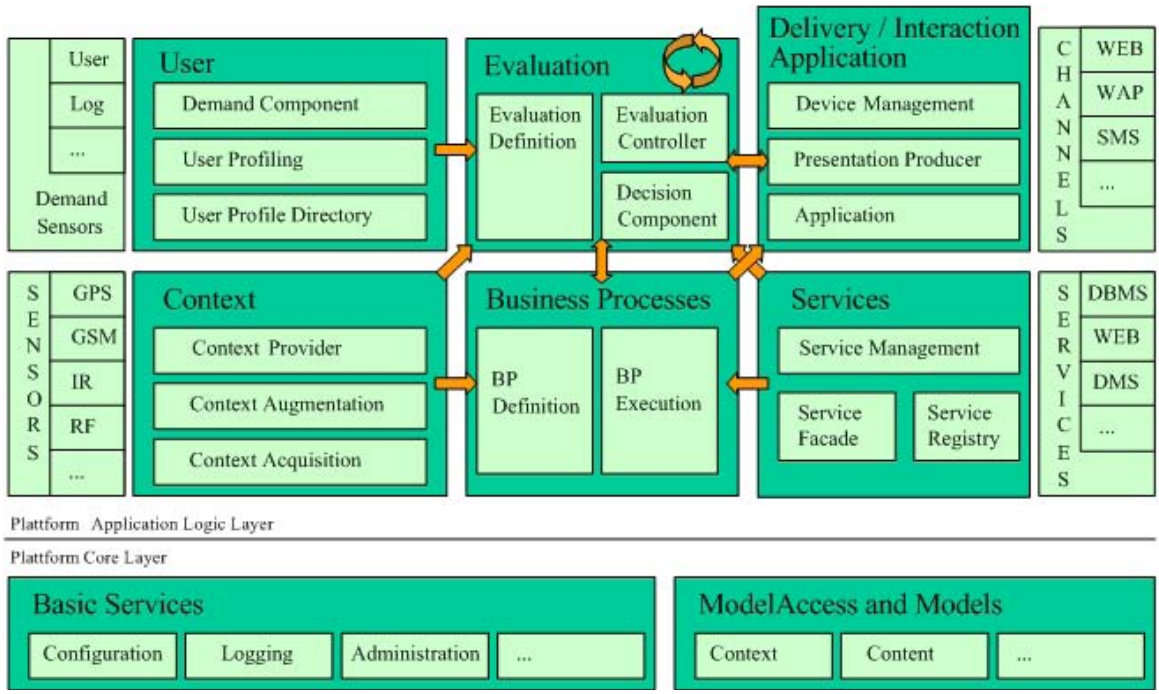
ModelAccess

Inference engines are not yet as mature as relational database systems. Especially, they are not as fast and only some of them support multithreading, which is a prerequisite for having a large number of concurrent users. Therefore, we developed a *ModelAccess* component with integrated basic and pragmatic inference support. The principle idea of *ModelAccess* is the generation and execution of *closed* structured query language (SQL) queries from semantic profiles based on ontologies that map the original semantics. The generation is based on an extensible set of registered parameterized SQL parts. Predefined parts for standard relationships like *subtype, instanceOf, partOf, geoContains* exist, and rules or characteristics for new kinds of relationships can be stored as user-defined SQL parts. The parts are selected and composed based on stored semantic metadata of table properties. The *closed* queries generated only need simple transactions handled

by the RDBMS automatically. The *ModelAccess* component was built with the main design goals to support dynamic online multi-user access to semantic data, to support efficient retrieval on voluminous persistent semantic data, and to combine relational concepts with semantic features by an abstract model access layer and runtime-engine used within all subsystems of the service platform.

Most inference engines and ontology design tools today enable to store ontologies in an RDBMS. For example, Protégé provides to store ontologies as Protégé database and others even offers to use database tables during inference (which often makes inference slower, and is intended for large ontologies that cannot completely be kept in main memory). However, *ModelAccess* is not the first inference engine using a relational database directly for inference. In Das, Chong, Eadon, and Srinivasan (2004), an approach is described to implement inference on top of an Oracle RDBMS. Semantic queries are formulated using SQL with additional operators, based on a general schema for storing concepts, properties and relationships. Due to performance reasons they perform an initial materialization of all OWL axioms (e.g., subproperties and transitivity of properties) after loading the ontology, followed by individual inferences for each semantic query. The differences to our approach are: they need initial materialization of, for example, transitivity (computing the transitive closure) to get meaningful performance and directly work on SQL level, while we use transitive discriminates (no transitive closure) and add semantic profiles and SQL generation as an optional abstraction level. In Chong, Das, Eadon, and Srinivasan (2005), the same authors describe a similar approach to realize inference based on resource description framework (RDF). Performance is optimized by

Figure 3. Gross architecture of the semantic service platform



providing indexed materialized views on the two tables of their normalized schema, which *results* in a table design similar to ours. Chong et al. (2005) conclude, "a promising storage representation is *partial* normalization" (2005, p.12).

Service Subsystem

This subsystem is responsible for selecting content and services. It is an open service infrastructure and provides functionality for management and provision of services. This includes the semantic description of services by definable ontology schemas, as described above. The semantic *ServiceRegistry* (implemented by *ModelAccess*) provides dynamic ad hoc integration of services of different kinds from third party providers. It allows for retrieval of registered services and customized service offers. The *ServiceFacade* supports use of services of any kind, provides basic mechanisms for controlling access rights and billing, and enables service roaming. Not only passive services are supported, but also subscribing active services which may fire events.

Context Subsystem

This subsystem provides functionality for definition and provision of application-specific context models, which are a machine readable representation of the part of the world relevant for an application, based on a context meta model. Normally, this model includes the user and other items like locations and relations between these objects. The subsystem provides functionality for detection and provision of context information for any entity. This includes ad hoc integration, management, selection, and use of distributed context sensors, the derivation of related context information and the detection of situations (to enable situation-awareness). The subsystem follows a layered component architecture that separates the different aspects of context detection, integration, refinement, model management and operation, and context information access.

User Subsystem

This subsystem defines the infrastructure for the personalization of any application, used for centralized management and provision of user information. This includes the provision of user data (relatively static user information like the user's name and gender), user preferences (like preferred language or modality), and user interests (in specific topics). Complex application-specific user model can be defined. Securing privacy of such information is important here. In the current version of the subsystem a lightweight directory access protocol (LDAP) server is used as the basis for management and provision of user information. It also includes a framework for integration of user profile learning components.

Evaluation Subsystem

This subsystem provides information-logistical evaluation logic. The jobs residing in the evaluation subsystem are value-added services defining the main application-specific interoperation patterns between the subsystems. They enable the evaluation of any resources, for example, information and services, its relevance for a specific user, and a delivery strategy. The subsystem executes in cooperation with the other subsystems, thus delegating special evaluation jobs to them, for example, notification of relevant context events or changes of service sets. Reusable scenarios abstract from the implementation of evaluation jobs within the other subsystems. The current implementation of the job model is based on a Boolean ECA-paradigm: events can be subscribed from the other subsystems. The condition is a Boolean expression on events that lead to the action part defining a coordinated execution of functionality using the other subsystems.

Instantiation for Application Scenarios

All application scenarios described above have common requirements on a supporting platform, namely information-logistical support by dynamic information and service supply, based on registered offers, relevant context information, and user profile data. These are the objective of the semantic service platform.

Instantiation of the platform for a new application possibly added to the set of already existing applications (ability to clientele processing) begins with extending the data models (namely ontologies). Each subsystem can be instantiated by configuration and by describing its application-dependent behavior using a domain-specific language. Then the platform component's application programming interfaces (APIs) are used by the new application, and services as well as application-specific jobs have to be registered.

PRACTICAL EXPERIENCES

As the information-logistical semantic service platform is implemented and operational, we have gained first practical experiences regarding ontology integration and performance. Having used the platform as a basis in the COMPASS2008 system that aims at providing visitors of the Olympic Games 2008 in Beijing with personalized situation-aware services, we are also able to include experiences from a recently performed field test in Beijing. During that field test the users were equipped with GPRS- und GPS-enhanced MDA Pro PDAs with the COMPASS front-end.

The field test was conducted July 8-10, 2006, in Beijing. To enable testing of the COMPASS system under real-life conditions, we defined a test scenario for Beijing. This scenario aims at covering the most common situations visitors (especially Western foreigners) experience when visiting Beijing. Regarding the resources available in the project we had to restrict the test to a part of Beijing, for example, to limit the content needed.

The test users represented Beijing Olympic visitors, that is, they acted in the role "tourist". For the field test we had foreign users from the U.S. Korea, Japan, and Italy as well as Chinese, thus representing native and non-native English speakers. Of the 15 users, 12 were male and 3 were female. Their average age was about 26 years. Approximately 40% of the users had experience in the use of PDAs and/or smartphones. The foreign users mostly had only little knowledge of the Chinese language and were to some extent familiar with Beijing. Six foreigners were in Beijing for one month or less.

In the next step, the test users were sent out to perform the test. Each user had to fulfil 16 tasks, some of them repeatedly, for example, find restaurant/coffee shop, order a drink, plan the day, pay, communicate destination to taxi driver, buy an item, and find restrooms. A COMPASS2008 team member accompanied each test user to assure a proper conduction of the different tasks.

Situation-aware service provision was considered useful by most subjects. No test person criticized it, and most people even desired to improve the feature. From the COMPASS system perspective we obtained the following results regarding the quality of the situation awareness feature: recall 95.8% (correct situation identified, only relevant services offered), precision 51.0% (only correct situation identified, redundant services offered). The recall value looks quite satisfying for the first deployment in the field. An analysis of the reason for wrong situation identifications turned out that deviation of the GPS signal led to mismatches of a user's position and the geographical locations of points-of-interest.

During the field test, the semantic service platform was integrated into the Internet infrastructure of a Chinese Internet service provider. It was fully available with no problems in providing its functionality. Even though there was a problem

in the context subsystem leading to an unnecessarily high number of context change events, there was no visible delay in providing the user with situation-specific services.

A problem faced was the unreliable and imprecise location detection of a user through GPS. Even when a user did not move, the GPS detector reported a position change of more than 30 meters. Another problem was the unreliability and limited performance of data communication using general packet radio service (GPRS) in China. Beside these problems, the technical performance of our platform during the field test was satisfying.

FUTURE TRENDS

Currently we observe a convergence of communication and information infrastructures towards Internet-based systems. This convergence eases the integration of information flows into applications. This trend is backed by service-oriented architectures where system components communicate via the Internet, residing at arbitrary locations. Consequently, information overflow of users will intensify. Customer satisfaction can only be achieved when an intelligent information supply is provided, taking care of individual user needs.

A broader adoption of semantic registries and situation-aware demand description as standards enables a guided use of offered services and service-specific contents in individual user contexts. This leads to higher acceptance on the user side and at the same time enables the forming of value chains on the business side, as service providers can establish networks where each provider covers a specific service offer that seamlessly integrates with others.

In summary, user profiles, context-awareness, and semantic service descriptions provide the basis for a demand-driven personalized information and service logistics using multistage value chains.

CONCLUSION

In this chapter, we tried to point out that ontologies and their evaluation are well suited to define a semantic reference system accessed by large heterogeneous user groups. In the COMPASS2008 project, an application ontology for Beijing Olympics tourists has been developed. On this basis a dynamic semantic matching of user demands derived from user profiles and context-driven situation detection with semantically described service offers is performed. The COMPASS pilot system proved the applicability of these concepts for situation-aware semantic Web applications in a field test in Beijing.

Although the results from the field test are satisfying, the entire development was not as smooth as it might seem. We had to solve problems on all levels, including nonsynchronized funding on the Chinese and German sides, content procurement, and system integration or technical problems when setting up the field test. Some of these problems are intrinsic to international projects with multiple partners; others are more specific, like the restricted access to digital maps in China or the impreciseness of GPS in a mega city like Beijing. The cooperative atmosphere within the consortium, however, was a major success factor. A more detailed discussion of the problems sketched above is beyond the scope of this contribution. Here we focused on ontology related issues.

The COMPASS system provides for user-individual demand description and situation-aware service filtering in the context of the Olympic Games 2008 in Beijing. The MONA prototype deploys the same technologies for situation-specific information and service provision in emergency cases, supporting emergency response teams on the spot. Here, situation awareness is used for a more precise content selection.

The insights gained from the deployment of semantic Web technologies show that they are very powerful and helpful for the development

of adequate models. On the implementation side, however, mass applications are still a critical issue as the performance of inference engines falls short compared with relational database technology. Hence, for larger applications we recommend use of ontology development tools for the conceptual phase and transferring the result in the implementation phase to a database solution.

ACKNOWLEDGMENTS

COMPASS/FLAME2008 was developed in the context of the project "Personalized Web Services on Internet III for the Olympic Games 2008 in Beijing", October, 2002 – September, 2006, supported by the German Ministry of Education and Research (BMBF Grant No. 01AK055) and the Chinese Ministry of Science and Technology (MOST).

Chapter 8.15
A Multi-Agent System Approach to Mobile Negotiation Support Mechanism by Integrating Case-Based Reasoning and Fuzzy Cognitive Map

Kun Chang Lee
Sungkyunkwan University, Korea

Namho Lee
Sungkyunkwan University, Korea

ABSTRACT

This chapter proposes a new type of multi-agent mobile negotiation support system named MAM-NSS in which both buyers and sellers are seeking the best deal given limited resources. Mobile commerce, or m-commerce, is now on the verge of explosion in many countries, triggering the need to develop more effective decision support systems capable of suggesting timely and relevant action strategies for both buyers and sellers. To fulfill a research purpose like this, two artificial intelligence (AI) methods such as CBR (case-based reasoning) and FCM (fuzzy cognitive map) are integrated and named MAM-NSS. The primary advantage of the proposed approach is that those decision makers involved in m-commerce regardless of buyers and sellers can benefit from the negotiation support functions that are derived from referring to past instances via CBR and investigating inter-related factors simultaneously through FCM. To prove the validity of the proposed approach, a hypothetical m-commerce problem is developed in which theaters (sellers) seek to maximize profit by selling their vacant seats to potential customers (buyers) walking

around within reasonable distance. For experimental design and implementation, a multi-agent environment Netlogo is adopted. A simulation reveals that the proposed MAM-NSS could produce more robust and promising results that fit the characteristics of m-commerce.

INTRODUCTION

The modern mobile computing world is characterized by one of both ubiquitous connectivity and ubiquitous computational resources (Edwards, Newman, Sedivy, & Smith, 2004). Recent popular forms of mobile computing encompass omnipresent short-range communications (including both infrastructure-based technologies such as WiFi and peer-to-peer technologies such as Bluetooth), and also omnipresent long-range communications (such as cellular telephony networks). This maturing mobile environment justifies conservative estimates based on the 2000 Census report suggesting that by 2006 10% of U.S. workers will be completely mobile, with no permanent office location (Lucas, 2001). This trend will be fueling development of new mobile applications as advances in mobile technology increase coverage, data speeds, and usability (Barbash, 2001; Crowley, Coutaz, & Bérard, 2000; Parusha & Yuviler-Gavishb, 2004; Pham, Schneider, & Goose, 2000; Turisco, 2000).

In this sense, it is no wonder that **mobile commerce** (or **m-commerce**) replaces traditional forms of electronic commerce rapidly. Various types of m-commerce services include mobile shopping, location sensitive information service, traffic updates, and logistic tracking services, all of which utilize the concepts of customization, personalization, location sensitive, context awareness (Lee & Yang, 2003; Schilit, 1995; Schilit, Adams, & Want 1994; Wang & Shao, 2004; Want, Hopper, Falcao, & Gibbons, 1992; Want, Schilit, Adams, Gold, Petersen, Ellis, et al., 1995). M-commerce has been successfully activated in some industries, leading to competitive advantage (Rodgera & Pendharkarb, 2004; Varshney, 1999) and improved workflow as well as reduced costs and risk management (Miah & Bashir, 1997; Porn & Patrick, 2002; Turisco, 2000). However, such a success story is confined to specific applications where the decision support framework is not considered seriously. To reap better results from the users' view, decision makers engaged in a specific type of m-commerce should be supported more intelligently and robustly.

It cannot be overstated that decision makers under a specific m-commerce situation need more timely and robust decision support because they are in several types of contexts. For example, they cannot afford to receive detailed information from a decision support system because of the limited display capability of mobile devices they carry. Besides, they do not have enough time to consider all the related factors before making decisions because they are usually on the move. This kind of environmental limitations require that a **decision support framework** should be developed for enhancing decision making effectiveness for m-commerce users.

For this purpose, this chapter proposes a new kind of decision support framework named **MAM-NSS_**(multi-agent mobile negotiation support system) which can benefit both m-commerce buyers and sellers. MAM-NSS is based on a multi-agent mechanism in which buyers and sellers are respectively represented by agents. Each agent tries to coordinate with each other until reaching a compromised decision. Especially, the proposed MAM-NSS focuses on the fact that decision makers engaged in a specific m-commerce situation are often facing two kinds of needs: (1) to refer to past instances carefully and (2) mull over inter-related factors simultaneously. A literature survey shows that there exist few studies dealing with those research needs. To fill such a research void, this chapter proposes two important mechanisms like **case based reasoning** (CBR) and **fuzzy cognitive map** (FCM).

The proposed MAM-NSS combining CBR and FCM is therefore expected to provide more robust decision support to m-commerce decision makers irrespective of buyers and sellers. To prove the validity of the proposed approach, a hypothetical m-commerce problem is developed in which theaters (sellers) seek to maximize profit by selling their vacant seats to potential customers (buyers) walking around within reasonable distance. For experimental design and implementation, a **multi-agent** environment ***Netlogo***[1] is adopted.

BACKGROUND

Recent Trends in M-Commerce

Electronic commerce applications recently provided by mobile communication services include mobile information agents (Cabri, Leonardi, & Zambonelli, 2001, 2002; Mandry, Pernul, & Rohm, 2000-2001), online kiosks (Slack & Rowley, 2002), government applications (e.g., online selling by the postal service, Web-based electronic data interchange, or EDI, in trade applications), and direct online selling systems such as Internet-based (or Web-based) shopping mall systems and Internet-based stock trading systems. In the m-commerce and mobile communication services, their ease of use and multimedia approach to the presentation of information attract potential customers. Some countries and regions have put in tremendous efforts in pushing the development and deployment of m-commerce. These countries include the U.S., Japan, South Korea, Hong Kong, and the Scandinavian countries. There have been many different kinds of m-commerce applications deployed to businesses in these areas. In the U.S., the current rush to wireless communication methods was triggered by the U.S. Federal Communication Commission's auctioning of personal communication-service spectrum space (Senn, 2000). The collaboration of public and private sectors has facilitated the development of m-commerce businesses.

Recently, a large number of organizations have adopted m-commerce for business purposes in order to gain competitive advantages in the electronic market. To cite a few examples, NTT DoCoMo, Vodafone, Verizon, Sprint PCS, and AT&T Wireless have provided "cybermediation" for greater efficiency in supply and marketing channels through m-commerce. M-commerce can benefit business transactions by providing more efficient payment systems, shortening time to markets for new products and services, realizing improved market reach, and customization of products and services (Barnes, 2002; Senn, 2000). Besides, innovative m-commerce applications have been constantly reshaping business practices in terms of enhancing customer service, improving product quality, and lowering cycle time in business processes (Seager, 2003).

As m-commerce supports online purchasing through an electronic channel, that is, the Internet, via electronic catalogs or other innovative formats, customers procure products, services, and information through m-commerce (Bailey & Lawrence, 2001). In m-commerce, potential customers can visit various "virtual malls" and "virtual shops," and browse through their catalogues to examine products in vast detail. New areas of business opportunities for retailers, producers, and consumers can be developed from these virtual markets on m-commerce. Mobile information agents provide an effective method to support the electronic marketplace by reducing the effort involved in conducting transactions (Wang, Tan, & Ren, 2002). Mobile agents can also help search other agents for contracting, service negotiation, auctioning, and bartering (Mandry et al., 2000-2001). Agents roam through Internet sites to locally access and elaborate information and resources (Omicini & Zambonelli, 1998). The introduction of mobile agents into the electronic market scenario reduces the load and the number of necessary connections to suppliers. In

this way, the multi-agent approach is a feasible way to model and analyze complex m-commerce applications.

Among the three distinct identifiable classes of electronic commerce applications (i.e., **business-to-customer (B2C)**, **business-to-business (B2B)**, and intra-organization (Applegate, Holsapple, Kalakota, Radermacher, & Whinston, 1996), m-commerce generally falls into the B2C class. M-commerce provides Web presence with information about company products and services and facilities for both online and off-line purchasing. M-commerce also facilitates other business related activities, such as entertainment, real estate, financial investment, and coupon distribution. Usually, m-commerce sellers are required to make competitive offers in order to sell their products or services to the target customers within reasonable distance. In location-based m-commerce applications, sellers should compete with each other to appeal to potential buyers because there could be only a few buyers in a limited area. For sellers, making timely and attractive offers to buyers on the move is very challenging because the buyers continue to receive information and offers from competing sellers.

Intelligent Agents

Fundamentals

The proposed MAM-NSS is basically based on the multi-agents. Both sellers and buyers engaged in a certain m-commerce are represented by specific agents, and each agent is entitled to receiving proper decision support from the MAM-NSS. An intelligent agent (or agent) has various definitions because of the multiple roles it can perform (Applegate et al., 1996; Hogg & Jennings, 2001; Persson, Laaksolahti, & Lonnqvist, 2001; Wooldridge, 1997; Wooldridge & Jennings, 1995). An intelligent agent is simply a software program that simulates the way decision makers think and make decisions. It performs a given task based on the information gleaned from the environment to act in a suitable manner so as to complete the task successfully. It is able to adjust itself to the changes in the environment and circumstances, so that it can achieve the expected result (Paiva, Machado, & Prada, 2001).

The term "**intelligent agent**" can be disintegrated into two words: intelligence and agency. The degree of autonomy and authority vested in the agent is called its agency. It can be measured at least qualitatively by the nature of the interaction between the agent and other entities in the system in which it operates. An **agent** is an individual and it runs independently. The degree of agency will be enhanced if an agent represents a user in some way. Therefore, collaborative agents represent a higher level of agency because they cooperate with other agents or programs or entities, and so on. The agent intelligence can be interpreted as the degree of reasoning and learned behavior. It is the ability to understand the user's statement of goals and carry out the task delegated to it. Such intelligence can be easily found in the reasoning process of many decision or AI models. Intelligence enables agents to discover new relationships, connections, or concepts independently from the human user, and exploit these in anticipating and satisfying a user's needs (Bonarini & Trianni, 2001; Hu & Weliman, 2001; Schaeffer, Plaat, & Junghanns, 2001).

To retain the characteristics of "intelligence" and "agency." an intelligent agent should possess the abilities of mobility, benevolence, rationality, adaptability, and collaboration (Wooldridge, 1997). Mobility is the ability to move around an electronic network (Bohoris, Pavlou, & Cruickshank, 2000; Lai & Yang, 1998; Lai & Yang, 2000). Benevolence is the assumption that an intelligent agent does not have conflicting goals, and therefore it will always try to complete the assigned tasks (Hogg & Jennings, 2001; Jung & Jo, 2000). Rationality is the assumption that an agent will act in order to achieve its goals and will not act in such a way as to prevent its goals

from being achieved, at least insofar as its beliefs permit (Hogg & Jennings, 2001; Persson et al., 2001). Adaptability indicates that an agent should be able to adjust itself to the habits, working methods, and preferences of its user (Jung & Jo, 2000). Collaboration is an ability to cooperate with other agents so that an agent can achieve what a goal decision maker wants to attain (Jung & Jo, 2000; Lee & Lee, 1997; Wu, Yuan, Tseng, & Fuyan, 1999). This chapter places a strong emphasis on the collaboration ability. Although no single agent possesses all these abilities in a real situation, it is certain that these kinds of characteristics are those that distinguish agents from ordinary programs.

Multi-Agent System

To investigate a computational model that actually encodes and uses conflict resolution expertise, a focus can be placed on the **multi-agent framework**, which is adopted from the distributed AI problem (Bird, 1993; Chaib-Draa & Mandiau, 1992; Cooper & Taleb-Bendiab, 1998; Luo, Zhang, & Leung, 2001; Sillince, 1998; Sillince & Saeedi, 1999; Tung & Lee, 1999). Multi-agent systems have offered a new dimension for coordination in an enterprise (Bonarini & Trianni, 2001; Hu & Weliman, 2001; Kwon & Lee, 2002; Sikora & Shaw, 1998; Strader, Lim, & Shaw, 1998; Ulieru, Norrie, Kremer, & Shen, 2000; Wu, 2001). Incorporating autonomous agents into **problem-solving** processes allows improved coordination of different functional units to define tasks independently of both the user and the functional units under control (Cabri et al., 2002). Under a multi-agent system, the problem-solving tasks of each functional unit becomes populated by a number of heterogeneous intelligent agents with diverse goals and capabilities (Lottaz, Smith, Robert-Nicoud, & Faltings, 2000; Luo et al., 2001; McMullen, 2001; Ulieru et al., 2000; Wu, 2001).

The multi-agent system, in which multiple agents work collaboratively to solve specific problems, provides an effective platform for coordination and cooperation among disputing multiple entities in real world cases. For example, when a conflict occurs between buyers and sellers over a limited resource, it is difficult for a single authority or committee to reconcile it to the full satisfaction of all the entities concerned. Therefore, it is likely that the use of a multi-agent system for coordination will result in a more systematic and organized method in reality without causing unnecessary emotional and behavioral side effects.

Decision Support Mechanisms

MAM-NSS is equipped by two decision support mechanisms such as CBR and FCM. First, **CBR** is a renowned artificial intelligence methodology that provides the technological foundations for intelligent systems (Kolodner, 1993). Given a case base where a number of **past instances** are stored, CBR consists of several phases: indexing cases, retrieving the appropriate candidate cases from the case base, approximating potential solutions from them, testing whether the proposed solutions are successful, and learning to upgrade the decision quality by updating the case base and retrieval mechanism. CBR is most applicable when there is (1) no decision model available; (2) a specific decision model is too hard to acquire; or (3) when past cases are available or easy to generate. With these CBR benefits, the CBR approach is extensively used for negotiation (Kowalezyk & Bui, 1999). Considering the advantages of CBR above, MAM-NSS adopts CBR to allow agents to refer to the past relevant instances that seem to explain a part of current decision making problem before making final decisions.

Second, **FCM** is utilized to provide agents with the capability of analyzing complicated **interrelationships of all the relevant factors** by viewing them simultaneously. FCM was introduced by Kosko (1986, 1987) in which fuzzy causality concept is introduced to represent un-

certainty embedded in problem domain. In this way, FCM provides a more flexible and realistic representation of the domain knowledge. For example, Ray and Kim (2002) used it as a tool for understanding and controlling intelligent agents. Liu and Satur (1999) have used FCM as a decision support mechanism for interpreting geographic information as well as designing automatic context awareness function that is one of the important characteristics in m-commerce.

By integrating CBR and FCM, MAM-NSS is designed to provide decision makers on the move with more improved decision support functions. CBR is especially useful for m-commerce users who do not have sufficient time to consider all the constraints before making decisions. By retrieving appropriate past examples and suggesting them as a benchmarking point, CBR can help m-commerce users make fast decisions. There are many factors that are influencing m-commerce decisions either indirectly or directly. However, users cannot afford to consider all the causal relationships among those factors thoroughly in a situation when they need to move and there is not enough time. In that situation, FCM can provide an analytical and systematic way of investigating causal relationships between all the factors related to the m-commerce situation.

MAM-NSS

Basics

Figure 1 depicts a hypothetical m-commerce situation where MAM-NSS is used to provide timely decision support to m-commerce users. Since the term "m-commerce" may cause different interpretations depending on situations, we need to define m-commerce conditions more clearly to make further discussions unambiguous. First, buyers are assumed to carry mobile devices such as PDAs or mobile phones. Second, buyers cannot have access to the telecommunication network line because they are moving. Third, buyers make reservations with sellers through mobile devices. Fourth, sellers provide information about their services and goods through mobile devices.

The **negotiation process** of MAM-NSS is composed of four steps. Since MAM-NSS runs on a multi-agent framework, a buyer is represented by **B-agen**t and a seller **S-agent** from now on. In other words, each agent possesses its own generic knowledge including either buyer's or seller's basic preference that has been predefined.

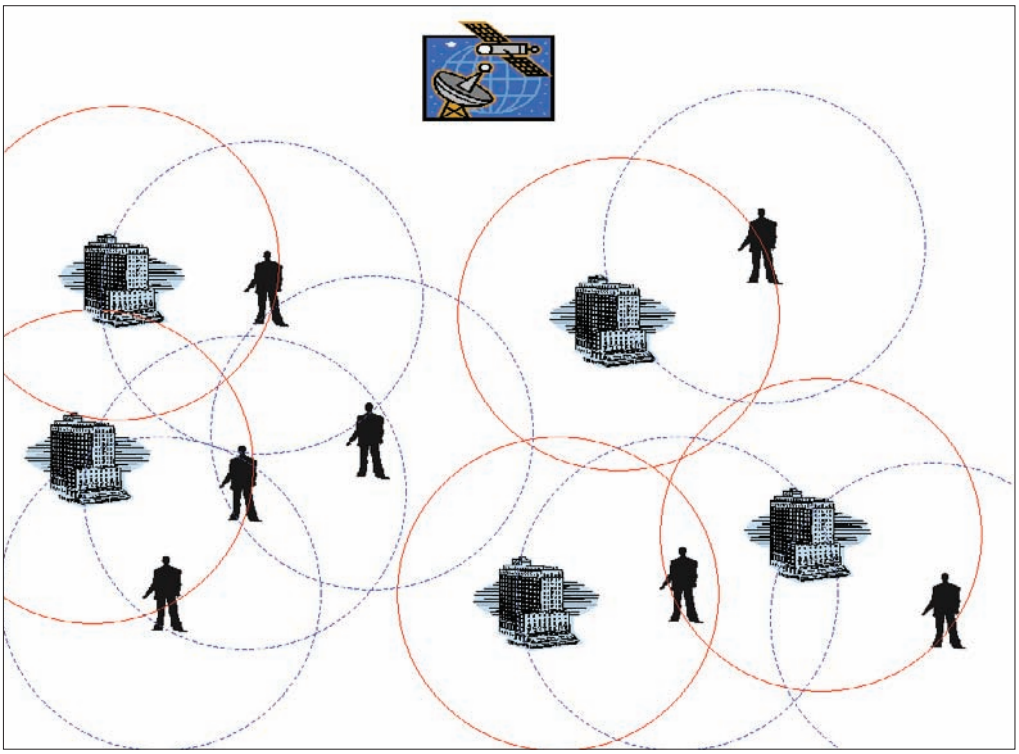
The first step is to identify buyers' and sellers' location. Such location identification is based on opt-in agreement with mobile telecommunication company.

The second step is for sellers to provide an offer to potential buyers within a fixed distance from where buyers can arrive after a reasonable time. For example, the seller's offer may include an appropriate product/service and its price quote, all of which are assumed to be obtained from CBR inference. For this CBR inference, sellers need various kinds of contextual information such as potential buyers' current location, weather, other events, and so forth.

The third step is for buyers to check the offer from sellers on their mobile devices in which buyers' personal preference is stored. Then the seller's offer is compared with the buyer's predefined preference. If the offer is not appealing, then the buyers modify the offer and send it to the seller. All this process is performed on a multi-agent basis.

The fourth step is for sellers to review the modified offer from buyers. At this time, FCM is used to induce an appropriate price level considering complicated causal relationships among qualitative and strategic factors simultaneously. Depending on marketing strategy, the sellers may change their price offer to lower or higher. Therefore, the sellers' decision can become more strategic and flexible in accordance with changing situations.

Figure 1. M-commerce situation



Architecture

MAM-NSS is composed of three entities like **B-agent**, **S-agent**, and **mobile telecommunication company**. B-agent is assumed to be downloaded into buyer's mobile device when she subscribes to the MAM-NSS service. The B-agent becomes personalized according to **buyer's personal preference** about specific products/services, and related prices, quality, brand, and other properties. Especially, B-agent specifies its own utility function following buyer's preference which is compiled from the online questionnaire when the buyer subscribes for the MAM-NSS service. Then the B-agent is stored in the memory of the buyer's carried **mobile device**. The B-agent uses this information to negotiate prices with sellers. S-agent is basically linked to the seller's back office system and negotiates with B-agent on the price of seller's products/services. S-agent's first price offer is composed referring to CBR inference, and relayed to potential buyers who are moving within a reasonable distance from the seller. When the buyer's modified price offer is entered, S-agent revises its price offer by using FCM and then feeds it back to the buyer. In this process, negotiations are going on until the final deal is struck between buyer and seller.

In the process of negotiations, the mobile telecommunication company acts as an intermediary between S-agents and B-agents. If the **sellers** and **buyers** subscribe to the MAM-NSS service

provided by the mobile telecommunication company, then they can share the information needed in negotiation such as the location of sellers and buyers, price offer, and related product/service information.

S-Agent

The ultimate goal of S-agent is to maximize profit. For this purpose, S-agent seeks a potential buyer in the range acceptable to the buyer within a specific time limit. Then it calculates the bid price of the selling product/service based on CBR, and sends the offer including price and product/service to the potential B-agents through the mobile telecommunications company. A wide variety of past selling instances are stored in the case base, and CBR uses the **similarity index** (SI) below to select the candidate case that seems to fit most with the current selling situation. Once such case is chosen successfully, then the price offer can be made appropriately referring to the price information attached to the selected case.

$$SI_i = \sqrt{\sum_{j=1}^{n} (N_j - S_{ij})^2}$$

where N_j indicates jth attribute value of a new case (j=1,2,…,n), and S_{ij} denotes jth attribute value of ith case in case base of CBR (i=1,2,…, m). Netlogo source code for implementing the CBR mechanism using SI is listed in Table 1.

If the buyer accepts the price offered by S-agent, then the deal between seller and buyer will be completed and the buyer stops negotiating. But if the buyer is not satisfied with the price offered by S-agent, the price level is adjusted and then relayed to S-agent. Finally, S-agent decides whether or not to accept the newly-adjusted price, using the FCM inference. If another price offer

```

is made, then negotiation proceeds to the next round. This process is repeated until all sellers and buyers find their appropriate partners that meet their respective goals. In Table 2, the FCM mechanism to be used for adjusting the **price offer** is represented in the Netlogo source code.

B-Agent

The buyer represented by B-agent seeks to maximize its own utility in the process of negotiating with the suppliers. Buyers can download B-agents from the subscribed telecommunication company's site and store them into their mobile devices. B-agents incorporate the following **utility functions** where i=1,2,…,m (number of sellers) and j=1,2,…,n (number of utility factors):

$$U_i = \sum_{j=1}^{n} W_{ij} \bullet F_{ij}$$

U_i denotes ith buyer's utility, W_{ij} buyer's preference for jth utility factor, and F_{ij} ith buyer's jth utility factor. It is certain that $\sum_{j=1}^{n} W_{ij} = 1$. Examples of utility factors include not only price, product, and quality, but also **contextual information** such as the buyer's current location and environmental constraints. Table 3 shows the Netlogo source code for calculating the B-agent's utility function.

If B-agent gets the price offer from S-agent and this offer does not meet the buyer's goal utility, then the B-agent suggests a new price using the mechanism shown in Table 4. If the seller accepts the new price offered by the buyer, then the deal is complete. However, if no sellers accept this price, then the B-agent increases the price decreasing its goal utility. In this case, a new round of negotiation resumes.

EXPERIMENTS

Problem Description

Three Groups

The target problem here is that there are a number of movie theaters in an area, and customers want to go to the theater depending on their personal situations. Based on whether customers (i.e., buyers) and theaters (i.e., sellers) are using mobile devices or not, we categorize them into three groups for the sake of the experiment. Group 1, called "**non-mobile group**," is not using mobile devices. Therefore, customers either reserve tickets through non-mobile channels, such as telephone or cable Internet, or buy onsite from the box office. Theaters are assumed to contact customers through the non-mobile channels too. Group 2, called "**passive mobile group**," is using mobile devices but no negotiation functions. Therefore, customers in this group can get information about movies through mobile channels, but they cannot negotiate with theaters through agents. Theaters are also using mobile channels to send movie information to customers. Group 3, called "**active mobile group**," is assumed to use the proposed MAM-NSS for negotiation through mobile channels and agents. Customers and theaters are offering their own preferences such as price and vacant seats utilizing the negotiation mechanism based on MAM-NSS. The three groups will be compared with each other through Netlogo simulation experiments. In fact, group 1 is inappropriate for m-commerce situations because they are not reached by mobile devices. However, group 1 is included so that the other two groups can be compared.

Sellers

- Assumptions about theaters are as follows: they have 200 seats, cost $700 per show, and

```

start to sell vacant seats an hour before the movie begins. List price for a ticket is $7, and movie genres a theater is showing have four types. All the theaters show the movie with box office ranking from 1 to 10. Every 20 minutes, theaters in group 2 are offering discriminated pricing strategies to buyers through mobile channels, depending on the

vacancy rate: \$6.5 if vacancy rate < 40%, \$6.0 if 40% ≤ vacancy rate ≤ 50%, \$5.0 if 50% ≤ vacancy rate ≤ 60%, \$4.0 if 60% ≤ vacancy rate ≤ 70%, \$3.0 if 70% ≤ vacancy rate ≤ 80%, and \$2.0 if 80% ≤ vacancy rate. However, as noted previously, customers cannot negotiate with the theaters in group 2, indicating that they have no choice but to accept the price or not.

- Meanwhile, theaters in group 3 are offering different ranges of price using CBR inference where a case is composed of four input attributes (*current vacancy rate (%), remaining time before the show (minutes), box office ranking of the current show, approximate number of reachable customers*) and one output attribute (*ticket price*). Therefore, the price changes in accordance with the input attribute values theaters are currently facing. Theaters decide whether or not to accept the newly adjusted price offered by the buyers, using FCM as shown in Figure 3. If the FCM result is less than 1, then the theater rejects the buyer's price. Otherwise, the theater accepts the buyer's price, and the buyer's seat number and show time are specified accordingly. When conducting FCM analysis, input constructs should be transformed into an appropriate value considering the input conditions. Table 5 shows input constructs, its conditions, and transformed values.

Customers

The customer's utility function includes the following five factors: (1) D (distance from customer's current location to theater; for this experiment, it is adjusted between -18 and 18 on the Netlogo platform); (2) R (box office ranking of the movie); (3) G (movie genre); (4) P (newly

Figure 3. Group 3 theaters'

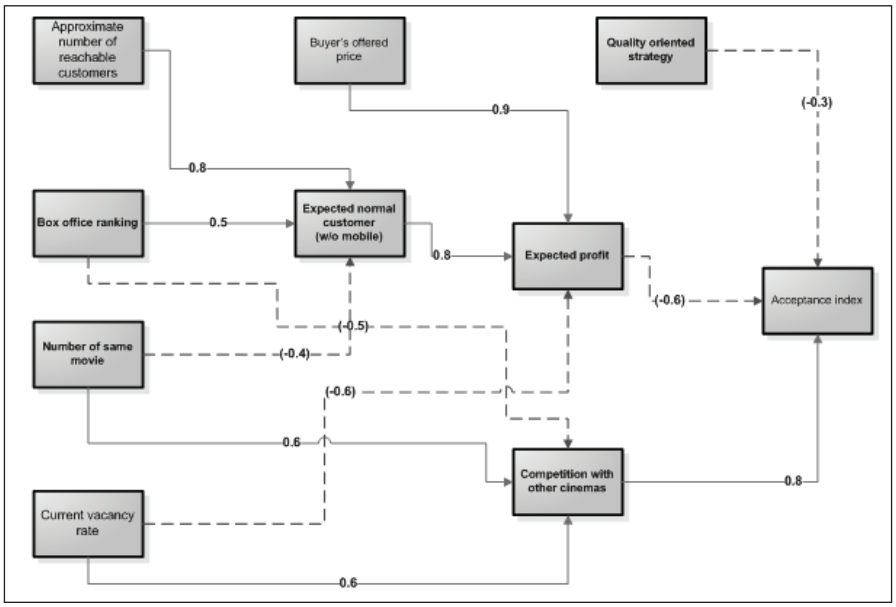

Table 5. Input constructs and conditions for theater's FCM

Input constructs	Condition	Transformed values
Approximate number of reachable customers	Many* Normal** Few***	1 0 -1

adjusted ticket price that customers want); and (5) T (timeliness showing whether it is the exact time that customer wants). Using the five factors like this, *i*th customer's utility function is denoted as follows:

$$U_i = W_{D_i} \cdot D_i + W_{R_i} \cdot R_i + W_{G_i} \cdot G_i + W_{P_i} \cdot P_i + W_{T_i} \cdot T_i$$

- Table 6 addresses the various conditions and their converted values for the five utility factors.

MAM-NSS Simulation

Basics

The MAM-NSS simulation prototype was performed on the Netlogo platform which is a programmable multi-agent modeling environment for simulating natural and social phenomena, and particularly well-suited for modeling complex systems that develop over time. The target m-commerce problem described previously can be well represented by multi-agents composed of B-agents, S-agents, and interactions between them for the effective negotiation. Therefore, MAM-NSS is capable of handling the problem very well.

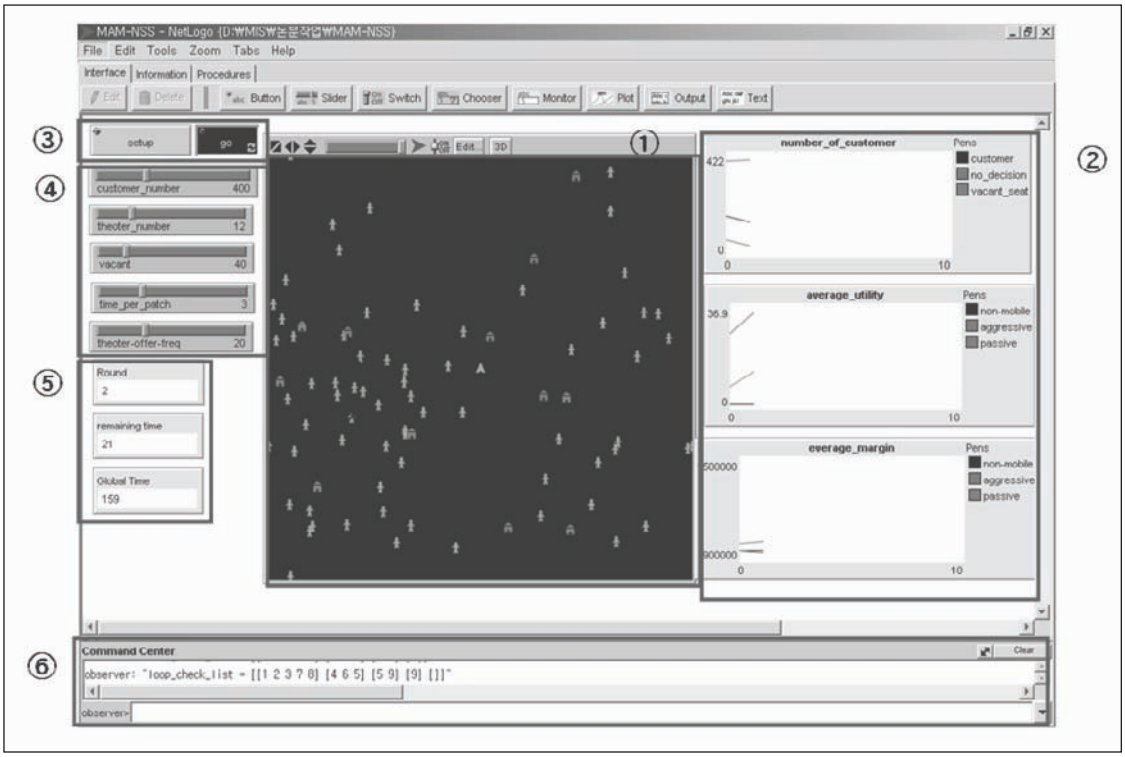
As shown in Figure 4, MAM-NSS has six types of user interface components as follows:

1. *Behavior space* shows the customer's movement and the location of theaters. The human shape indicates a customer and the house shape represents a theater. Gray color means group 1, green color group 2, and pink color group 3. All customers are designed to move one unit of position over to the random direction at a time. The customers go out of simulation after they buy tickets.
2. *Graph* monitors the change of values such as number of customers, vacant seats, number

Table 6. Customer's utility factors

Utility factor	Condition	Converted value
Distance from the theater (D)	In 20 minutes In 30 minutes In 40 minutes In 50 minutes More than 60 minutes	50 40 30 20 10
Box office ranking (R)	1,2 3,4 5,6 7,8 9,10	50 40 30 20 10
Movie genre (G)	Customer wanted Customer did not want	50 0
Ticket price (P)	For any new ticket price adjusted by customers	50 – (new ticket price / list price) * 50
Timeliness (T)	Exact time that customer wants Otherwise	50 0

Figure 4. MAM-NSS simulator



of customers who have not bought a ticket, customers' average utilities, and theaters' average margins.

3. *Control button* prepares and prompts simulation.
4. *Slider* controls the initial conditions of simulation such as number of customers, number of theaters, and maximum number of vacant seats for each theater. Each theater has a number of vacant seats falling between

0 and the "vacant" number that is set by this slide.

5. *Monitor* shows the number such as rounds of simulation, remaining/elapsed before the next show starts, and simulation time.
6. *Command center* shows temporary data generated from the agent activities.

Results and Implications

Twenty six rounds of simulation were done on MAM-NSS with the initial conditions as follows. Total rounds of simulation is 35, number of theaters 12, number of customers ranging between 100 and 600 (evenly assigned to three groups), group 2 theaters sending discriminated price every 20 minutes, and theaters starting to offer discounted price 60 minutes before the show. The simulation results with MAM-NSS are summarized in Table 7 numerically, and in Figure 5 graphically. Under a 95% confidence level, statistical results in Table 8 reveal that in terms of average utilizes and average profits, group 3 can yield the highest value compared with the other two groups. Its implication is as follows:

First, those users belonging to the passive mobile group can benefit from using the mobile devices. However, such mutual benefits increase much more when they use the negotiation support function provided by the proposed MAM-NSS.

Second, multi-agents are very convenient as well as effective for the m-commerce entities to handle them in their decision making process through the use of MAM-NSS. The reason is that agents are basically capable of autonomous operation once the entity's preference is predefined and stored into its memory. In the MAM-NSS environment, users do not have to bother themselves to interact with negotiation partners.

Third, both preference and conditions that users want their own agents to consider in the process of negotiations can be easily incorporated into agents. Since MAM-NSS is installed in the central server of the telecommunication company, it is very easy for users to use it.

Fourth, since m-commerce users are limited by narrow screen and specified functions of their mobile devices, and agents are capable of replacing users in the real negotiation process in an almost automatic manner, the use of negotiation support mechanism like MAM-NSS would greatly contribute to enhancing users' utilities and profits as well.

CONCLUDING REMARKS

To resolve the negotiation process between buyers and sellers in the context of m-commerce, we proposed a multi-agent mobile negotiation support system called MAM-NSS, in which all the buyers and sellers engaged in a m-commerce situation are represented by multi-agents embedded with each entity's preference and corresponding conditions. Its potentials were proved by the simulation experiments using the theaters' vacant seats negotiation problems. Main contributions of the MAM-NSS are as follows.

First, CBR inference is incorporated to help S-agents decide an appropriate price for a vacant seat. Without using CBR, S-agents will have difficulty finding such appropriate price which is consistent with previous decision making results. Especially, such consistency in setting price for various situations is very important to customers who want be opportunistically exploited by sellers.

Second, FCM finds its great potential in the process of negotiation, due to its generalized inference capability in a presence of a number of inter-related factors. Without FCM, decision makers would feel very stressed to consider all the complicated causal relationships among the relevant factors and expect future inference results. In this chapter, FCM was used to help S-agents accept B-agent's price offer or not.

Third, multi-agent schemes were found very meaningful in being used in the process of m-

commerce negotiation. Such multi-agent approach has been proved useful and effective in a wide variety of problems in literature, but its potentials were not proved yet in m-commerce contexts. Therefore, this study adds meaning to literature in that sense.

This study has several positive implications for future m-commerce research. First, m-commerce is blooming as mobile devices are providing increased convenience in users' daily activities. However, there has been no important negotiation support system to leverage the potentials of m-commerce. In that meaning, this study will shed a positive light on using the generalized multi-agent framework for designing a mobile negotiation support system. Second, we proposed practical algorithms to be used in upgrading agents' capability in problem solving. Such algorithms would be used in the other business settings with minor adjustments.

But, this study has limitations in the point that (1) all data used in experiment are not real world data; (2) we do not suggest detailed mechanisms for extracting the buyer's preference; and (3) there

is no comparing our negotiation algorithm with other algorithms. To compare the performance of negotiation algorithms is not simple. Measures need to be developed for comparing negotiation performance before comparing existing algorithms. Additionally, performance measures need to include not only quantitative factors, but also qualitative factors. These three limitations are left as future research topics.

Chapter 8.16
Intelligent User Interfaces for Mobile Computing

Michael J. O'Grady
University College Dublin, Ireland

Gregory M. P. O'Hare
University College Dublin, Ireland

ABSTRACT

In this chapter, the practical issue of realizing a necessary intelligence quotient for conceiving intelligent user interfaces (IUIs) on mobile devices is considered. Mobile computing scenarios differ radically from the normal fixed workstation environment that most people are familiar with. It is in this dynamicity and complexity that the key motivations for realizing IUIs on mobile devices may be found. Thus, the chapter initially motivates the need for the deployment of IUIs in mobile contexts by reflecting on the archetypical elements that comprise the average mobile user's situation or context. A number of broad issues pertaining to the deployment of AI techniques on mobile devices are considered before a practical realisation of this objective through the intelligent agent paradigm is presented. It is the authors hope that a mature understanding of the mobile computing usage scenario, augmented with key insights into the practical deployment of AI in mobile scenarios, will aid software engineers and HCI professionals alike in the successful utilisation of intelligent techniques for a new generation of mobile services.

INTRODUCTION

Mobile computing is one of the dominant computing usage paradigms at present and encapsulates a number of contrasting visions of how best the paradigm should be realized. Ubiquitous computing (Weiser, 1991) envisages a world populated with artefacts augmented with embedded computational technologies, all linked by transparent high-speed networks, and accessible in a seamless anytime, anywhere basis. Wearable computing (Rhodes, Minar, & Weaver, 1999) advocates a

world where people carry the necessary computational artefacts about their actual person. Somewhere in between these two extremes lies the average mobile user, equipped with a PDA or mobile phone, and seeking to access both popular and highly specialized services as they go about their daily routine.

Though the growth of mobile computing usage has been phenomenal, and significant markets exists for providers of innovative services, there still exist a formidable number of obstacles that must be surpassed before software development processes for mobile services becomes as mature as current software development practices. It is often forgotten in the rush to exploit the potential of mobile computing that it is radically different from the classic desktop situation; and that this has serious implications for the design and engineering process. The dynamic nature of the mobile user, together with the variety and complexity of the environments in which they operate, provides unprecedented challenges for software engineers as the principles and methodologies that have been refined over years do not necessarily apply, at least in their totality, in mobile computing scenarios.

How to improve the mobile user's experience remains an open question. One approach concerns the notion of an application autonomously adapting to the prevailing situation or context in which end-users find themselves. A second approach concerns the incorporation of intelligent techniques into the application. In principle, such techniques could be used for diverse purposes, however, intelligent user interfaces (IUIs) represent one practical example where such techniques could be usefully deployed. Thus the objective of this chapter is to consider how the necessary intelligence can be effectively realized such that software designers can realistically consider the deployment of IUIs in mobile applications and services.

BACKGROUND

Research in IUIs has been ongoing for quite some time, and was originally motivated by problems that were arising in standard software application usage. Examples of these problems include information overflow, real-time cognitive overload, and difficulties in aiding end-users to interact with complex systems (Höök, 2000). These problems were perceived as being a by-product of direct-manipulation style interfaces. Thus, the concept of the application or user interface adapting to circumstances as they arose was conceived and the terms "adaptive" or "intelligent" user interfaces are frequently encountered in the literature. How to effectively realize interfaces endowed with such attributes is a crucial question and a number of proposals have been put forward. For example, the use of machine learning techniques has been proposed (Langley, 1997) as has the deployment of mobile agents (Mitrovic, Royo, & Mena, 2005).

In general, incorporating adaptability and intelligence enables applications to make considerable changes for personalization and customization preferences as defined by the user and the content being adapted (O'Connor & Wade, 2006). Though significant benefits can accrue from such an approach, there is a subtle issue that needs to be considered. If an application is functioning according to explicit user defined preferences it is functioning in a manner that is as the user expects and understands. However, should the system autonomously or intelligently adapt its services based on some pertinent aspect of the observed behavior of the user, or indeed, based on some other cue, responsibility for the system behavior moves, albeit partially, from the user to the system. Thus, the potential for a confused user or unsatisfactory user experience increases.

A natural question that must now be addressed concerns the identification of criteria that an

application might use as a basis for adapting its behavior. Context-aware computing (Schmidt, Beigl & Gellersen, 1999) provides one intuitive answer to this question. The notion of context first arose in the early 1990s as a result of pioneering experiments in mobile computing systems. Though an agreed definition of context has still not materialized, it concerns the idea that an application should factor in various aspects of the prevailing situation when offering a service. What these aspects might be is highly dependent on the application domain in question. However, commonly held aspects of context include knowledge of the end-user, for example through a user model; knowledge of the surrounding environment, for example through a geographic information system (GIS) model; and knowledge of the mobile device, for example through a suitably populated database. Other useful aspects of an end-user's context include an understanding of the nature of the task or activity currently being engaged in, knowledge of their spatial context, that is, location and orientation, and knowledge of the prevailing social situation. Such models can provide a sound basis for intelligently adapting system behavior. However, capturing the necessary aspects of the end-user's context and interpreting it is frequently a computationally intensive process, and one that may prove intractable in a mobile computing context. Indeed, articulating the various aspects of context and the interrelationships between them may prove impossible, even during system design (Greenberg, 2001). Thus, a design decision may need to be made as to whether it is worth working with partial or incomplete models of a user's context. And the benefit of using intelligent techniques to remedy deficiencies in context models needs to be considered in terms of computational resources required, necessary response time and the ultimate benefit to the end-user and service provider.

SOME REFLECTIONS ON CONTEXT

Mobile computing spans many application domains and within these, it is characterized by a heterogeneous landscape of application domains, individual users, mobile devices, environments and tasks (Figure 1). Thus, developing applications and services that incorporate a contextual component is frequently an inherently complex and potentially time-consuming endeavor, and the benefits that accrue from such an approach should be capable of being measured in some tangible way. Mobile computing applications tend to be quite domain specific and are hence targeted at specific end-users with specialized tasks or objectives in mind. This is in contrast to the one-size-fits-all attitude to general purpose software development that one would encounter in the broad consumer PC arena. For the purposes of this discussion, it is useful to reflect further on the following aspects of the average mobile user's context: end-user profile, devices characteristics, prevailing environment and social situation.

Figure 1. An individual's current activity is a notoriously difficult aspect of an individual's context to ascertain with certainty

User Profile

Personalization and customization techniques assume the availability of sophisticated user models, and currently form an indispensable component of a number of well-known e-commerce related Web sites. Personalizing services for mobile computing users is an attractive proposition in many domains as it offers a promising mechanism for increasing the possibility that the end-users receive content that is of interest to them. Though this objective is likewise shared with owners of e-commerce sites, there are two issues that are of particular importance when considering the mobile user. Firstly, mobile interactions are almost invariably short and to the point. This obligates service providers to strive to filter, prioritize, and deliver content that is pertinent to the user's immediate requirements. The second issue concerns the question of costs. Mobile users have to pay for services, which may be charged on a KB basis, thus giving mobile users a strong incentive to curtail their use of the service in question if dissatisfied.

A wide number of features and characteristics can be incorporated into user models. As a basic requirement, some information concerning the user's personal profile, for example, age, sex, nationality and so on, is required. This basic model may then be augmented with additional submodels that become increasingly domain-specific. In the case of standard e-commerce services, a record of the previous purchasing history may be maintained and used as a basis for recommending further products. Electronic tourist guides would require the availability of a cultural interest model, which as well as indicating cultural topics of interest to the user, would also provide some metric that facilitated the prioritization of their cultural interests.

Device Characteristics

Announcements of new devices are occurring with increasing frequency. Each generation successively increases the number of features offered, some of which would not be associated with traditional mobile computing devices, embedded cameras and MP3 players being cases in point. Though offering similar features and services, there are subtle differences between different generations, and indeed interim releases within the same generation, that make the life of a service provider and software professional exceedingly difficult and frequently irritating. From an interface perspective, screen size and support for various interaction modalities are two notable ways in which devices differ, and these have particular implications for the end-user experience. This problem is well documented in the literature and a number of proposals have been put forward to address this, the plasticity concept being a notable example (Thevenin & Coutaz, 1999). Other aspects in which mobile devices differ include processor, memory and operating system; all of which place practical limitations on what is computationally feasible on the device.

Prevailing Environment

The notion of environment is fundamental to mobile computing and it is the dynamic nature of prevailing environment in which the mobile user operates that most distinguishes mobile computing from the classic desktop usage paradigm. As an illustration, the case of the physical environment is now considered, though this in no way diminishes the importance of the prevailing electronic infrastructure. Scenarios in which mobile computing usage can occur are multiple and diverse. The same goes for physical environments. Such environments may be hostile in the sense that they do not lend themselves to easily accessing electronic infrastructure such as telecommunications networks. Other environments may experience extreme climatic conditions thus causing equipment to fail.

Developing a service that takes account of or adapts to the local physical environment is an attractive one. Two prerequisites are unavoidable, however. A model of the environment particular to the service domain in question must be available, and the location of the end-user must be attainable. In the former case, the service provider must construct this environmental model, possibly an expensive endeavor in terms of time and finance. In the latter case, an additional technological solution must be engaged—either one based on satellites, for example GPS, or one that harnesses the topology of the local wireless telecommunications networks. Each solution has its respective advantages and disadvantages, and a practical understanding of each is essential. However, by fulfilling these prerequisites, the service provider is in a position to offer services that take the end-users' physical position into account. Indeed, this vision, often termed location-aware computing (Patterson, Muntz & Pancake, 2003), has grasped the imagination of service providers and end-users alike. In essence, it is a practical example of just one single element of an end-user's context being interpreted and used as a basis for customizing services.

Social Situation

Developing a service that adapts to the end-user's prevailing social context is fraught with difficulty, yet is one that many people would find useful. What exactly defines social context is somewhat open to interpretation but in this case, it is considered to refer to the situation in which end-users find themselves relevant to other people. This is an inherently dynamic construct and capturing the prevailing social situation introduces an additional level of complexity not encountered in the contextual elements described previously.

In limited situations, it is possible to infer the prevailing social situation. Assuming that the end-user maintains an electronic calendar, the detection of certain keywords may hint at the prevailing social situation. Examples of such keywords might include lecture, meeting, theatre and so on. Thus, an application might reasonably deduce that the end-user would not welcome interruptions, and, for example, proceed to route incoming calls to voicemail and not alert the end-user to the availability of new email. Outside of this, one has to envisage the deployment of a suite of technologies to infer social context. For example, it may be that a device, equipped with a voice recognition system, may be trained to recognize the end-user's voice, and on recognizing it, infer that a social situation is prevailing. Even then, there may be a significant margin of error; and given the power limitations of the average mobile device, running a computationally intensive voice recognition system continuously may rapidly deplete battery resources.

ARTIFICAL INTELLIGENCE IN MOBILE COMPUTING

Artificial intelligence (AI) has been the subject of much research, and even more speculation, for almost half a century by now. Though failing to radically alter the world in the way that was envisaged, nevertheless, AI techniques have been successfully harnessed in a quite a number of select domains and their incorporation into everyday applications and services continues unobtrusively yet unrelentingly. Not surprising, there is significant interest amongst the academic community in the potential of AI for addressing the myriad of complexity that is encountered in the mobile computing area. From the previous discussion, some sources of this complexity can be easily identified. Resource management, ambiguity resolution, for example, in determining contextual state and resolving user intention in multimodal interfaces, and adaptation, are just some examples. Historically, research in AI has focuses on various issues related to these very topics. Thus, a significant body of research

already exists in some of the very areas that can be harnessed to maximum benefit in mobile computing scenarios. A detailed description of these issues may be found elsewhere (Krüger & Malaka, 2004).

One pioneering effort at harnessing the use of intelligent techniques on devices of limited computational capacity is the Ambient intelligence (AmI) (Vasilakos & Pedrycz, 2006) initiative. AmI builds on the broad mobile computing vision as propounded by the ubiquitous computing vision. It is of particular relevance to this discussion as it is essentially concerned with usability and HCI issues. It was conceived in response to the realization that as mobile and embedded artefacts proliferate, demands for user attention would likewise increase, resulting in environments becoming inhabitable, or more likely, people just disabling the technologies in question. In the AmI concept, IUIs are envisaged as playing a key role in mediating between the embedded artefacts and surrounding users. However, AmI does not formally ratify the use of any particular AI technique. Choice of technique is at the discretion of the software designer whose selection will be influenced by a number of factors including the broad nature of the domain in question, the requirements of the user, the capability of the available technology and the implications for system performance and usability.

Having motivated the need for AI technologies in mobile contexts, practical issues pertaining to their deployment can now be examined.

STRATEGIES FOR HARNESSING AI TECHNIQUES IN MOBILE APPLICATIONS

It must be reiterated that AI techniques are computationally intensive. Thus, the practical issue of actually incorporating such techniques into mobile applications needs to be considered carefully. In particular, the implications for performance must be determined as this could easily have an adverse effect on usability. There are three broad approaches that can be adopted when incorporating AI into a mobile application and each is now considered.

Network-Based Approach

Practically all mobile devices are equipped with wireless modems allowing access to data services. In such circumstances, designers can adopt a kind of client/server architecture where the interface logic is hosted on the mobile devices and the core application logic deployed on a fixed server node. The advantage of such an approach is that the designer can adopt the most appropriate AI technologies for the application in question. However, the effect of network latency must be considered. If network latency is significant, the usability of the application will be adversely affected. Likewise, data rates supported by the network in question must be considered. Indeed, this situation is aggravated when it is considered that a number of networks implement a channel sharing system where the effective data rate at a given time is directly proportional to the number of subscribers currently sharing the channel. It is therefore impossible to guarantee an adequate quality of service (QoS) making the prediction of system performance difficult. Often, the worst case scenario must be assumed. This has particular implications where the AI application on the fixed server node needs either a significant amount of raw data or a stream of data to process.

One key disadvantage of placing the AI component on a fixed server node concerns the issue of cost. There is a surcharge for each KB of data transferred across the wireless network, and though additional revenue is always welcome, the very fact that the subscriber is paying will affect their perception of application in question and make them more demanding in their expectations.

A network–based AI approach is by far the most common and has been used in quite a number of applications. For example, neural networks have been used for profiling mobile users in conversational interfaces (Toney, Feinberg & Richmond, 2004). InCa (Kadous & Sammut, 2004) is a conversational agent that runs on a PDA but uses a fixed network infrastructure for speech recognition.

Distributed Approach

In this approach, the AI component of the service may be split between the mobile device and the fixed network node. The more computationally expensive elements of the service are hosted on the fixed network node while the less expensive elements may be deployed on the device. Performance is a key limitation of this approach as the computational capacity of the devices in question as well as the data-rates supported by the wireless network can all contribute to unsatisfactory performance. From a software engineering perspective, this approach is quite attractive as distributed AI (DAI) is a mature research discipline in its own right; and a practical implementation of DAI is the multi-agent system (MAS) paradigm.

One example of an application that uses a distributed approach is Gulliver's Genie (O'Grady & O'Hare, 2004). This is a tourist information guide for mobile tourists, realized as a suite of intelligent agents encompassing PDAs, wireless networks and fixed network servers. Agents on the mobile device are responsible for manipulating the user interface while a suite of agents on the fixed server collaborate to identify and recommend multimedia content that is appropriate to the tourist's context.

Embedded Approach

As devices grow in processing power, the possibility of embedding an AI based application on the actual physical device becomes ever more feasible. The key limitation is performance, which is a direct result of the available hardware. This effectively compromises the type of AI approach that can be usefully adopted. Overtime, it can be assumed that the capability and variety of AI techniques that can be deployed will increase as developments in mobile hardware continue and the demand for ever-more sophisticated applications increases. From an end-user viewpoint, a key advantage of the embedded approach concerns cost as the number of connections required is minimized.

One example of an application that uses the embedded approach is iDorm (Hagras et al., 2004), a prototype AmI environment. This environment actually demonstrates a variety of embedded agents including fixed motes, mobile robots and PDAs. These agents collaborate to learn and predict user behavior using fuzzy logic principles and, based on these models, the environment is adapted to the inhabitant's needs.

Deployment Considerations

Technically, all three approaches are viable, but the circumstances in which they may be adopted vary. For specialized applications, the networked AI approach is preferable as it offers greater flexibility and maximum performance, albeit at a cost. For general applications, the embedded approach is preferable, primarily due to cost limitations, but the techniques that can be adopted are limited. The distributed approach is essentially a compromise, incorporating the respective advantages and disadvantages of both the networked and embedded approach to various degrees. Ultimately, the nature of the application domain and the target user base will be the major determinants in what approach is adopted. However, in the longer term, it is the embedded approach that has the most potential as it eliminates the negative cumulative effect of network vagrancies, as well as hidden costs.

Thus, for the remainder of this chapter, we focus on the embedded approach and consider how this might be achieved.

So what AI techniques can be adopted, given the inherent limitations of mobile devices? Various techniques have been demonstrated in laboratory conditions but one paradigm has been demonstrated to be computationally tractable on mobile devices: intelligent agents. As well as forming the basis of mobile intelligent information's systems, a number of toolkits have been made available under open source licensing conditions thus allowing software engineers access to mature platforms at minimum cost. Before briefly considering some of these options, it is useful to reflect on the intelligent agent paradigm.

THE INTELLIGENT AGENT PARADIGM

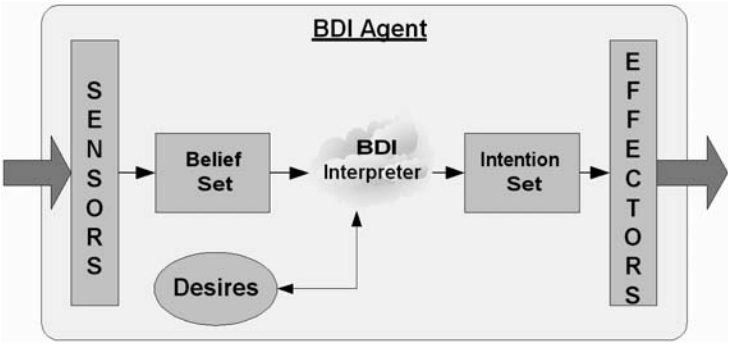
Research in intelligent agents has been ongoing since the 1970s. Unfortunately, the term agent has been interpreted in a number of ways thereby leading to some confusion over what the term actually means. More precisely, the characteristics that an arbitrary piece of software should possess before applying the term agent to it are debatable. In essence, an agent may be regarded as a computational entity that can act on behalf of an end-user, another agent or some other software artefact. Agents possess a number of attributes that distinguish them from other software entities. These include amongst others:

- **Autonomy:** The ability to act independently and without direct intervention from another entity, either human or software-related
- **Proactivity:** The ability to opportunistically initiate activities that further the objectives of the agent
- **Reactivity:** The ability to respond to events perceived in the agent's environment;
- **Mobility:** The ability to migrate to different nodes of a network as the need to fulfill its objectives dictates; and
- **Social ability:** The ability to communicate with other agents using a shared language and ontology leading to shared or collaborative efforts to achieve individual and shared objectives.

To what extent an agent possesses or utilizes each of those attributes is at the discretion of the designer. For clarity purposes, it is useful to consider agents as existing on a scale. At the lower end are so-called reactive agents. Such agents act in a stimulus-response manner, and a typical usage scenario might involve the agent monitoring for user interaction and reacting to it. Such agents are generally classified as weak agents (Wooldridge & Jennings, 1995). At the other end of the scale are so-called strong agents. Such agents maintain a sophisticated model of their environment, a list of goals or objectives, and plans detailing how to achieve these objectives. Such agents support rational reasoning in a collaborative context and are usually realized as multi-agent systems (MAS). This strong notion of agenthood is synonymous with the view maintained by the AI community.

One popular interpretation of the strong notion of agency is that of the belief-desire-intention (BDI) paradigm (Rao & Geogeff, 1995). This is an intuitive and computationally tractable interpretation of the strong agency stance. To summarize: beliefs represent what the agent knows about its environment. Note that the term environment can have diverse meanings here and may not just relate to the physical environment. Desires represent the objectives of the agent, and implicitly the raison d'être for the application. However, at any moment in time, an agent may be only capable of fulfilling some of its desires, if even that. These desires are then formulated as intentions and the agent proceeds to fulfill these intentions. The cycle of

Figure 2. Architecture of a BDI agent



updating its model of the environment, identifying desires that can be fulfilled, and realizing these intentions is then repeated for the duration of the agent's lifecycle (Figure 2).

When should agents be considered for realizing a software solution? Opinion on this is varied. If the solution can be modeled as a series of dynamic interacting components, then agents may well offer a viable solution. However, many see agents as being particular useful in situations that are inherently complex and dynamic as their native capabilities equip them for handling the myriad of situations that may arise. Naturally, there are many situations that fulfill the criteria but, for the purposes of this discussion, it can be easily seen that the mobile computing domain offers significant opportunities for harvesting the characteristics of intelligent agents.

Intelligent Agents for Mobile Computing

As the capability of mobile devices grew, researchers in the intelligent agent community became aware of the feasibility of deploying agents on such devices, and perceived mobile computing as a potentially fertile area for the intelligent agent paradigm. A common approach was to extend the functionality of existing and well-documented MAS environments such that they could operate on mobile devices. It was not necessary to port the entire environment on to the device; it was just necessary to develop an optimized runtime engine for interpreting the agent logic. In this way, the MAS ethos is persevered and such an approach subscribes to the distributed AI approach alluded to previously. A further benefit was that existing agent-oriented software engineering (AOSE) methodologies could be used. In the case of testing, various toolkits have been released by the telecommunications manufacturers that facilitate the testing of mobile applications. A prudent approach is of course to test the application at various stages during its development on actual physical devices, as this will give a more accurate indication of performance, the look and feel (L&F) of the application and so on. For a perspective on deploying agents on mobile devices, the interested reader should consult Carabelea and Boissier (2003).

While a number of environments may be found in the literature for running agents on mo-

bile devices, the following toolkits form a useful basis for initial consideration:

1. **LEAP (Lightweight Extensible Agent Platform)** (Bergenti, Poggi, Burg, et al., 2001) is an extension of the well-documented JADE platform (Bellifemine, Caire, Poggi et al., 2003). It is FIPA (http://www.fipa.org/) compliant and capable of operating on both mobile and fixed devices.
2. **MicroFIPA-OS** (Laukkanen, Tarkoma & Leinonen, 2001) is a minimized footprint of the FIPA-OS agent toolkit (Tarkoma & Laukkanen, 2002). The original FIPA-OS was designed for PCs and incorporated a number of features that did not scale down to mobile devices. Hence, MicroFIPA-OS minimizes object creation, reduces computational overhead and optimizes the use of threads and other resource pools.
3. **AFME (Agent Factory Micro Edition)** (Muldoon, O'Hare, Collier & O'Grady, 2006) is derived from Agent Factory (Collier, O'Hare, Lowen, & Rooney, 2003), a framework for the fabrication and deployment of agents that broadly conform to the BDI agent model. It has been specifically designed for operation on cellular phones and such categories of devices.
4. **JACK** is, in contrast to the three previous frameworks, a commercial product from the Agent Oriented Software Group (http://www.agent-software.com). It comes with a sophisticated development environment, and like AFME, conforms to the BDI agent model.

A detailed description of the each of these systems is beyond the scope of this discussion. However, the interested reader is referred to (O'Hare, O'Grady, Muldoon & Bradley, 2006) for a more advanced treatment of the toolkits and other associated issues.

FUTURE TRENDS

As mobile devices proliferate, and each generation surpasses its predecessor in terms of raw computational capacity and supported features, the potential for incorporating additional AI techniques will increase. In a similar vein, new niche and specialized markets for mobile services will appear. If a more holistic approach is taken towards mobile computing, it can be seen that developments in sensor technologies, fundamental to the ubiquitous and pervasive vision, will follow a similar trajectory. Indeed, the possibility of deploying intelligent agents on sensors is being actively investigated in widespread expectation that the next generation of sensors will incorporate processors of a similar capability to the current range of PDAs. Such a development is essential if the AmI vision to reach fruition.

As the possibility of incorporation of ever more sophisticated AI techniques increases, the potential for extending and refining the adaptability and IUI constructs for the support of mobile users increase. Indeed, adaptability may reach its fulfillment through the incorporation of autonomic computing precepts (Kephart & Chess, 2003). Self-configuring, self-healing, self-optimizing and self-protecting are the key attributes of an autonomic system, and it can be seen that incorporation of AI techniques may make the realization of these characteristics more attainable.

Finally, the practical issues of engineering mobile AI solutions must be considered. Mobile computing poses significant challenges to the traditional software engineering process, and the broad issue of how best to design for mobile services still needs to be resolved. The situation is exacerbated when AI technologies are included. However, it may be envisaged that as experience and knowledge of the mobile computing domain deepens and matures, new methodologies and best practice principles will emerge.

CONCLUSION

Mobile computing scenarios are diverse and numerous, and give rise to numerous challenges that must be overcome if the end-user experience is to be a satisfactory one. IUIs offers one viable approach that software designers can adopt in their efforts to make their systems more usable in what is frequently a hostile environment. However, the pragmatic issue of realizing mobile applications that incorporate intelligent techniques is of critical importance and gives rise to significant technical and design obstacles.

In this chapter, the broad issue of realizing an intelligent solution was examined in some detail. At present, the intelligent agent paradigm offers an increasingly viable proposition for those designers who wish to include intelligent techniques in their designs. To illustrate the issues involved, the intelligent agent paradigm was discussed in some detail.

As mobile developments continue unabated, the demand for increasingly sophisticated applications and services will likewise increase. Meeting this demand will pose new challenges for software and HCI professionals. A prudent and selective adoption of intelligent techniques may well offer a practical approach to the effective realization of a new generation of mobile services.

KEY TERMS

Ambient Intelligence: (AmI) was conceived by the Information Society Technologies Advisory Group (ISTAG) as a means of facilitating intuitive interaction between people and ubiquitous

computing environments. A key enabler of the AmI concept is the intelligent user interface.

BDI Architecture: The Belief-Desire-Intention (BDI) architecture is an example of a sophisticated reasoning model based on mental constructs that can be used by intelligent agents. It is allows the modeling of agents behaviors in an intuitive manner that complements the human intellect.

Context: Context-aware computing considers various pertinent aspects of the end-user's situation when delivering a service. These aspects, or contextual elements, are determined during invocation of the service and may include user profile, for example language, age, and so on. Spatial contextual elements, namely location and orientation, may also be considered.

Intelligent Agent: Agents are software entities that encapsulate a number of attributes including autonomy, mobility, sociability, reactivity and proactivity amongst others. Agents may be reactive, deliberative or hybrid. Implicit in the agent construct is the requirement for a sophisticated reasoning ability, a classic example being agents modeled on the BDI architecture.

Intelligent User Interface: Harnesses various techniques from artificial intelligence to adapt and configure the interface to an application such that the end-user's experience is more satisfactory.

Mobile Computing: A computer usage paradigm where end-users access applications and services in diverse scenarios, while mobile. Mobile telephony is a popular realization of this paradigm, but wearable computing and telematic applications could also be considered as realistic interpretations of mobile computing.

Multi-Agent System: A suite of intelligent agents, seeking to solve some problem beyond their individual capabilities, come together to form a multi-agent system (MAS). These agents collaborate to fulfill individual and shared objectives.

Ubiquitous Computing: Conceived in the early 1990s, ubiquitous computing envisages a world of embedded devices, where computing artefacts are embedded in the physical environment and accessed in a transparent manner.

Chapter 8.17
mCity:
User Focused Development of Mobile Services Within the City of Stockholm

Anette Hallin
Royal Institute of Technology (KTH), Sweden

Kristina Lundevall
The City of Stockholm, Sweden

ABSTRACT

This chapter presents the mCity Project, a project owned by the City of Stockholm, aiming at creating user-friendly mobile services in collaboration with businesses. Starting from the end-users' perspective, mCity focuses on how to satisfy existing needs in the community, initiating test pilots within a wide range of areas, from health care and education, to tourism and business. The lesson learned is that user focus creates involvement among end users and leads to the development of sustainable systems that are actually used after they have been implemented. This is naturally vital input not only to municipalities and governments but also for the IT/telecom industry at large. Using the knowledge from mCity, the authors suggest a new, broader definition of "m-government" which focuses on mobile people rather than mobile technology.

INTRODUCTION

All over the world, ICT technologies are used to an increasing extent within the public sector. For cities, ICTs not only provide the possibilities of improving the efficiency among its employees and its service towards tourists, citizens, and companies; it is also an important factor in the development of the city and its region, as ICTs today generally are considered to constitute the driving force of economy and social change (Castells, 1997). It is also argued that ICTs can improve efficiency, enhance transparency, control, networking and innovation (Winden, 2003). Thus, several cities are involved in projects concerning the development, testing, and implementation of ICTs. A few examples include Crossroads Copenhagen in Denmark, Testbed Botnia, and TelecomCity from the cities of Luleå and Karlskrona in

Sweden. Within all these projects, triple-helix like organizations are used involving the local municipality or national government, the local university, and the locally-based companies (Jazic & Lundevall, 2003)

Also within the City of Stockholm, there is such a project—the mCity Project. This was launched by the City of Stockholm in January of 2002, with the aim of organizing "the mobile city" through the implementation of relevant ICTs. The mCity Project consists of several small pilot projects, focusing on identifying needs in the community and creating solutions to these. In this chapter, we intend to describe this project, its organization, work processes, and the results. We also discuss the experiences made and how the project can serve as an inspiration towards a broader understanding of "m-government".

BRIEFLY ABOUT THE CITY OF STOCKHOLM

The City of Stockholm is Sweden's largest municipality with about 760,000 inhabitants,[1] but is, compared to other capitals in the world, a small city. Due to the Swedish form of government, Stockholm—as well as all other Swedish cities—has large responsibilities, including child care, primary and secondary education, care of the elderly, fire-fighting, city planning, and maintenance, and so forth. All these responsibilities are financed through income taxes, at levels set by the cities themselves, with no national interference. The operational responsibility lies, in the case of Stockholm, on 18 district councils and on 16 special administrations, depending on the issue. Through 15 different fully-owned or majority-interest, joint-stock and associated companies (hereafter called "municipal companies"), the City of Stockholm also provides water, optical fibre-infrastructure, housing (the City of Stockholm has the largest housing corporation in the country), shipping-facilities (the ports in the Stockholm area), parking, tourist information, the city theatre, the Globe Arena (for sports, concerts and other events) etc. In total, the city has an organization comprising 50,000 employees, and a yearly turn over of 31.5 billion SEK,[2] which is equivalent to about 5 million USD. For the City of Stockholm, it is only natural to engage in ICT projects of different kinds, as this could be expected to have both financial and pedagogical benefits within this large organization—just as it had for other public organizations in Sweden (Grenblad, 2003).

In fact, ICT projects are encouraged by the City of Stockholm through the Stockholm "E-Strategy". This is a visionary and strategic document, issued by the City Council[3] in the beginning of 2001 which—among other things—firmly states the role of the citizen as the central figure for all activities in the city organization; the development of mobile technologies to enhance flexibility, as well as the importance of the city acting to aid Swedish ICT industry (*The City of Stockholm's E-Strategy, 19th of February 2001*). It is the City Executive Board[4] which is responsible for implementing the resolution of the City Council, but the "E-Strategy" document also points to the responsibility of the management of the different district councils, special administrations, and municipal companies for the strategic development of ICTs within each organization. The document also describes the function of "the IT Council", which is to ensure that the e-strategy is implemented in a good way within the municipal organization, that is, not as a separate strategy, but in close contact with the activities for which the organizations are responsible.

BACKGROUND, ORGANIZATION, AND GOALS

The idea of mCity was born in 2000 when the former EU Commissioner Martin Bangeman suggested a cooperation between European cities

in order to stimulate the use of the upcoming 3G network and its services. In January 2001, a workshop was held with representatives from a number of major cities, telecom operators, vendors, and investors. A project proposal was submitted by Bangeman, suggesting that a few other European cities—Stockholm, Bremen, and Berlin among others—should start a holding corporation in order to develop and sell 3G services. However, this collaboration project did not become a reality. Instead, the City of Stockholm decided to proceed with a smaller scale project—mCity.

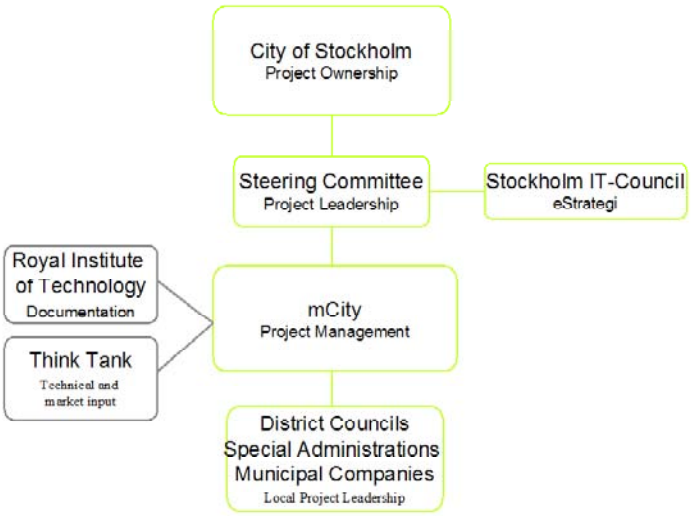
The following goals have been specified for the mCity Project in Stockholm:

- **To improve the working environment for the employees of the City of Stockholm.** By putting people in the center and letting them lead the development of mobile services, they will help develop services that will ease their own work tasks and their everyday lives.
- **To increase the quality of services for citizens.** The mCity Project strives to improve the service of the city to its citizens and visitors by improving the work environment for employees and by introducing citizen-specific solutions.
- **To stimulate the regional business (IT/Telecom).** By developing new solutions in collaboration with industry, new opportunities for the ICT industry within Stockholm, and throughout Sweden are developed, thereby creating a strong home market for companies in Stockholm.
- **To reinforce Stockholm's profile as an IT capital.** By developing new and useful mobile services, Stockholm's reputation as a leading IT capital will be further reinforced.
- **To spread the good example.** By working with small-scale test environments and small-scale tests, the results can be duplicated if successful. By involving the end users closely in the project, sustainability is ensured. An effect of more deeply involved users is that the users themselves become spokespersons for the services and actually help spread the word.

During its first year, the project was located in one of Stockholm's district councils, which meant close contact with the end users. The project manager felt, however, that in order to keep up with the ICT development in other parts of the city, the project would be better off if it could be located more centrally in the organization. Since then, the project has been moved closer to the central administrative organization in the city.

The project organization of mCity is described in Figure 1. The Steering Committee, organized with representatives from different parts of the city, for example the IT Department and the City of Stockholm Executive Office,[5] make strategic decisions about budget issues, what projects to initiate, and so forth. Different heads have chaired the Steering Committee during the course of the project. There are also members from the Stockholm IT Council in the Steering Committee, to ensure that the mCity Project follows Stockholm's E-Strategy. The different pilot projects are initiated together with district councils, special administrations, or municipal companies which undertake the responsibility of local project management in each case. The mCity Project Manager is in charge of initiating and setting up the local projects in collaboration with the local project management and then keeps track of the day-to-day development of the projects. He/She is also responsible for collecting and spreading information about the projects, and for preparing the meetings with the Steering Committee as well as implementing the decisions of the Steering Committee. In their work, he/she can also use the Think Tank, to which a number of companies within the mobile technology industry belong, to ask for advice concerning technology or market requirements/development. Finally, a researcher

Figure 1. Organization of the mCity Project



from KTH, the Royal Institute of Technology, has been responsible for documenting the project.

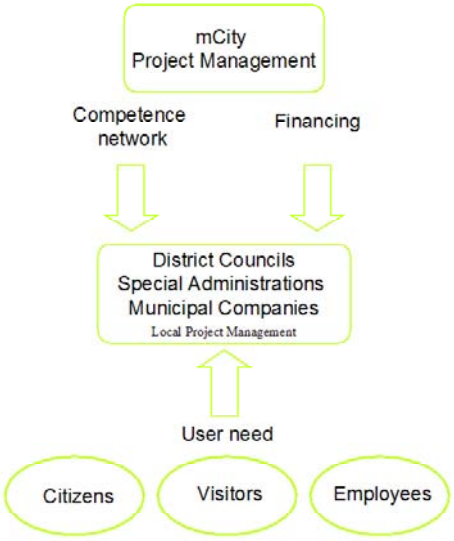
WORKING PROCESS

Within the mCity Project, services for both private and public sectors are tested and thereafter developed in a larger scale if proven relevant. The services are operated and tested in "small islands" because it makes it easier to get close to the users and to change the tested services if something needs to be improved. Using this model, mCity has been able to connect groups with specific needs with companies developing mobile services that can satisfy these needs.

End-user needs, that is, the needs of citizens, visitors and employees within the City of Stockholm, form the starting point of every initiative within mCity—see Figure 2. One way of creating situations where users can make their voices heard is by initiating hearings, focus groups, interviews, and so forth. In some cases, the mCity Project Manager has been involved in this first part of the process; in other cases, the local management of the different district councils, special administrations, or municipal companies take the initiative of formulating an application, specifying the need. The exact details of the working process have shifted, depending on the organizational setting of the project.

In the next step, the mCity Project management uses their Competence Network to form a group with technical expertise to which the user's need is presented. The group ponders about the possible technical solutions suitable to solve the problems and in this process, the end-users' knowledge of ICTs, their workload, and the financial/technical situation of the user environment are also taken into account. Depending on the situation, mCity can also contribute financially to the pilot project.

Figure 2. Working process within mCity



Through mCity, the hope is to accomplish a better every day life for end users. Therefore, the benefits of the services developed in relation to the concrete needs of users, are of high interest and hopefully, it is also possible to measure the added value. End solutions should be easy to use—it should be almost intuitive to understand how to use the provided service. This is one reason for why simple technology is mostly used in mCity Projects—technology is seldom the problem, the focus is rather on what to introduce and how to introduce it. To summarize, the working process can be described in three keywords:

- user-oriented
- benefit-driven
- simple

It should be pointed out that mCity primarily does small-scale pilot projects; when these have been launched, it is the responsibility of the district councils, the special administrations, or the municipal companies involved to decide whether to keep running the project, to enlarge it, and also to take the full operational and financial responsibility for the future project.

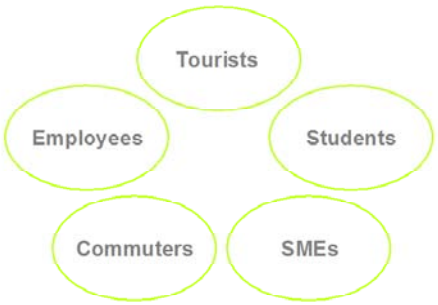
PILOT PROJECTS

mCity has started and financed several pilot projects since its launch in 2002. Different user groups are in need of different services and the largest segments identified are people who work, live in, and visit the City of Stockholm, as shown earlier in Figure 2. Through the pilot projects, these segments have been further specified, as described in Figure 3: tourists, students, SMEs, commuters, and city employees.

Tourists

The very first project within mCity was carried out in 2002 for tourists, when the official event database owned by Stockholm Visitors' Board[6] was made available via mobile Internet. The city wanted to do this in relation to its 750th anniversary which was to be celebrated that year, and it was decided that something new should be tested, which is why WAP was chosen.

Figure 3. Focus groups of the mCity Project



A few years later in 2004, another service targeting tourists was developed by mCity. This time the development process was conducted by a group of talented students taking a project course at the Royal Institute of Technology. This project, *.tourism,* was initiated by the Art Council at the Cultural Administration in order to find new ways of making information about Stockholm available through new technology. The result, a Web site with information on statues, art objects, and buildings of interest is available via mobile or fixed Internet on the address, www.explore.stockholm.se. The server recognizes if the user is accessing the Web site from a PDA, a laptop, or a mobile phone. By using XML functionality, separate interfaces for the different devices are shown, giving the user the best experience possible depending on the device used.

On the Web site, it is possible to search by the name of an object, a location, or a street. It is also possible to list all attractions within a city district. One can also make a guided tour through the Web site, and making this accessible for others to benefit from. Naturally, the personal tours have to be authorized by an administrator in order to filter non-ethic information.

Students

mStudent is a joint project venture between the Federation of Student Unions in Stockholm (SSCO), the Stockholm Academic Forum, and the City of Stockholm within the framework of mCity. The objective is to develop mobile services which are useful to 80,000 students in the Stockholm region. For example, if students can receive an SMS telling them that a lecture has been cancelled, they might not have to come to the university campus at all that day, saving time to be better used for studies or other activities.

During the spring of 2003, 28 students from eight different universities and university-colleges in the Stockholm region participated in a feasibility study to identify a number of services interesting to students. This first phase of the project was carried out together with Telia,[7] Ericsson, and Föreningssparbanken.[8] The objective was to identify mobile services that would be useful to students in their everyday life. In order to really use the most of the students' innovative minds, they were all given one of Ericsson's most modern mobile phones and were allowed to use them without limitations. This made them experts on the available services and also good judges on new services.

Today, mStudent initiates and administrates different forms of tests and evaluations of mobile services in cooperation with businesses in Stockholm. The purpose is to encourage companies and universities to develop and use improved mobile services and thereby increase the quality of service to students as a group. The activities carried out are based on the list of mobile services that the students identified as interesting in the first phase; but apart from this, mStudent has also become a testbed which tests and evaluates all types of mobile services that can be useful for students. The "test pilots" are all students from Stockholm's universities and university colleges, and mStudent gathers the students in focus groups for workshops, evaluations, and other activities. Some companies are already working together with student reference groups in order to gain feedback on their planned services.

SMEs

mCity has been involved in one project aiming toward higher use of mobile services among SMEs.[9] In one of the shopping malls in central Stockholm, Söderhallarna, the stores can use the Internet and mobile technology to communicate, both with customers and the mall administration. The choice of Söderhallarna was not a coincidence. The property is actually owned by the City of Stockholm, and it is of importance

to the mall administration to keep up with the technological development to be able to attract stores to the premises.

By working closely with the storeowners and the mall administration, mCity managed not only to improve the internal communication, but also to provide new ways of treating customer relations with the aid of mobile services. For instance, stores can now inform their customers of last-minute offers or arrivals of new products with SMS or e-mail. Also, customers can easier interact with some of the companies. One of the lunch providers receives the orders from their customers via SMS. This increases the probability of preparing the food on time when not having to take orders on the phone. The technology is also used by the Head of Marketing for the mall, in order to create VIP offers to customers, and to communicate with SME owners and other mall staff, such as janitors.

Commuters

Up-to-date traffic information, provided by the City of Stockholm and the Swedish Road Administration among others, is today available on the Internet site, www.trafiken.nu. The information can be reached via WAP and Internet, but more ways of accessing the information have been developed. To make traffic information available regardless of place or time is important since it brings the choice to commute at a given time to the commuter. The commuters can improve their itinerary and choice of transportation based on the information about the current traffic situation.

mCity is involved in several pilot projects within the traffic area all initiated with a pre-study to find out what kind of information commuters are interested in and would benefit from. In one project, mCity has financed the development of the use of dynamic voice to present information available on the Internet site. The synthetic voice starts reading the new information when a commuter calls a special telephone number available from both fixed and mobile telephones. In another project, commuters are able to subscribe to information on specific routes. The commuter submits information about specific time spans during which he/she is interested in knowing about traffic disturbances on a Web page. As soon as something happens on the route of interest on the specific time span, an SMS is sent out with this information.

Employees

mCity has initiated several SMS management systems within the municipal organizations of Stockholm. Even though the technology used often is the most basic one, the impact has been extensive. Three examples of SMS solutions developed within mCity are described in the following sub-sections.

Schools: Absence Management

A few compulsory and upper-secondary schools have been provided with an absence management system. By keying in their social security number and a four-digit code, pupils can report themselves absent into an automated solution provided by the school. The information is then automatically sent as an e-mail or an SMS to the teachers, thereby reducing administrative work. The flow of information between the school and the parents is also improved since parents may receive an SMS when the child skips class or when parents should remember to pack extra clothes for special extracurricular activities.

The Care Sector: Scheduling Services

Within the care sector, scheduling is a time-consuming effort. Now, staff can plan and book time slots through the Internet, and changes can be made by management through SMS. Positive

effects with the solution is that staff motivation has increased and the Head of Staff can now work with core activities as the administrative workload is reduced. This solution was tested together with the SMS solution described next.

The Care Sector: Substitute Management

Within the care sector, a group SMS service has been implemented to facilitate substitute management. Instead of trying to reach substitutes through regular phone calls, managers can send SMSs to groups of staff, saving several hours every time. This creates better opportunities for planning, resulting in less stress for care staff and great financial benefits for the City of Stockholm. Also, managers have discovered the possibilities of encouraging staff through group SMS; an occasional "Have a nice weekend!", or the like, is very much appreciated by the staff working in mobile care units, not seeing much of their colleagues and managers when spending much time out in the field.

This SMS system has been so successful that it has now been made available to all employees within the City of Stockholm to use and benefit from. An interesting fact is that as more people are getting the opportunity to use the system, new areas of use are discovered every day by the users themselves.

MCITY EXPERIENCES

Looking at the mCity Project, it is clear that by focusing on and involving users who traditionally are considered underdeveloped within the field of ICTs, mCity reduces the digital divide. Areas like education and the care sector present great potential for municipalities and ICT companies as large savings of time and money can be made when administrative tasks are simplified. Also, by focusing on the areas with largest potential, one can increase average levels of use and knowledge of ICTs in the organization, even if simple technology is used. Thus, even the use of SMS might be an important step toward the use of more advanced mobile services (Williamson & Öst, 2004).

By involving the end user early on, the development process becomes more time consuming. On the other hand, there seems to be a higher chance of successful development and implementation. The involvement of end users in the development of mobile services leads to the appreciation of the users who feel that their experiences are valuable and have real impact. It is important to note that the "end user" is the very person who will use the system in the end, not his or her supervisor or manager. Thus, in small-scale projects, it is often necessary to involve several levels of management, involving the ones who will use the system, the ones who can oversee work processes, as well as the ones who will pay for the system.

It is not always easy to involve people with limited skills and knowledge in technology in projects involving technology. Some people are also more skeptical of changes than others; they may have gone through several organizational changes within a short time span, or might not be interested in revising their working processes at all. This is especially obvious when implementing new technology. Thus, it is important to recognize that technological artefacts are as much social as technological objects, affecting people's way of life as time and space are changing (Brown, 2002; Glimell & Juhlin, 2001; Urry, 2000).

In order to involve the end users, the project must be presented in a way which makes it come across as a project which will lead to obvious changes for the better and not primarily as a technological project. "We're not necessarily positive to technology per se, but we are positive to all new projects and ideas that will improve our work", a manager involved in the SMS project for substitute management stated in an interview (Hallin, 2003).

The information generated through the process also provides the companies involved with valuable input on user behavior and preferences. To engage companies in an m-government project like mCity has been very rewarding for all parties, but even though the pilot projects have been too small to make it necessary to issue invitations to tender, a discussion about the delimitations of working together with the private sector in development projects has taken place within the Steering Committee. This discussion has been similar to the general discussion going on in Sweden, as several public institutions find that the Public Procurement Act makes innovation in the area of public e-services difficult (Grenblad, 2003). In Sweden, there are not many precedents concerning these kinds of simple and quick forms of cooperations between the private and the public sectors. Clear directives as to how and when companies should be involved are needed.

A final lesson from the mCity Project is that simple technology offers great possibilities. mCity has not per se been interested in testing new technology just for the sake of testing new technology; the effects should be real and readily measurable, as described previously. This said, new technological inventions may also be tested and used, as has been the case within the mStudent Project and within the early tourist project. The clue is to always have in mind who is going to use the service. Students are in the forefront when it comes to usage of technology, and tourists also tend to be open minded to use new technology when travelling. Administrators in elderly care or in the school sector might not be as mature in their use of ICTs.

The choice of technology is also often subjected to other types of limitations. When developing new systems based on new technology, you have to be able to answer a lot of questions. One is whether the service should be available for all or just for a small group of people. In the case of mCity, this has been a difficult aspect since all services are tested on a small scale, enlarged when proving relevant. In small-scale environments, technological integration is not really necessary, but when making a service available on a larger scale, it is. In the projects in elderly care and in school administration, this was clearly evident. When making the group SMS project a large-scale implementation, integration to several internal programs was necessary, such as the mail system and the identification portal. This was not impossible, but of course involved more work and thorough consideration.

In a municipality, it is also necessary to consider the cost of implementing new technology. The new services have to deliver lowered cost or some other kind of gain for the city; developing services just for fun or because they are high-tech at the moment is not good enough.

TOWARD A NEW DEFINITION OF M-GOVERNMENT

Is mCity an m-government project? Generally, "m-government" is defined as "a subset of e-government", involving the use of mobile/wireless applications in the public sector, making the public information and services available anytime, anywhere (Lallana, 2004). According to this definition, it could be questioned whether mCity is an m-government project, as there are pilot projects with other goals than the one stated earlier. The mStudent Project, for example, aims at improving the life for students in the Stockholm region by introducing new mobile services from different providers, and in the SME project, small- and middle-sized companies and their customers benefit from the mobile service introduced.

It is clear that the City of Stockholm through the mCity Project takes a broader grip on the task of providing people with the possibility of accessing public information and services, by also taking on a pedagogical role of encouraging people to use ICTs in different areas of city life, and by stimulating the ICT industry to develop

new applications as well as rethink old applications. In order to understand this approach we must establish the relationship between the mCity Project and the municipal and national ICT strategies as well as the project's relationship to the vision of Stockholm as an IT capital.

mCity in Relation to Municipal and National Strategy

As described previously, the Stockholm E-Strategy is the policy document according to which the ICT work in the city is done. On its very first page, the document points out that the globalization process inevitably will lead to a new Europe where Stockholm will face tougher competition from other European cities, and that in order to face these challenges, the use of ICTs is an important factor. "IT must help to make Stockholm more attractive by securing the city's long-term goals that Stockholm should continue to be a fine place to live and work in"(*The City of Stockholm's E-Strategy, 19th of February 2001*).

The "E-Strategy" of Stockholm is, on a municipal level, what the "24/7 Agency" is on the national level. The "24/7 Agency" was issued in 2000 by the Swedish government, aiming at extending the public sector's use of ICTs, making services available 24 hours a day, 7 days a week (*The 24/7 Delegation*). The vision entails all parts of the public sector—municipalities, county councils as well as central government—and is the Swedish government's way of trying to cope with expected demographic changes leading to a larger aging population which will demand more of a public administration with fewer employees. At the same time, citizens in general are expected to demand more value for money and a growing internationalization is thought to increase the competitive pressure on public bodies. The development of e-government in Sweden is a way of meeting these challenges (Lund) and the belief of the 24/7 Agency is that the Swedish administrative model, with independently managed central government agencies, is a factor for the success of rapid development of digital applications and e-services (Lundbergh, 2004).

Swedish authorities primarily call for the most appropriate services, not specific technologies. Thus, the name of "the 24/7 Agency" places focus on the time aspects of service-provision—public services should be provided around the clock—not on specific technologies. The question "how" is subordinated, as, "Accessibility, irrespective of time of day and geographical location, may be achieved through a range of established service channels" (Östberg, 2000). Also, the Stockholm E-Strategy is on purpose called the "E-Strategy", and not the "IT-policy", in order to shift "…focus from IT to activities and show [..] how enhanced integration of *electronic services* ('e-services') can develop the municipality's work" (*The City of Stockholm's E-Strategy, 19th of February 2001*). According to this, the E-Strategy does not prescribe certain technologies, but only points at different areas that the city should work with: Internet, information management, mobile technologies (in general), and so forth.

mCity and the Vision of Stockholm as an IT Capital

The mCity Project not only aims at developing technology which make the city available around the clock. It is also a project used to enhance the image of Stockholm as an IT capital; an image based for example on the fact that Ericsson and other major players within the ICT sector have their development offices within the area. According to the Stockholm E-Strategy, IT can play an important role in making Stockholm an attractive city for people to live and work in, and therefore, the city must take an active part in creating business opportunities for ICT companies. One of the goals stated in the E-Strategy is to, "Be one of the most attractive municipalities for relocation, start-up and running of businesses, in competition with the foremost European cit-

ies" (*The City of Stockholm's E-Strategy, 19th of February 2001,* p. 14).

Through the mCity Project, the city has given several ICT companies in the Stockholm area the opportunity to test ideas, develop new applications and market themselves in and outside the country—naturally, in compliance with the Public Procurement Act. This strife to encourage local development conveys an entrepreneurial stance which might be perceived as contrasting with the managerial practices of earlier decades which primarily focused on the local provision of services, facilities, and benefits to the population (Harvey, 1989). However, when cities find themselves competing on a global—not only on a national—arena, a new kind of city management develops, involving proactive management of the images of the city as a management tool. Today, city managers are not only active administrators of the traditional areas of responsibility (Czarniawska, 2000) and the "branding" of the city involves much more than producing colorful brochures (Ward, 1998).

mCity and M-Government

As described earlier, the mCity Project aims at creating "the mobile city", as this is thought to be a good place for people to live, work, and spend their holidays in, since mobility means flexibility. But this does not necessarily mean that the project only deals with the development of mobile technologies, which makes information and services of the City of Stockholm available. "Mobile" here does not refer to the technology, but to the people using it, and "the mobile city" is the city where people have the flexibility to do what they want, where and when they choose. The mobile city can be achieved by the city becoming a role model, using mobile technology for its own activities, for example in schools, in homes for the elderly, or through mobile services which give commuters information about traffic, but also by stimulating the use of mobile technology in general, for example by encouraging students in the Stockholm area to ask for and use mobile services.

It is also obvious, that for mCity, the traditional m-government definition is not sufficient, as the city itself is not limited to its municipal organization. As we have showed earlier, the projects within mCity involve cooperation with both national institutions (for example, within the traffic projects), regional institutions (for example, within the mStudent Project) as well as private companies. Thus, rather than focusing on technology or the municipal organization, mCity focuses on people, and to see this project as an m-government project is to broaden the definition of m-goverment from only encompassing the use of mobile/wireless applications in the public sector, making the public information and services available anytime, anywhere. And rather than having the municipal organization as the starting point for its activities, the city, as it is perceived by its citizens, visitors, and employees, is the unit from where the project takes off. Thus, we suggest a new definition of m-government:

A public body which supports the mobility of its people, by providing its services when and where the people need them, and by supporting the development of whatever wireless technologies are needed, and the education of people in these.

THE FUTURE OF M-CITIES

It has been argued that the organizing capacity of a city determines whether the city will be able to develop in a sustainable way, and that the ability to include ICTs is becoming a more important aspect of the organizing capacity of cities (Winden, 2003). This, we believe is true.

Once a small, local initiative, mCity has grown into a project which covers many application areas. Through the project, it has become clear that mobile services can help Stockholm simplify routines, minimize administration, save both time

and money, and make life a bit easier for people thus contributing to a better working and living environment by improving the service quality offered by the city. These results further strengthen the notion that the building of m-government is important, probably not only for cities, but for all public bodies. But in order to be successful, a people's perspective has to be adopted and the traditional borders of the public body might have to be challenged. To start with people rather than with technology or with the organization, is an important prerequisite for success.

Chapter 8.18
Mobile Speech Recognition

Dirk Schnelle
Technische Universität Darmstadt, Germany

ABSTRACT

This chapter gives an overview of the main architectures for enabling speech recognition on embedded devices. Starting with a short overview of speech recognition, an overview of the main challenges for the use on embedded devices is given. Each of the architectures has its own characteristic problems and features. This chapter gives a solid basis for the selection of an architecture that is most appropriate for the current business case in enterprise applications.

OVERVIEW

Voice-based interaction is a common requirement for ubiquitous computing (UC). However, the idea of having speech recognition on wearable devices is not simply copying the recognizer to such a device and running it. The limitations of the device, especially computational power and memory, pose strong limitations that cannot be handled by desktop size speech recognizers. This chapter gives a brief overview of the different architectures employed to support speech recognition on wearable devices. A background in speech recognition technology is helpful in order to understand them better, but is not required. At some points you will be provided with pointers to the literature to achieve a better understanding. A detailed understanding of the available architectures is needed to select the appropriate architecture for the enterprise, if it wants to support audio-based applications for mobile workers. The selection process has to consider the available resources, such as servers, wireless network, the software that has already been bought in order to save the investment, and to be able to justify the decision to invest more money in required infrastructure.

Most of the figures use UML 2.0 as a means of communicating architectural descriptions. The diagrams are easy to read, even if the reader is not familiar with this modeling language. The UML specification can be obtained from the Object Management Group (OMG, 2006).

A speech recognizer has the task of transcribing spoken language into a text (see Figure 1). The input is the *speech signal,* the human voice

that is recorded, for example, with a microphone. The textual output, in this case "*one two three*," is called an *utterance*.

The architecture of a speech recognizer has not changed over the past decades. It is illustrated in Figure 2 based on Jelinek (2001).

It comprises the main components of recognizers as they are used today, regardless of the technology used. They are available as pure software solutions or implemented in hardware to gain speed. In the following sections we focus only on the main components involved. Some recognizers may use additional components or components that are slightly different. However, the architectures presented show the main functionalities of each of them and discuss the main challenges that have to be faced when applied to mobile devices.

The *signal processor* generates real valued vectors σ_i from a speech signal, obtained from a microphone. They are also called feature vectors. Currently, most speech recognizers use at least 13

Figure 1. Speech recognition

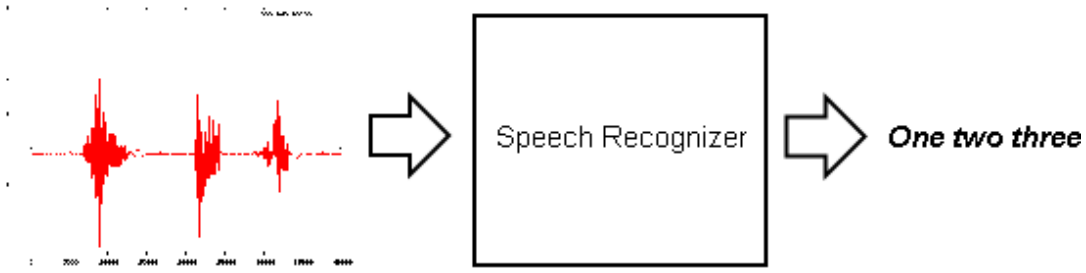

Figure 2. General architecture of a speech recognizer

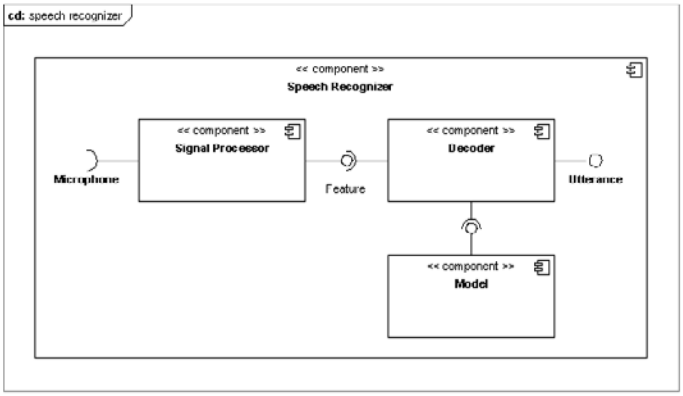


features in each vector. We will have a closer look at them in the section "Evaluation of Sphinx 3.5." Normally computation of the features happens at regular intervals, that is, every 10msec., where the feature vectors are passed to the *decoder* to convert it into the utterance. The *decoder* uses the *model* for decoding. In the simplest case, the *model* contains a set of prototypes ρ_i, which are of the same kind as σ_i. Then, the *decoder* finds the ρ_i closest to σ_i for a given distance function *d*

$$a_i = \min_{j=1}^{k} d(\sigma_i, \rho_j) \quad (1)$$

a_i is the acoustic symbol for σ_i, which is emitted to the rest of the recognizer for further processing.

For **word-based speech recognizers** these acoustic symbols are the single words. For the example shown in Figure 1, this would be the concatenation of $\{a_1$=*one*, a_2=*two*, a_3=*three*$\}$.

A **phoneme-based speech recognizer** would output a concatenation of phonemes for each word. Phonemes are small sound units. The word *this* comprises the following phonemes $\{a_2$=*TH*, a_2=*I*, a_2=*is*, a_2=*S*$\}$. Obviously this output requires some post processing to obtain an output comparable to word-based recognizers that can be used by an application.

The benefit of phoneme-based speech recognizers is that they are generally more accurate, since they reduce the decoding problem to small sound units, and that they are more flexible and can handle a larger vocabulary more easily. Remember the first attempts in writing, starting from symbols for each word over symbols for each syllable to the letters that we find today.

This chapter is organized as follows: the section "Speech Recognition on Embedded Devices" gives an overview about the limitations of embedded devices to address speech recognition functionality. Then the two main architectures to work around these limitations are presented, which will be discussed in the two following sections in more detail. The section "Parameters of Speech Recognizers in UC" names some aspects that are needed to rate the solutions presented in the section "Service Dependent Speech Recognition" and the section "Device Inherent Speech Recognition." The section "Future research directions" concludes this chapter with a summary and an overview of the required computational resources on the device and the server for the architectures discussed.

SPEECH RECOGNITION ON EMBEDDED DEVICES

Speech recognition is computationally expensive. Advances in computing power made speech recognition possible on off-the-shelf desktop PCs beginning in the early 1990s. Mobile devices do not have that computing power and speech recognizers do not run in real time. There are even more limitations, which will be discussed later in this section. Moore's law states that memory size and computational performance increase by a factor of two every 18 months.

Frostad (2003) writes:

"Most of what is written on speech is focused on server based speech processing. But there is another speech technology out there that's powerful enough to sit on a stamp-sized microchip. It's called "embedded speech." Advances in computing power gave server side speech the power boost it needed in the early 90s. Now that same rocket fuel is launching embedded speech into the limelight."

Although computing power is increasing on these smaller computers, making it possible to run a small recognizer, performance is still not efficient enough to enable speech recognizers off-the-shelf on such devices. The attempt to use speech recognition on a mobile device, such as a computer of PDA size or a mobile phone, encounters the same problems that were faced

on desktop PCs years ago and which have been solved by the growth of computing power. The following section gives an overview of these limitations.

Limitations of Embedded Devices

The development of all applications, especially speech recognition applications for embedded devices has to tackle several problems, which arise as a result of the computational limitations and hardware resources on the device. These limitations are:

- **Memory:** Storage Capacity on embedded devices, such as a PDA or a cell phone, is very limited. This makes it impossible to have large *models.*
- **Computational Power:** Although the computational power of embedded devices has grown continuously over the last few years, it is still far from that what is available on desktop size PCs. The *signal processor* and the *decoder* perform computationally intense tasks.
- **Power Consumption:** Battery lifetime is a scarce resource on embedded devices. The device will stop working if the battery is empty. Since speech recognition is computationally intensive, processing consumes a lot of energy.
- **Floating Point:** Most processors for PDAs, like the Strong ARM or XScale processor, do not support floating-point arithmetic. It has to be emulated by fixed-point arithmetic, which is much slower than direct support. The value vectors σ_i are real valued and most state-of-the-art recognizers work with statistical methods. Thus, support of floating point arithmetic is essential and emulation results in loss of speed. Moreover, this may lead to a loss of precision. Especially signal processing is a critical task, since the quality of the output has a direct impact on the preserved information. Jelinek (2001) states that "Bad processing means loss of information: There is less of it to extract."

In the following the approaches to work around these limitations will be discussed. A short overview of the technology used is given to understand how they cope with the challenges of embedded devices.

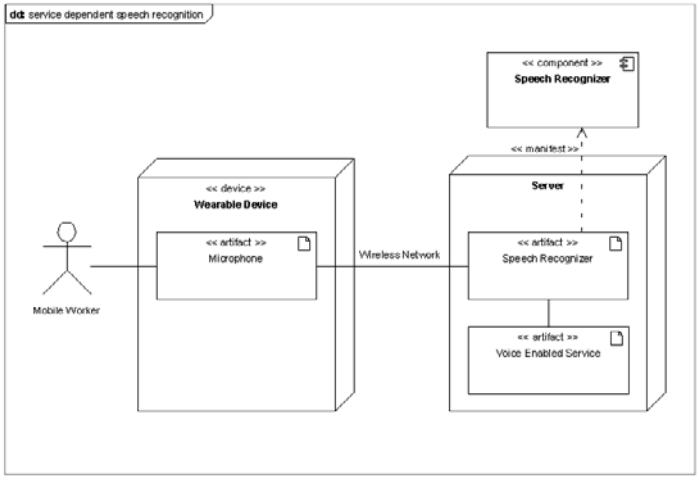
Main Architectures for Speech Recognition on Embedded Devices

Progress in speech recognition has made it possible to have it on embedded devices. Cohen (2004) states that, "Although we did not know in the 1990s all of the tricks we know today, we can use 1990s-like computing resources … to good advantage to compute a task which would have been difficult in 1990, but is simpler today because of our technical advancements." However, the limitations of mobile devices that were mentioned in the previous section still pose a lot of challenges. There have been several attempts to deal with them and enable speech recognition on embedded devices. An overview of these approaches is given in the following sections. We concentrate on the most common approaches that can be divided into two main categories:

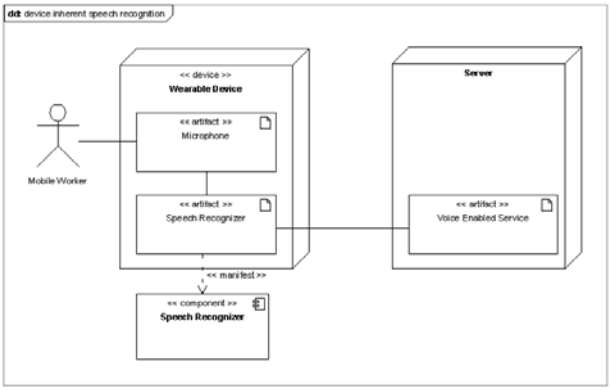
- Service dependent speech recognition, Figure 3(a)
- Device inherent speech recognition, Figure 3(b)

The main difference between these two architectures is the node where the *speech recognizer* component is deployed. Architectures for service dependent speech recognition will be introduced in the section "Service Dependent Speech Recognition" and those for device inherent speech recognition in the section "Device Inherent Speech Recognition."

Figure 3. Deployment of voice enabled service usage with mobile devices



(a) Service dependent speech recognition



(b) Device inherent speech recognition

Zaykovskiy (2006) proposed another categorization. He distinguishes:

- Client,
- Client-server, and
- Server-based architectures.

The main reason for his differentiation is the location of the *signal Processor* and the *decoder.* In the service-oriented view of ubiquitous computing it makes more sense to emphasize the ability to have speech recognition as a network service or as an independent functionality of the

device itself. This is a fundamental fact in smart environments, where services can be inaccessible while the user is on the move. Bailey (2004) requires that "there need to be clear boundaries between the functionality of the device, and the functionality of the network." The technological orientation of these approaches confirms this differentiation. Whereas service dependent speech recognition deal with APIs for remote access to a speech recognizer, device inherent speech recognition uses the techniques of desktop size speech recognition technology to enable speech recognition on the device itself.

Parameters of Speech Recognizers in UC

In order to rate the different architectures, we need an understanding of the core parameters. This section will give a short overview of these parameters.

- **Speaking Mode:** Word boundaries are not easy to detect. The presence of pauses is not enough, since they may not be present. Early speech recognizers forced the user to pause after each word. This is called *isolated word* recognition. If there are no such constraints, the speech recognizer is able to process *continuous speech.*
- **Speaking Style:** This parameter states if a speech recognizer for continuous speech is able to process *read speech*, meaning a very precise and clear pronunciation, or if it is capable of processing *spontaneous speech*, as used when we talk to each other.
- **Enrollment:** Some speech recognizers require an initial training before they can be used. This training is used to adapt to the speaker in order to achieve higher accuracy. These recognizers are called *speaker dependent.* This concept is often used on desktop PCs, but is also possible in UC, where the device is personalized. The opposite case is *speaker independent* speech recognizers that are trained to work with multiple speakers. Thus they have a lower accuracy. This concept is used, for example, in telephony applications. There are only a few scenarios that really require speaker independence with embedded devices. For these applications, speaker-independent systems do not have an advantage over speaker-dependent systems, but can benefit from a better accuracy.
- **Vocabulary:** The size of the vocabulary is one of the most important factors, since this strongly influences the way in which users can interact with the application. A vocabulary is said to be *small* if it contains up to 20 words. A *large* vocabulary may contain over 20,000 words.
- **Perplexity:** Perplexity defines the number of words that can follow a word. This is an important factor if the recognizer has to decode an utterance consisting of multiple words and tries to find the path with the lowest error rate.
- **SNR:** SNR is the acronym of **s**ignal-to-**n**oise-**r**atio. It is defined as the ratio of a given transmitted signal to the background noise of the transmission medium. This typically happens where the microphone also captures some noise from the background, which does not belong to the signal to decode.
- **Transducer:** A transducer is the device that converts the speech into a digital representation. For speech recognition this may be, for instance, a noise-cancelling headset or telephone. Each of them features different characteristics, such as the available bandwidth of the voice data or the ability to cut background noise as with a noise cancelling headset. In UC environments noise-cancelling headsets are typically used.

In a UC world there are some additional parameters depending on the location, where

recognition takes place. These parameters, as presented in Bailey (2004) are:

- **Network Dependency:** One major aspect is the dependency on a network resource. A recognizer located on the device will not need any network to be operated, while a recognizer streaming raw audio data to a server (see the section "Audio Streaming") will not work without a network. Apart from the technical aspect, the user expects the device to work and may not be able to distinguish between a non-functional recognizer and missing network connectivity if the device is "broken."
- **Network Bandwidth:** Available network bandwidth is a scarce resource. Architectures performing recognition on the device have a more compact representation of the data that has to be transmitted than those architectures streaming pure audio data.
- **Transmission Degradation:** With the need to transmit data from the mobile device to a server, the problem of transmission degradation arises. Failures, loss of packets or corrupted packets while transmitting the data means a loss of information. If the raw audio is transmitted to a server, recognition accuracy goes down.
- **Server Load:** In a multi-user scenario it is important that the application scales with an increasing number of users.
- **Integration and Maintenance:** Embedded devices are hard to maintain, especially if parts of the functionality are implemented in hardware. A server, on the other hand, is easy to access and bug fixes are available for all clients at once. This issue goes in a similar direction to the discussion of centralized server architectures versus rich clients.
- **Responsiveness:** A must for speech recognition is that the result is available in real time. This means that the result of the recognition process must be available as fast as possible.

In the following sections the different architectures will be characterized according to these parameters.

SERVICE DEPENDENT SPEECH RECOGNITION

The architectures presented in this section have in common that they require network connectivity to work.

Audio Streaming

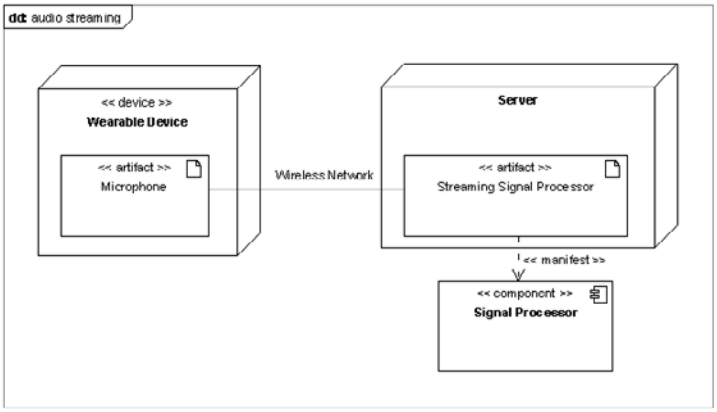
An immediate idea to solve the performance bottleneck on embedded devices is not to perform the recognition process on the device itself. A general model of the recognizer, shown in Figure 4, uses the audio recording capabilities of the embedded device as a microphone replacement to record the raw audio as the input for the *signal processor.*

The audio is streamed over the wireless network, for example, Wi-Fi or Bluetooth, to the *signal processor* on a server. This allows the use of a full-featured recognizer with a large vocabulary running on the server. A disadvantage of this solution is that a stable wireless network connection is required. Another disadvantage is a possibly very large amount of data streamed over the network. Since recognition is not performed on the embedded device, we have all the benefits of a desktop-size speech recognizer at the cost of high network traffic.

MRCP

Since server side speech recognition is mainly an immediate idea, developers tend to implement this architecture on their own using a proprietary

Figure 4. Architecture of an audio streaming speech recognizer



protocol, which makes it unusable with other applications that do not know anything about that proprietary protocol. In addition, real time issues are generally not considered which can result in misrecognition. A standard for server side speech recognition that has been adopted by industry is MRCP. MRCP is an acronym for **m**edia **r**esource **c**ontrol **p**rotocol. It was jointly developed by Cisco Systems, Nuance Communications and Speechworks and was published by the IETF as an RFC (Shanmugham, 2006).

MRCP is designed as an API to enable clients control media processing resources over a network to provide a standard for audio streaming. Media processing resources can be speech recognizers, text-to-speech engines, fax, signal detectors and more. This allows for a use in distributed environments, for example, a small device that accesses a recognizer on the network.

The specification is based on RTSP in Schulzrinne (1998), the **r**eal **t**ime **s**treaming **p**rotocol, as a MIME-type the **M**ultipurpose **I**nternet **M**ail **E**xtension. MIME is used to support, for example, no-text attachments in e-mail messages. RTSP defines requests, responses, and events needed to control the media processing resources. The protocol itself is text based. Mechanisms for the reliable exchange of binary data are left to protocols like SIP, the **S**ession **I**nitiation **P**rotocol, or RTSP. SIP enables control of sessions such as Internet telephone calls.

A media server that can be accessed by RTSP mechanisms controls all resources, in this case, recognizer and synthesizer.

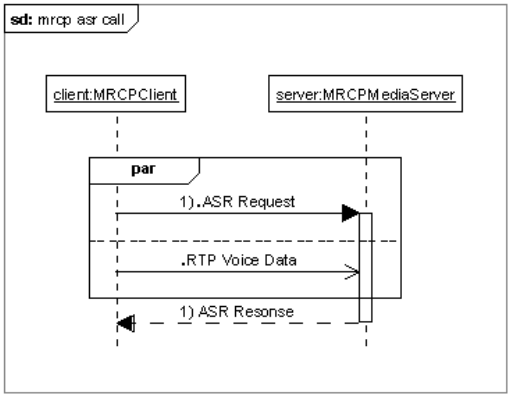
Figure 5 shows a simplified view on the messages that are exchanged in an **a**utomatic **s**peech **r**ecognition (ASR) request and a **t**ext-**t**o-**s**peech (TTS) request.

In an *ASR request*, the MRCP client initiates the request and delivers the voice data via RTP in parallel. The recognition process is executed on the *MRCP Media Server* and the result of the recognition is delivered to the client as the *ASR Response*.

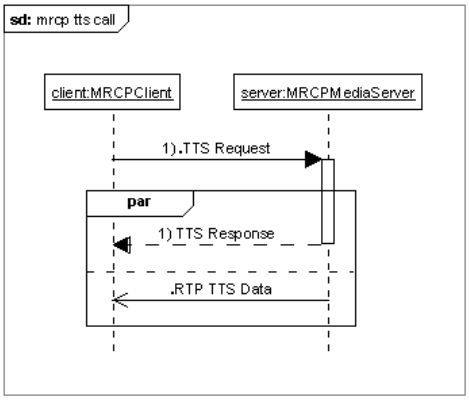
In a *TTS request*, the MRCP client initiates the request. The *MRCP Media Server* answers with a *TTS response* and delivers the synthesized voice data via RTP in parallel.

Figure 5. Simplified view on MRCP requests for ASR and TTS

(a) MRCP ASR request



(b) MRCP TTS request



Distributed Speech Recognition

Another possibility to enable speech recognition on mobile devices uses an architectural compromise. Since full-featured recognizers are hard to implement on embedded devices and streaming of raw audio data produces too much network traffic, ETSI, the **E**uropean **T**elecommunication **S**tandard **I**nstitute, introduced a solution to perform parts of the recognition process on the device and the rest is handled on a server. This architecture is called *Distributed Speech Recognition* (DSR). Pearce (2000) named the component, which is deployed on the device the *DSR Front-end* and the component deployed on the server the *DSR Backend*. This concept is shown in Figure 6.

An obvious point for such splitting is the separation of *signal processor* and *decoder*. Instead of sending all the audio over the network, the feature vectors ρ_i are computed on the embedded device and sent to the *decoder* on a server. In order to reduce the amount of data and to ensure a secure transmission, the data is compressed and a CRC value is added. The architecture of the DSR Frontend is shown in Figure 7.

The DSR Backend, shown in Figure 8, checks the CRC value and decompresses the data before it is passed to the *decoder*.

In this way, the computational capabilities of the device are used for the tasks of the *signal processor* in the *DSR Front-end*, whereas the *decoder* and the *model* reside on the server in the *DSR Backend*. The architecture is a result of discussion between multiple companies, that is, Nokia and Motorola in the Aurora project. The data exchange of DSR Frontend and DSR Backend is standardized by ETSI. This specification includes the features used, CRC check and their compression. Compared to pure audio streaming, the transmitted data is reduced without much loss of information. This also means that the error rates in transmission are reduced. As a positive consequence, DSR also works with lower signal strength, as shown in Figure 9.

Figure 6. Architecture of a distributed speech recognizer

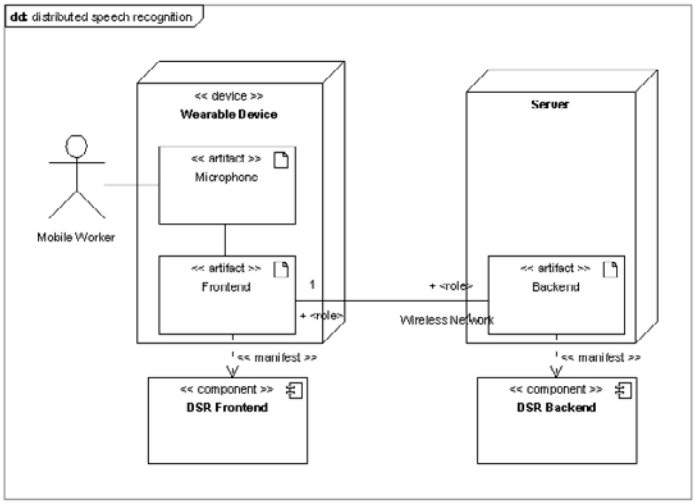


Figure 7. DSR front-end

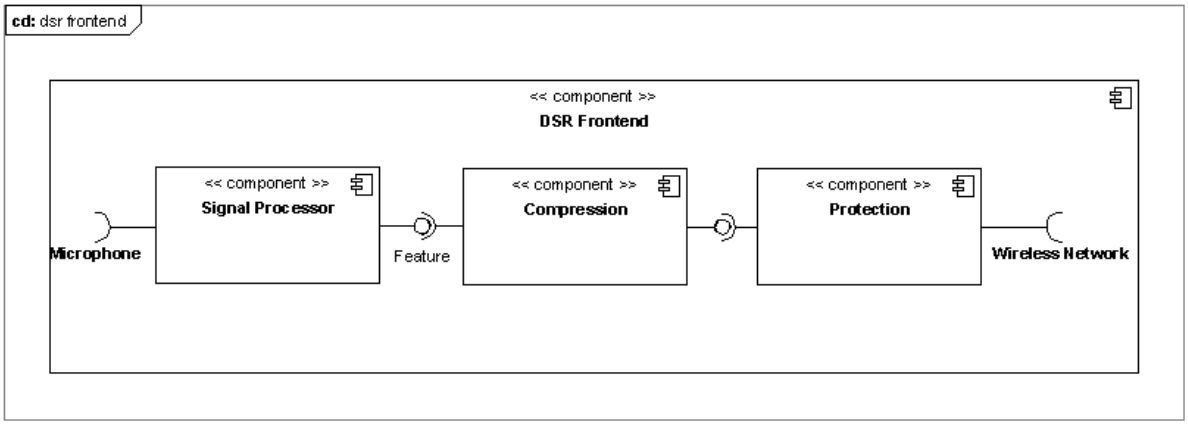

The experiment was conducted in the Aurora project and is described in more detail in Pearce (2000). The figure shows the recognition performance of DSR compared to a mobile speech channel. The measurement proves that recognition still works with lower signal quality. A great advantage of this technology over streaming solutions like audio streaming or MRCP is the reduced network

Figure 8. DSR backend

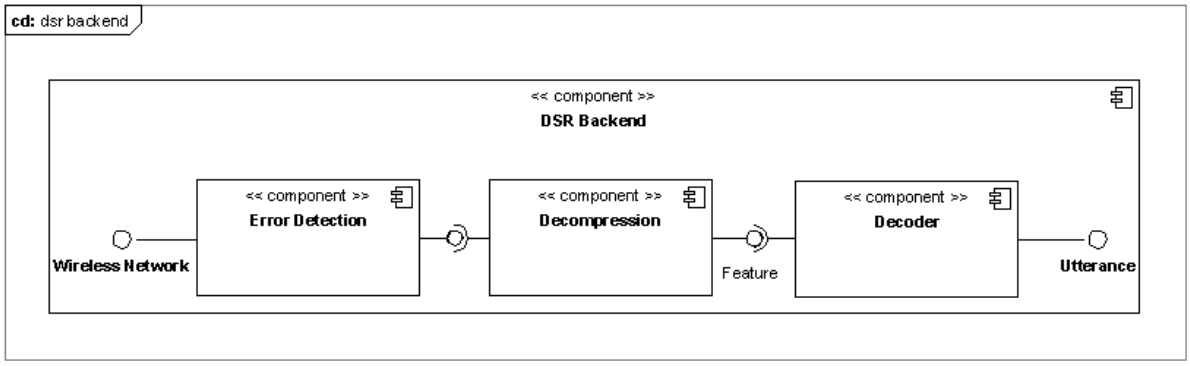

Figure 9. Performance of DSR with channel errors according to Pearce (2000)

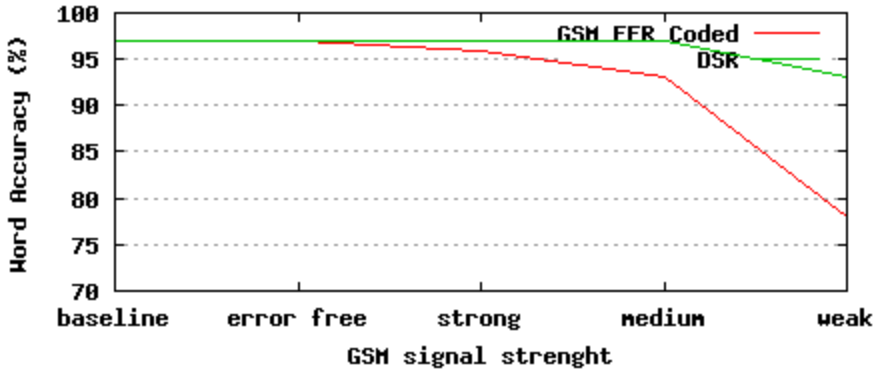

traffic. Like MRCP it defines a standard, but with less acceptance. Speech recognition can be used in various environments, as long as they are compliant to the DSR standard. Unlike MRCP it relies on computation on the device, decreasing its chances of being established in a company's network in contrast to a pure protocol. Again, the recognition has all the features of a desktop size recognizer.

As a negative point, the set of feature vectors is a compromise. This also means that other or additional features used in specific recognizers cannot be transmitted using this technology.

ETSI promises a better use of available resources and better transmission. The following section gives some insight into the computational requirements.

Evaluation of Sphinx 3.5

Sphinx is an open source speech recognizer from Carnegie Mellon University. It was DARPA funded and was used in many research projects in speech recognition.

The anatomy of Sphinx can be divided into three phases:

1. Front-end processing,
2. Gaussian probability estimation, and
3. Hidden Markov evaluation.

The Gaussian phase and the HMM phase are part of the *decoder*. A closer look at it is given in the section "Hidden Markov Models." Mathew (2002) gives an overview of the time that Sphinx 3.5 spends on each phase (see Figure 10).

Obviously, the front-end processing constitutes the smallest part of the computation to be performed. This shows that this is an ideal candidate to be performed by smaller devices, as it is done with DSR. Consequently, Mathew et al. (2000) consider it to be not worthy of further investigation, stopping their analysis at this point. They focus more on the optimization of the latter two phases.

Front-end processing usually comprises the computational steps shown in Figure 11.

The following paragraphs show how these steps are handled in Sphinx. A more general view can be found in the literature, for example, in Schukat-Talamazzini (1995).

Processing starts with a speech signal, as captured, for example, from a microphone. An example of such a speech signal is shown as the input to the speech recognizer in . The transformation into a digital representation, also called *quantization*, means also a loss of information, but this can not be avoided.

Figure 10. Profile information of Sphinx 3.5 phases according to Mathew (2002)

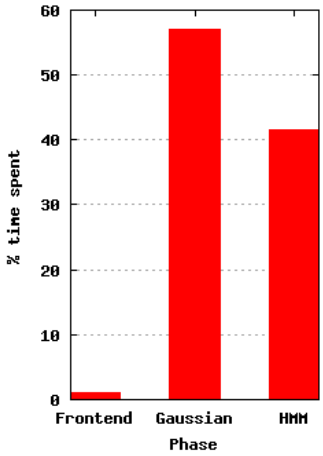

Figure 11. Front-end processing

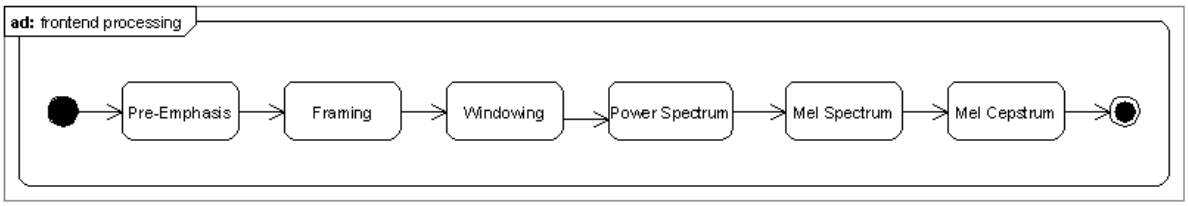
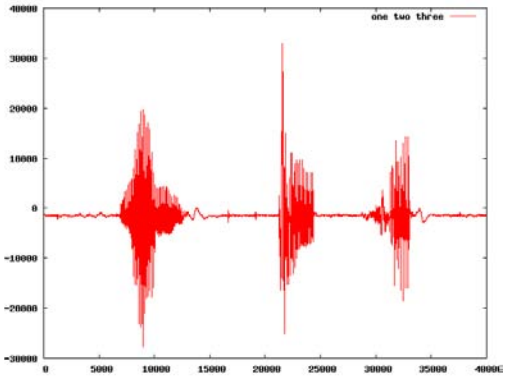


- **Pre-Emphasis:** In this step the quantized signal is filtered. This step becomes necessary from the observation that the signal is weaker in higher frequencies, which can be solved using a digital high-pass filter. Figure 12 shows an example of the speech signal and the effect of this filtering step.
- **Framing:** The input signal is divided into overlapping frames of *N* samples. The frame shift interval, that is, the difference between the starting points of consecutive frames, is *M* samples.
- **Windowing:** The **F**ast **F**ourier **T**ransformation (FFT) is known from the domain of signal processing to compute the spectrum of a signal. FFT requires a periodical signal, it is assumed that the time segment continues to be periodical. Since speech changes over time, we try to get segments of the signal, where it can be considered to be constant. These time segments last from 5-30 ms. An example for such a windowing function is the *Hamming Window*. The following figure shows four such time segments of the utterance. It is noticeable that the signal is smoothed to the borders of the time segments.
- **Power Spectrum:** For speech recognition, the discrete case of the FFT, the **d**iscrete **f**ourier **t**ransformation (DFT) is used. The output of the DFT usually consists of a power of 2 of complex numbers. The power spectrum is computed by the squared magnitude of these complex numbers. The following figure shows the power spectrum for the word *one* of the utterances.
- **Mel Spectrum:** The next step is a filtering step to filter the input spectrum through individual filters. One of these filters is the Mel filter. An impression of this filter is given in the following figure.

The output is an array of filtered values, typically called Mel-spectrum, each corresponding to the result of filtering the input spectrum through an individual filter. Therefore, the length of the output array is equal to the number of filters created.

Figure 12. Pre-emphasis of the speech signal

(a) Quantized speech signal



(b) Pre-emphasized speech signal

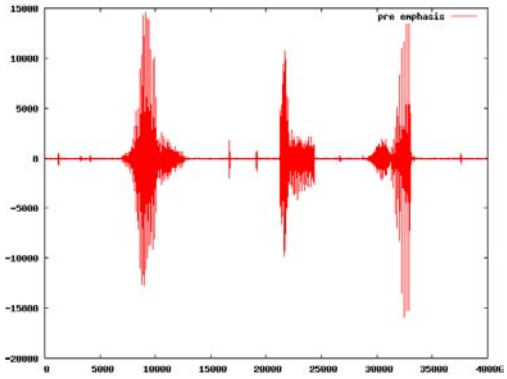


Figure 13. Framing

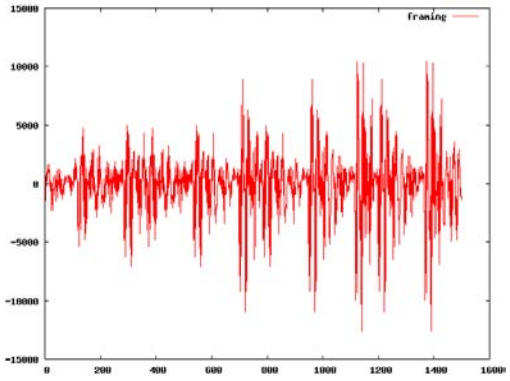

Figure 14. Windowing

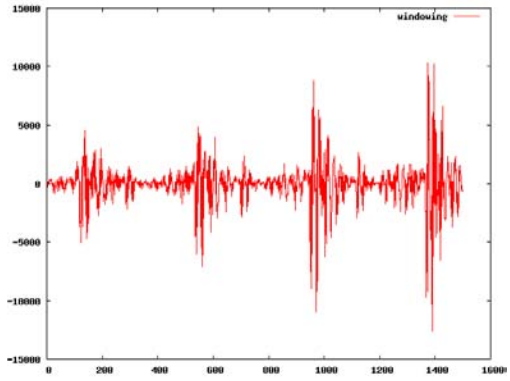

Figure 15. Power spectrum

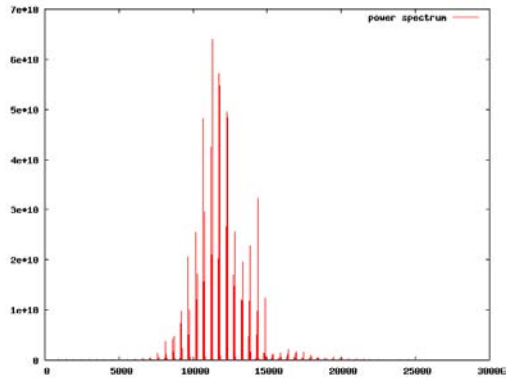

Mel Cepstrum

Davis (1980) showed that Mel-frequency cepstral coefficients present robust characteristics that are good for speech recognition. The artificial word cepstrum is obtained by reversing the letter order in the spectrum to emphasize that this is an inverse transformation. These cepstral coefficients are computed via a discrete cosine transform.

Sphinx uses 16-bit raw audio data as input and produces 13 cepstral parameters as output for each time segment. In order to determine

Figure 16. Mel filter

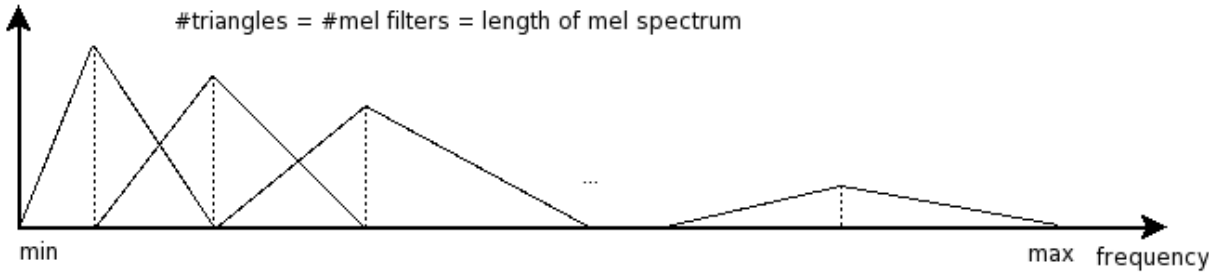

Figure 17. Mel-Spectrum

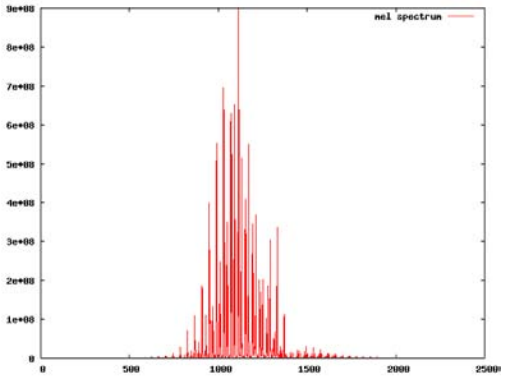

Figure 18. Mel cepstrum

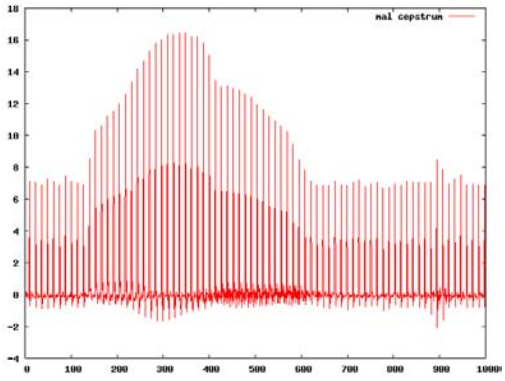

Figure 19. Profile information of sphinx 3.5 front-end

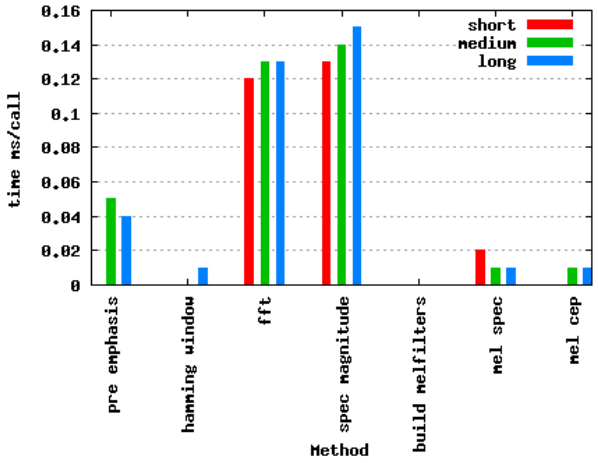


the execution time consumption by individual parts of Sphinx, we used a profiling tool to get detailed information on functions and routines on a Sparc processor-based platform. The profiling was done with three audio files of different lengths as input:

- Short (2.05 sec),
- Medium (6.02 sec), and
- Long (30.04 sec).

The profiling result is shown in Figure 19.

Obviously, the computation of the power spectrum, which comprises the methods fft and spec magnitude, consumes most of the time. Both are part of the power spectrum computation. Tuning this method can speed up the computation a great deal. Alternatively, it can be replaced by a hardware solution, such as a **d**igital **s**ignal **p**rocessor (DSP). This issue will also be addressed in the section "Hardware-Based Speech Recognition."

The process becomes more complicated if the device does not support floating-point operations. Junqua (2001) mentions, "While most automatic speech recognition systems for PC use are based on floating-point algorithms, most of the processors used in embedded systems are fixed-point processors. With fixed-point processors there is only a finite amount of arithmetic precision available, causing an inevitable deviation from the original design." A study by Delaney (2002) showed that for Sphinx 2 a Strong ARM simulator spent over 90% of the time on the floating-point emulation. These results can be transferred to Sphinx 3.5, since they use the same code base for front-end processing.

A way in which to solve these issues is to substitute floating-point arithmetic by fixed-point arithmetic. This is done using scaled integers to perform basic math functions. The scaling factor, that is, the location of the decimal point, must be known in advance and requires careful decision. For adding two numbers, the number n of bits after the decimal point must line up. A multiplication of two numbers yields a number with $2n$ bits after the decimal point.

Unfortunately, this also means a loss of information and the risk of overflowing the register size of 32 bits. This is especially important for the computation of the power spectrum and the Mel-spectrum. Delaney (2002) suggests changing the computation for the Mel-spectrum using a square root to compute the Mel coefficients. It is guaranteed that the square root results in small values, which means that the result of multiplication is small. They also suggest storing the Mel coefficients in a lookup table to avoid the computationally complex calculations of the square root. An experiment conducted in Huggins (2005) showed that feature extraction on a Sharp Zaurus had a 2.7-fold gain in speed using this method. The loss in precision for the result in computing the Mel Cepstrum increased from 9.73% to 10.06%.

DEVICE INHERENT SPEECH RECOGNITION

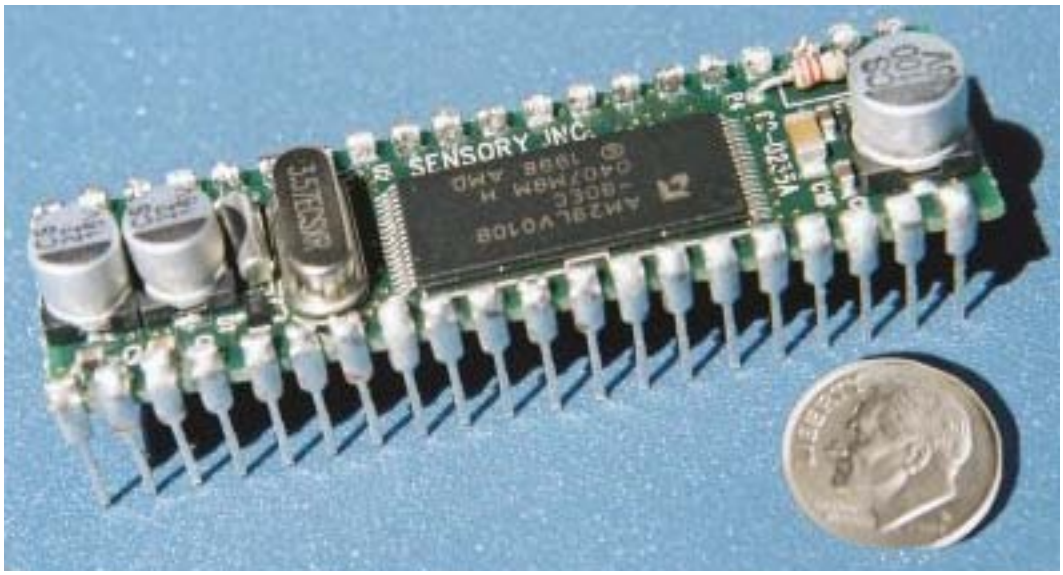
In contrast to the architectures described above, those described in this section are handled on the device only, without the need for a server or service from the network. These architectures are also often referred to as *software-only* and *embedded* architectures (Eagle, 1999; Frostad, 2003). Embedded architectures require the existence of a dedicated DSP. They reside as hardware-based speech recognition, since the term *embedded* is totally overloaded with the meanings of a DSP, an embedded device or embedded into an application. So this architecture does not deal only with software-based architectures, but also include partial or full support with hardware.

Hardware-Based Speech Recognition

Some manufacturers offer designated chips for mobile devices. An example of such a chip is shown in Figure 20.

The technology that is used in these chips differs. All software-based speech technologies for device inherent speech recognition, as described in the following sections, can be found implemented as a port to a DSP. It is even possible to replace just certain parts of the recognizer, that is, the FFT computation for the feature extraction in DSR, with a hardware solution. The main advantage is that a hardware-based solution does not have the runtime problems of software-based approaches,

Figure 20. Sensory voice recognition module



since the hardware is designed to address this specific problem. This is gained at the cost of less flexibility. The range of hardware implementations is as broad as the underlying technology. It starts from a fixed vocabulary used in toys through dynamic time warping, the technology used in most mobile phones, up to programmable DSPs like the sensory chip shown in.

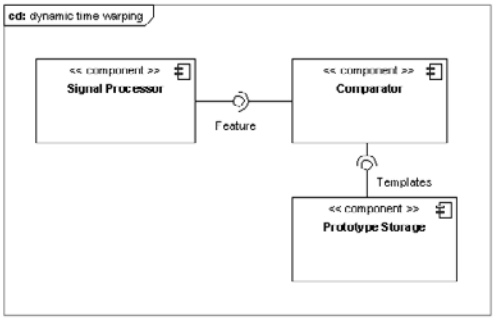
Advantages and drawbacks of these solutions are not discussed in this section, since they are inherited from the technology used. Benefits and drawbacks of the architectures are discussed in the corresponding sections.

Dynamic Type Warping

One of the earliest approaches of enabling speech recognition is the dynamic time warping (DTW). The architecture is shown in Figure 21.

The *signal processor* is responsible for the feature analysis of the raw speech signal. The computational steps are the same as the front-end

Figure 21. Dynamic time warping



processing of DSR (see). An output of the feature analysis component is a feature vector of a test utterance $\sigma = (\sigma_1,..., \sigma_n)^T$ which is compared in the *comparator*, which replaces the *decoder*, with all reference feature vectors $\rho_i = (\rho_{i,1},..., \rho_{i,m})^T$ stored in the *prototype* storage, replacing the *model* of the utterances ρ_i in the set of trained utterances with the help of a distance function $d(\sigma_i, \rho_j)$ that was already mentioned in the section "Overview." Usually the prototypes are gained in a single recording. The features of this recording are computed, stored in the *prototype storage* and associated with the output. If the distance of the currently spoken word to the template is too big $d(\sigma_i, \rho_j) > \mu$, it is likely that no prototype matches the utterance. In this case, the comparator rejects the input.

The problem of calculating the distance from σ_i to ρ_j with the help of a distance function $d(\sigma_i, \rho_j)$ consists of two parts:

1. Definition of a distance function to calculate the distance of two related feature vectors
2. Definition of a time warping function to define a relationship between the elements of σ_i and ρ_j

Multiple distance functions exist and are used. For a Gaussian distribution, Mahalanobis distance is used. Since this is complex and we do not have many computational resources on the device, Euclidean distance is more common. This requires that the features be normalized to unity variance.

The problem with a pairwise distance calculation is that it is unlikely that the lengths of the template and of the input are the same, that is, the length of the *o* in *word* may vary. DTW uses dynamic programming to find an optimal match between two sequences of feature vectors allowing for stretching and compression of sections [see Sakoe (1990)]. The template word having the least distance is taken as a correct match, if its value is smaller than a predetermined threshold value μ.

The technique of comparison with a template word makes this an ideal candidate for isolated word recognition with a small vocabulary, but unsuitable for continuous speech. Since the templates are generally taken in a single recording, DTW is also speaker dependent with little computational effort. The computational requirements are slightly higher than those for DSR, see the section "Distributed Speech Recognition," but lower than those for hidden Markov models (see next section), or artificial neural networks, see the section "Artificial Neural Networks."

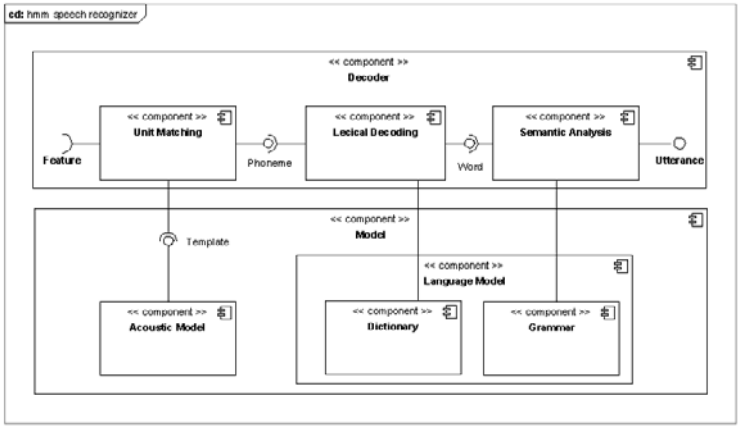
Hidden Markov Models

Most modern speech recognizers are based on **h**idden **M**arkov **m**odels (HMM). An overview of the architecture of a HMM based recognizer is shown in Figure 22, which is in fact a phoneme-based recognizer.

It is also possible to use HMM-based recognition for word-based models. In this case, the architecture is slightly different, as Schukat-Talamazzini (1995) points out. More about the basics of Markov chains and their use can be obtained from the literature, for example, Rabiner (1989). Although this approach is very old, it is still the most successful approach for speech recognition.

Instead of using the computed features as a seed for the states, most recognizers use **v**ector **q**uantization (VQ) to reduce the data rate. Since speech recognition deals with a continuous signal, a certain amount of data arrives periodically. This is called the *data rate*. Since HMM decoding is time consuming, a lower data rate promises real time performance. Furthermore, the storage size is reduced, since only the codebook is stored instead of the cepstral parameters. A *codebook* stores the mapping of the feature vectors as they are computed from the speech signal to a discrete label. Thus the codebook is a discrete representation of the continuous speech data.

Figure 22. Architecture of a HMM-based recognizer



Unit Matching

HMMs are the core of the *unit matching* component. They are described as a tuple $\lambda = (S, A, B, \pi, V)$ with

- $S = \{s_1,..., s_n\}$ representing a set of states,
- $A = \{a_{i,j}\}$ representing a matrix of transition probabilities, where $a_{i,j}$ denotes the probability $p(s_j, s_i)$ for the transition from state s_i to s_j,
- $B = \{b_1,..., b_n\}$ representing a set of output probabilities, where $b_i(x)$ denotes the probability $q(x|s_i)$ to observe x in state s_i and
- O as a set of observations, which means the domain of b_i.

A schematic view on a HMM is given in the following figure.

The probability of observing an output sequence $O = O_1O_2...O_r$ is given by

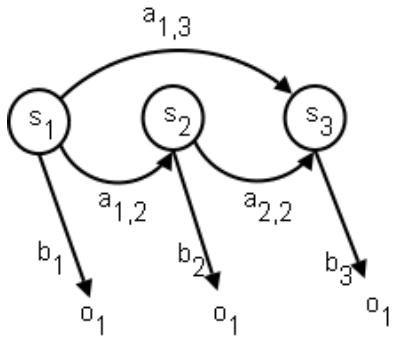
$$P(O = O_1O_2...O_r) = \sum_{\{s_1,s_2,...s_T\}} \prod_{i=1}^{T} p(s_i \mid s_{i-1})q(x_i \mid s_{i-1}) \quad (2)$$

Rabiner (1989) raises three basic questions that are to be solved for speech recognition with HMMs.

1. Given the observation sequence $O = O_1O_2...O_r$ and a model λ, how do we efficiently compute $P(O|\lambda)$, the probability of the observation sequence, given the model?
2. For decoding, the question to solve is, given the observation sequence $O = O_1O_2...O_r$ and the model λ how we choose a corresponding state sequence $Q = q_1, q_2,...q_T$, which is optimal in some meaningful sense (i.e., best "explains" the observations)?
3. How do we adjust the model parameters λ to maximize $P(O|\lambda)$?

The first problem is also known as the *evaluation problem*, but it can also be treated as a *scoring*

Figure 23. Schematic view on a HMM



problem. In that case, the solution to this problem allows us to choose the model that best explains the observations.

The third problem tries to optimize the model parameters to describe a given observation sequence as well as possible. This optimization can be used to *train* the model. Training means to adapt the model parameters to observed training data.

The most important one for speech recognition is the second problem, since it tries to find the *correct* state sequence.

A well-known approach to this is the Viterbi algorithm, based on dynamic programming (DP) to find the most likely sequence of hidden states. A more detailed description, related to speech recognition, can be found in the literature, for example, Rabiner (1989) and Jelinek (2001). The Viterbi algorithm tries to find the best score, which means the highest probability, along a single path at time *t*, also known as *trellis.*

Computational Optimization

The Viterbi algorithm is computationally intensive, especially for larger vocabularies. It requires roughly $|A_u|$ multiplications and additions, where $|A_u|$ is the number of transitions in the model (Bahl, 1993). In order not to search the entire Viterbi trellis, the number of branch-out search candidates can be limited using beam-search, as Lowerre (1976) points out.

The idea is to eliminate all states from the trellis that have a probability above a certain threshold, which depends on the maximum probability of the states at this stage. This reduces the number of states without affecting the values, if the threshold is appropriately chosen.

Novak et al. (2003) suggest an even more aggressive pruning with their two-pass strategy. Instead of using the probabilities directly, they convert them to probabilities based on their rank. Thus, the probability space is bounded and the values of the best and worst state output probabilities remain the same for each time frame. Instead of computing the output probabilities, they simply take a single value from the tail of the ranked probability distribution. This is based on the approach described in Bahl et al. (1993) where the authors claim a speedup by a factor of 100.

There are many more attempts to simplify the computational effort of Viterbi search. Most of them try to replace multiplications by additions, which are faster to compute (Ming, 2003). Usually these attempts increase speed at the cost of accuracy and/or memory demands.

Lexical Decoding and Semantic Analysis

The result of the unit matching is a scoring for the different recognition hypotheses. The next two steps help to determine the word chain with the highest probability with respect to the constraints imposed by the language model. For word-based recognition with HMMs, the recognition process is finished at this point.

In the *lexical decoding* phase those paths are eliminated that do not have an existing word in the dictionary. In an alternative approach, using a so-called *statistical grammar*, the sequences

are reduced a couple of phonemes in a row, for example, trigrams. The output of the latter case is a list of trigrams, ordered according to their probability. This is not suitable for isolated word recognition. The next step is *syntactic analysis*, where those paths are eliminated that do not match an allowed sequence of words from the dictionary.

These steps do not require intensive computation except for fast memory access to the dictionary and the grammar. Again, smaller vocabularies offer a faster result and require less memory.

The word or utterance with the highest probability in the remaining list of possible utterances is taken as the recognition output.

HMM-based recognition is computationally intensive, but shows good results in isolated word recognition as well as continuous speech. If the HMM is trained well, it is also a suitable technology for speaker independent recognition.

Artificial Neural Networks

Artificial **n**eural **n**etworks (ANN) is a method in computer science that is derived from the way the human brain works. The goal is to create a system that is able to learn and that can be used for pattern classification. More detailed information about ANN is given in the chapter "Socionics & Bionics: Learning from 'The Born.'" The use of ANN for classification and their use in speech recognition can be found in the literature, for example, Cholet (1999).

Expectations were very high when ANNs were discovered as a means for speech recognition. Modelling of speech recognition by artificial neural networks doesn't require *a priori* knowledge of the speech process and this technique quickly became an attractive alternative to HMM (Amrouche, 2006).

Neural nets tend to be better than HMMs for picking out discrete words, but they require extensive training up front [see Kumagai (2002)].

An output of an artificial neuron (see the chapter "*Socionics & Bionics: Learning from 'The Born'*") in multi-layer perceptron (MLP) networks is computed via

$$f_z = \sum_{i=1}^{n} w_i x_i \qquad (3)$$

There is nearly no optimization to reduce the large amount of calculations that have to be done to compute the output of a complex multilayer perceptron. The good point is that there are only additions and multiplications. The bad point is that there are too many of them, which makes it unusable on devices with a lower CPU frequency. A way out of this dilemma is the use of proprietary hardware, as used in hardware-based speech recognition, consult the section "Hardware-Based Speech Recognition".

Nowadays ANNs play a minor role in continuous speech recognition, but are still used in hybrid architectures with HMM-based recognition. In contrast to HMMs, which try to achieve their goal based on statistical and probability models, ANNs deal with classification. They are able to classify a given pattern into phonemes, but are not ideal for the processing of continuous speech. This means that neural networks are used as a replacement for various pieces of a HMM-based recognizer. This is more a philosophical difference with little relevance to use in embedded environments.

As an example of such a network, we look at the multilayer perceptron developed by Bourlard (1992). This network has nine 26-dimensional feature vectors to compute 61 phonemes with 500-4000 neurons in a hidden layer. It allows computing the a posteriori probability $p(q_k|x_i)$. The Viterbi algorithm requires $p(x_i|q_k)$, which can be guessed using the Bayes theorems via

$$p(x_i \mid q_k) = \frac{p(q_k \mid o_T)\, p(o_T)}{p(q_k)} \qquad (4)$$

where $p(o_T)$ can be treated as a constant for all classes and $p(q_k)$ is the frequency distribution of all phonemes, which is known in advance.

FUTURE RESEARCH DIRECTIONS

This chapter gave an overview of the challenges of implementing speech recognition on mobile devices. None of the architectures is ideal in all aspects. Most researchers in speech recognition hope that embedded devices will become powerful enough to have enough performance running off-the-shelf speech recognizers on embedded devices. However, this attitude does not solve the problems that users have if they want to use speech recognition today.

Currently, there are two main approaches to enabling speech recognition on future mobile devices. The first one is followed by hardware engineers who are trying to improve the performance of embedded devices. The development of better hardware will not be able to solve all the challenges in a short time, but will at least address some of them. One aspect is the lack of support for floating point arithmetic, which is also present for rendering of graphical interfaces. Others, like limited memory capacity, will persist. Evolution in recognition performance currently entails a shorter battery life. This is where research in the domain of electrical engineering is required. An alternative is presented by streaming technologies like MRCP that are increasingly used, for example, on mobile phones. Here, standards are needed that allow the distribution of mass data over a wireless connection, or better reduce the traffic.

The second approach is research in speech recognition, looking for tricks to enable speech recognition on these devices with limited capabilities. Advancements in recognition technology are needed too to overcome the challenges. The current approaches have the drawback that they are accompanied by a loss of precision. Here we need better strategies.

The first steps have been taken, but more work is needed to make the vision of voice input on embedded devices come true.

SUMMARY

There are multiple architectures and technologies for implementing speech recognition on mobile devices. They can be divided into *service dependent speech recognition* and *device inherent speech recognition*. Service dependent architectures require a service running on the network to move the computational burden from the client. These architectures offer the same potential as desktop speech recognition at the cost of environmental dependencies. Speech recognition on the device is independent of services running on the network, but pose high computational effort to the mobile device.

This is also the main reason why the speech recognition parameters of service dependent speech recognition cannot be determined exactly. They depend on the technology used on the server side, resulting in full network dependency and high server load. The values of the additional parameters for UC are generally worse than those for device inherent speech recognition.

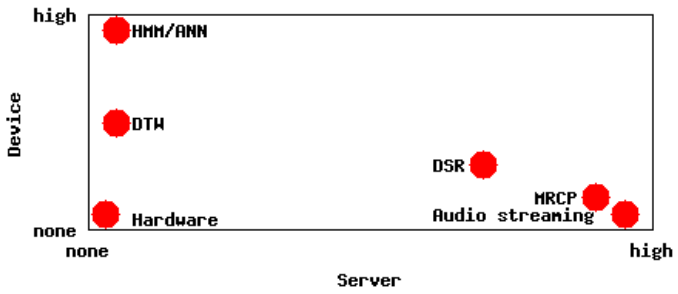
The required network bandwidth is better for DSR than for the streaming architectures, since it aims at reducing the transmitted data. As a consequence, transmission degradation and server load is slightly better.

HMM and ANN based recognizers offer the greatest flexibility and have the best scores for the parameters of speech recognition systems. This is the main reason why service dependent speech recognition performs better in that area.

The transducer is in all cases a noise-canceling microphone. Thus SNR is not a crucial factor.

Implemented on the device, these technologies require too many resources to achieve the same performance as their counterparts on the server. This results in smaller vocabularies, smaller

Figure 24. Distribution of computational resources



models and lower perplexity. They have generally a lower recognition rate than server implementations. In addition, implementations may not have real time capabilities, resulting in a low scoring for responsiveness. The decisive factor is the use of computational resources.

Figure 24 gives a graphical representation of how the type of architecture influences the distributed use of computational resources on the device and on the server.

Hardware-based speech recognition seems to be an appropriate candidate to enable speech recognition on mobile devices, but its rigidity makes it impossible to address multiple application scenarios. Thus it has the worst value for integration and maintenance. DTW requires fewer resources on the device than HMM or ANN, but is highly speaker dependent. It requires enrollment, and supports only isolated word-based recognition, which makes it unusable for certain scenarios.

This analysis can serve as a decision criterion for the architecture to implement or to use. None of the architectures is ideal in all contexts. Especially server dependent architectures require a higher invest, hampering their use in enterprise applications.

Chapter 8.19
Voice-Enabled User Interfaces for Mobile Devices

Louise E. Moser
University of California, Santa Barbara, USA

P. M. Melliar-Smith
University of California, Santa Barbara, USA

ABSTRACT

The use of a voice interface, along with textual, graphical, video, tactile, and audio interfaces, can improve the experience of the user of a mobile device. Many applications can benefit from voice input and output on a mobile device, including applications that provide travel directions, weather information, restaurant and hotel reservations, appointments and reminders, voice mail, and e-mail. We have developed a prototype system for a mobile device that supports client-side, voice-enabled applications. In fact, the prototype supports multimodal interactions but, here, we focus on voice interaction. The prototype includes six voice-enabled applications and a program manager that manages the applications. In this chapter we describe the prototype, including design issues that we faced, and evaluation methods that we employed in developing a voice-enabled user interface for a mobile device.

INTRODUCTION

Mobile devices, such as cell phones and personal digital assistants (PDAs), are inherently small, and lack an intuitive and natural user interface. The small keyboards and displays of mobile devices make it difficult for the user to use even the simplest of applications. Pen input is available on PDAs, but is difficult to use on handheld devices.

Voice input and output for mobile devices with small screens and keyboards, and for hands- and eyes-free operation, can make the user's interaction with a mobile device more user friendly. Voice input and output can also facilitate the use of Web Services (Booth, Hass, McCabe, Newcomer, Champion, Ferris, & Orchard, 2004) from a mobile device, making it possible to access the Web anytime and anywhere, whether at work, at home, or on the move. Global positioning system (GPS) technology (U.S. Census Bureau, 2006)

can provide location information automatically for location-aware services.

Many everyday applications can benefit from voice-enabled user interfaces for a mobile device. Voice input and voice output for a mobile device are particularly useful for:

- Booking theater and sports tickets, making restaurant and hotel reservations, and carrying out banking and other financial transactions
- Accessing airline arrival and departure information, weather and traffic conditions, maps and directions for theaters, restaurants, gas stations, banks, and hotels, and the latest news and sports scores
- Maintaining personal calendars; contact lists with names, addresses, and telephone numbers; to-do lists; and shopping lists
- Communicating with other people via voice mail, e-mail, short message service (SMS), and multimedia message service (MMS).

It is important to provide several modes of interaction, so that the user can use the most appropriate mode, depending on the application and the situation. The prototype system that we have developed supports client-side, voice-enabled applications on a mobile device. Even though the applications support multimodal input, allowing keyboard and pen input, we focus, in this chapter, on voice input and on multimodal output in the form of voice, text, and graphics. The prototype includes a program manager that manages the application programs, and six voice-enabled applications, namely, contacts, location, weather, shopping, stocks, and appointments and reminders.

BACKGROUND

A multimodal interface for a mobile device integrates textual, graphical, video, tactile, speech, and/or other audio interfaces in the mobile device (Hjelm, 2000; Oviatt & Cohen, 2000). With multiple ways for a user to interact with the applications, interactions with the device become more natural and the user experience is improved. Voice is becoming an increasingly important mode of interaction, because it allows eyes- and hands-free operation. It is essential for simplifying and expanding the use of handheld mobile devices. Voice has the ability to enable mobile communication, mobile collaboration, and mobile commerce (Sarker & Wells, 2003), and is becoming an important means of managing mobile devices (Grasso, Ebert, & Finin, 1998; Kondratova, 2005).

The increasing popularity of, and technological advancements in, mobile phones and PDAs, primarily mobile phones, is leading to the development of applications to fulfill expanding user needs. The short message service (SMS) is available on most mobile phones today, and some mobile phones provide support for the multimedia messaging service (MMS) to exchange photos and videos (Le Bodic, 2002). The mobile phone manufacturers are no longer focused on making a mobile phone but, rather, on producing a mobile device that combines phone capabilities with the power of a handheld PC. They recognize that the numeric keypad and the small screen, common to mobile phones of the past, do not carry over well to handheld PCs (Holtzblatt, 2005).

With the emergence of Web Services technology (Booth et al., 2004), the Web now provides services, rather than only data as it did in the past. Of the various Web Services available to mobile users today, the map application seems to be the most popular, with online map services available from Google (2006) and Yahoo! (2006b). Much progress has been made in creating the multimodal Web, which allows not only keyboard and mouse navigation but also voice input and output (Frost, 2005).

GPS technology (U.S. Census Bureau, 2006) already exists on many mobile devices, and can be used to provide location-aware services (Rao

& Minakakis, 2003), without requiring the user to input geographical coordinates, again contributing to user friendliness.

Speech recognition technology (Rabiner & Juang, 1993) has been developed over many years, and is now very good. Other researchers (Kondratova, 2004; Srinivasan & Brown, 2002) have discussed the usability and effectiveness of a combination of speech and mobility. Currently, handheld voice-enabled applications use short commands that are translated into functional or navigational operations. As observed in Deng and Huang (2004), speech recognition technology must be robust and accurate, and close to human ability, to make its widespread use a reality. Noisy environments present a particular challenge for the use of speech recognition technology on mobile devices and, therefore, multimodal interactions are essential. For example, the MiPad system (Deng, Wang, Acero, Hon, Droppo, Boulis, et al., 2002; Huang, Acero, Chelba, Deng, Droppo, Duchene, Goodman, et al., 2001) uses a strategy where the user first taps a "tap & talk" button on the device and then talks to the device.

Distributed speech recognition (Deng, et al., 2002), in which the speech recognition happens at a remote server exploits the power of the server to achieve fast and accurate speech recognition. However, studies (Zhang, He, Chow, Yang, & Su, 2000) have shown that low-bandwidth connections to the server result in significant degradation of speech recognition quality. In contrast, *local speech recognition* (Deligne, Dharanipragada, Gopinath, Maison, Olsen, & Printz, 2002; Varga, Aalburg, Andrassy, Astrov, Bauer, Beaugeant, Geissler, & Hoge, 2002) utilizes speech recognition technology on the mobile device, and eliminates the need for high-speed communication. Local speech recognition limits the kinds of client handsets that are powerful enough to perform complicated speech processing and, thus, that can be used; however, the computing power of mobile handsets is increasing.

THE PROTOTYPE

The prototype that we have developed allows mobile applications to interact with the user without the need for manual interaction on the part of the human. Speech recognition and speech synthesis software are located on the mobile device, and make the interaction with the human more user friendly. The prototype that we have developed processes natural language sentences and provides useful services while interacting with the user in an intuitive and natural manner. A user need not form a request in a particular rigid format in order for the applications to understand what the user means.

For our prototype, we have developed six application programs and a Program Manager. These applications are Contacts, Location, Weather, Shopping, Stocks, and Appointments and Reminders applications. The Program Manager evaluates sentence fragments from the user's request, determines which application should process the request, and forwards the request to the appropriate application.

The prototype is designed to interact with a human, using voice as the primary means of input (keyboard, stylus, and mouse are also available but are less convenient to use) and with voice, text, and graphics as the means of output. The speech recognizer handles the user's voice input, and both the speech synthesizer and the display are used for output. Characteristics of certain applications render a pure voice solution infeasible. For example, it is impossible to convey the detailed contents of a map through voice output. However, voice output is ideal when it is inconvenient or impossible for the user to maintain visual contact with the display of the mobile device, and it is possible to convey information to the user in that mode. Voice output is also appropriate when the device requests confirmation from the user.

Thus, an appropriate choice of speech recognition and speech synthesis technology is vital to

the success of our prototype. Our choices were constrained by:

- The processing and memory capabilities of typical mobile devices
- The need for adaptability to different users and to noisy environments

The use of speech recognition and speech synthesis technology on a mobile device is different from its use in call centers, because a mobile device is associated with a single user and can learn to understand that particular user.

The Underlying Speech Technology

The prototype uses SRI's DynaSpeak speech recognition software (SRI, 2006) and AT&T's Natural Voices speech synthesis software (AT&T, 2006). It currently runs on a handheld computer, the OQO device (OQO, 2006). We chose this device, rather than a cell phone, because it provides a better software development environment than a cell phone.

Speech Recognition

The DynaSpeak speech recognition engine (SRI, 2006) is a small-footprint, high-accuracy, speaker-independent speech recognition engine. It is based on a statistical language model that is suitable for natural language dialog applications. It includes speaker adaptation to increase recognition accuracy for individuals with different accents or tone pitches. It can be configured so that it performs speech recognition specific to a particular individual. DynaSpeak is ideal for handheld mobile devices, because of its small footprint (less than 2 MB of memory) and its low computing requirements (66 MHz Intel x86 or 200 MHz Strong Arm processor).

DynaSpeak supports multiple languages, adapts to different accents, and does not require training prior to use. It incorporates a Hidden Markov Model (HMM) (Rabiner & Juang, 1993). In an HMM, a spoken expression is detected as a sequence of phonemes with a probability associated with each phoneme. A probability is also associated with each pair of phonemes, that is, the probability that the first phoneme of the pair is followed by the second phoneme in natural speech. As a sequence of phonemes is processed, the probability of each successive phoneme is combined with the transition probabilities provided by the HMM. If the probability of a path through the HMM is substantially greater than that of any other path, the speech recognizer recognizes the spoken expression with a high level of confidence. When the response is below an acceptable confidence threshold, the software seeks confirmation from the user or asks the user questions.

The HMM is augmented with grammars for the particular applications that are required for understanding natural language sentences (Knight, Gorrell, Rayner, Milward, Koeling, & Lewin, 2001). When the user says a new word, the word can be added to the vocabulary dynamically. The HMM is also extended by adapting the vocabulary of the speech recognizer to the current and recent past context of interactions of the user with the applications.

Accuracy of the speech recognition system can be increased by training it for the voice of the particular user. There are two kinds of training, explicit and implicit. *Explicit training* requires the user to read a lengthy script to the device, a process that is likely to be unpopular with users. *Implicit training* allows the device to learn to understand better its particular user during normal use. Implicit training can be provided in two modes, confirmation mode and standard mode.

In *confirmation mode*, the system responds to a user's sentence, and the user confirms or corrects the response. If the user corrects the sentence, the learning algorithm tries to match a rejected, lower probability, interpretation of the original sentence with the user's corrected intent. If a match is found, the learning algorithm adjusts

the HMM transition probabilities to increase the probability of selecting the user's intent. Initially, a new user of the system will probably prefer confirmation mode.

In *standard mode*, the system does not confirm sentences for which there is one interpretation that has a much higher probability than any other interpretation. If no interpretation has a high probability, or if several interpretations have similar probabilities, the speech recognition system responds as in confirmation mode. More experienced users of the system are likely to use standard mode.

The success of implicit training strategies depends quite heavily on starting with a speech recognizer that is well matched to the individual speaker. It is possible, from relatively few sentences, to classify a speaker and then to download, to the mobile device, an appropriate initial recognizer for subsequent implicit training.

DynaSpeak can be used with either a *finite-state grammar* or a *free-form grammar*. We used the finite-state grammar because it offers greater control over parsed sentences. The tendency for DynaSpeak to accept or reject spoken sentences is heavily influenced by the complexity of the grammar. The *complexity of the grammar* is quantified by the number of paths by which an accepting state can be reached. The greater the complexity of the grammar, the higher is its tendency to accept an invalid spoken request. Conversely, the lower the complexity of the grammar, the higher is its tendency to reject a valid spoken request. To minimize the complexity of the grammar and to improve speech recognition accuracy, each application has its own relatively simple grammar. The program manager determines which applications are involved in a sentence and then reparses the sentence using the appropriate grammars.

Speech Synthesis

Natural Voices (AT&T. 2006) is a speech synthesis engine that provides a simple and efficient way of producing natural (rather than electronic) sounding device-to-human voice interactions. It can accurately and naturally pronounce words and speak in sentences that are clear and easy to understand, without the feeling that it is a computer that is speaking.

Natural Voices supports many languages, male and female voices, and the VoiceXML, SAPI, and JSAPI interface standards. Using Natural Voices, we created text-to-speech software for our prototype that runs in the background and accepts messages in VoiceXML format. Each message contains the name of the voice engine (i.e., "Mike" for a male voice and "Crystal" for a female voice) and the corresponding text to speak.

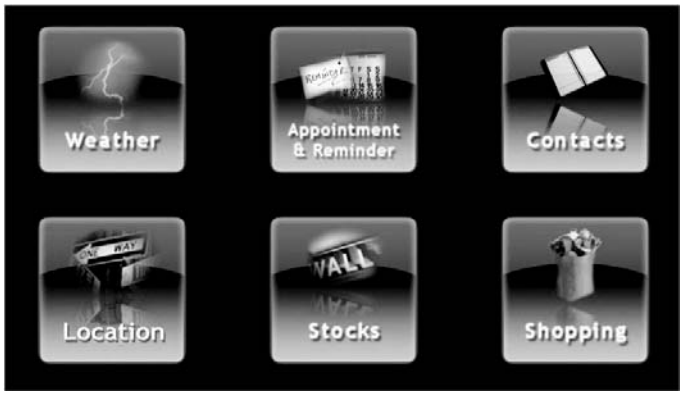
Managed Applications

For the prototype we developed six multimodal applications (contacts, location, weather, shopping, stocks, appointments, and reminders) that use speech as the main form of input. The stocks, maps, and weather applications exploit existing Web Services on the Internet. Communication with those Web Services uses a local WiFi 802.11 wireless network. The program manager controls the operation of the applications. The graphical user interface for the program manager with the six applications is shown in Figure 1. We now present an explanation of the functionality of each application and its role in the overall system.

Contacts

The contacts application stores personal information regarding friends and acquaintances in a database, including their addresses and phone numbers. The contacts application is a mobile extension of a physical contact list or address book that is controlled by voice input. It retrieves data from Microsoft Office Outlook® to populate the database when in docking mode. After using the mobile device and possibly entering new contact information, the user can synchronize informa-

Figure 1. The GUI of the program manager, showing six applications



tion on the mobile device with that on a desktop or server computer. The contacts application is configured to interact with other applications that require information about names, addresses, phone numbers, and so forth. The contacts grammar is the least complex of the application grammars that we developed. The contacts vocabulary grows linearly as contacts are added to the user's contact list.

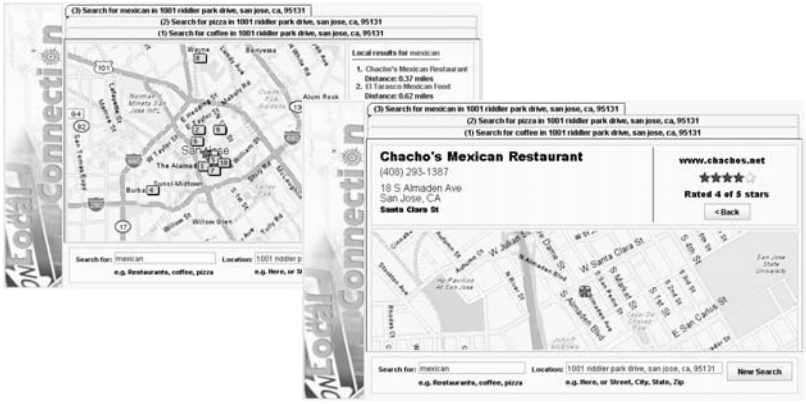
Location

The Location application allows the user to search for restaurants, movie theaters, banks, and so forth, in a given area, using the Yahoo! LocalSearch Web Service (2006b). For example, if the user says to the mobile device "Search for a Mexican restaurant in 95131," the location application on the mobile device sends a Web Service request to Yahoo! LocalSearch, gets back the results, and presents up to 10 results to the user in list form. The user can then view additional information about a single location by indicating the location's number in the presented list. For example, the user can choose to view additional information about "Chacho's Mexican Restaurant" by speaking, "Get more information about number one." On processing this request, the location application presents the user with detailed information about the restaurant including its phone number, address, and a detailed street map showing its location. Figure 2 shows a screen shot of the graphical user interface for the location application.

The location application is loosely coupled with the contacts application to provide responses related to individuals listed in the user's contact list. For example, the request, "Search for a movie theater around Susan's house" uses the contacts grammar to determine the location of Susan's house and replaces the phrase "Susan's house" with the specific address so that the actual search request looks something like this: "Search for a movie theater around 232 Kings Way, Goleta, CA, 93117." The location application then searches for a movie theater in the vicinity of that address.

The location application is also loosely coupled with a GPS module that is contacted when the user has a question related to the user's current location. For example, if the user says "Look for a pizza place around here.", the word "here" is

Figure 2. An example graphical user interface for the location application



recognized by the application and replaced with the GPS coordinates of the user's current location. The location application then sends a Web Service request to Yahoo! LocalSearch, which returns a map of the user's current location, indicating where the user is, along with the 10 nearest pizza places. The Yahoo! LocalSearch Web Service is ideal to use with GPS because of its ability to locate positions on the map on the basis of longitude and latitude. With GPS, the user is no longer limited to requests involving a particular city or zip code. The user now has the ability to create requests that are truly location-aware.

Compared to the grammars of the other applications, the location grammar is one of the most complex. For information like maps and lists, it is desirable to use a graphical or textual display, as well as speech output, in a multimodal user interface. Thus, the most appropriate kind of output can be chosen, depending on the kind of information, the capabilities of the mobile device, and the context in which the user finds himself or herself.

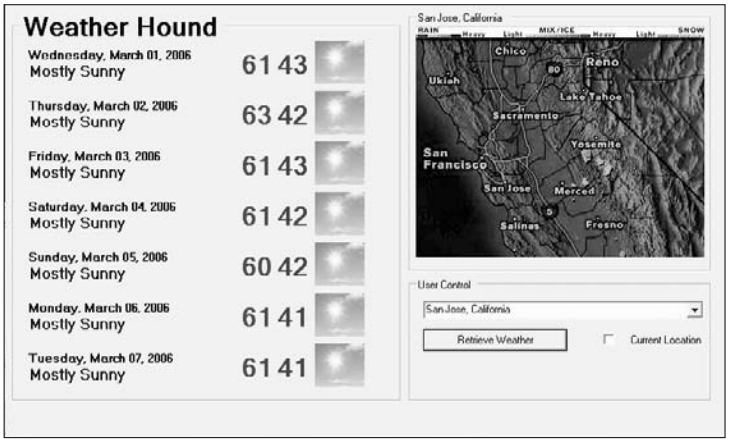
Weather

The weather application supplies weather forecasts obtained from the Web Service provided by the National Weather Service (NOAA, 2006). It allows the user to query for weekly, daily, and 3-day weather information in major U.S. cities using voice input. It allows the user either to select a city or to use the user's current location, as the location for which the weather forecast is to be retrieved from the National Weather Service. The weather application knows the geographical coordinates of dozens of cities in the continental United States. It references those coordinates when the user requests a weather forecast from the National Weather Service for one of those cities.

A user can say "Tell me the weather forecast in San Jose," which then uses "today" as the starting time of the forecast, and produces the graphical user interface for the weather application shown in Figure 3.

Because the weather application operates on a mobile device, it is necessary to be able to deter-

Figure 3. An example graphical user interface for the weather application



mine the user's location dynamically. If the user asks "What's the weather like here two days from now?", the weather application consults the GPS module to obtain the geographical coordinates of the user, contacts the Web Service, and responds with the high and low predicted temperatures and an indication that there is a change to cloudy in Santa Barbara. Thus, the user does not need to provide his/her current location or to obtain the weather forecast for that location.

Our prototype takes into account the many ways in which a person can convey, semantically, equivalent requests in English. For example, a user can ask for the weather in many ways including "What is the weather in Boston like?" or "Tell me what the forecast is like in Boston." These two requests are semantically equivalent because they both contain the same essential parameter, namely the Boston location.

Shopping

The shopping application provides the user with a service capable of reducing the time that the user spends on grocery shopping and the associated stress. The shopping application maintains shopping lists, recipes, and floor plans of supermarkets. The multimodal interface includes speech, text, and graphics, which makes the shopping application easy to use. Figure 4 shows a screen shot of the graphical user interface for the shopping application.

The shopping application allows a user to update his/her shopping list and to forward it to another user. When a user issues a command, like "Remind John to go grocery shopping," the contacts application is used to find John's phone number or e-mail address in the user's contact list. A dialog box then appears asking the user if he/she wants to send, to John, not only a reminder to go shopping but also the shopping list. If so, the shopping list, consisting of the product ids and the quantities of the items needed, is formatted in XML, and appended to the message containing the reminder. The message is then sent to John's shopping application.

The shopping application also displays graphically the floor plan of the supermarket and the

Figure 4. An example graphical user interface for the shopping application

location of items in the store, as shown in Figure 4. This feature provides assistance to the user without the need for the user to contact an employee of the supermarket. The shopping application also allows the user to retrieve recipes while shopping, possibly on impulse, for an item that is on sale. A newly chosen recipe is cross-referenced with the current shopping list, so that needed items can be added automatically. The shopping application has the largest grammar of the applications that we developed, with a vocabulary that depends on the items that the user has purchased recently.

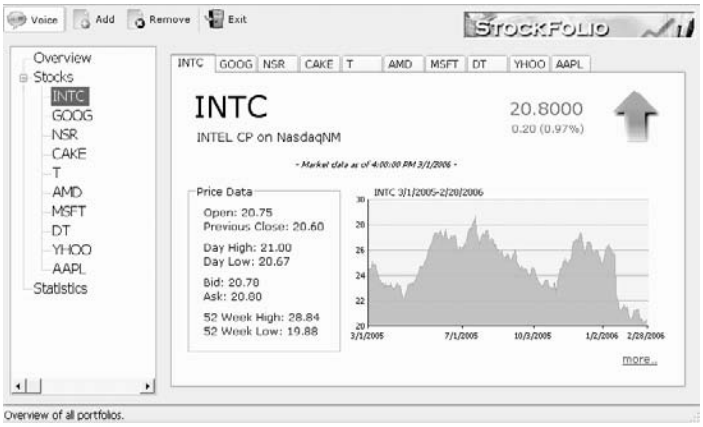
Stocks

The stocks application allows the user to manage his/her stock portfolio using voice input and output. The objective of the stocks application is to monitor stock fluctuations, rather than to trade stocks. The stocks application exploits the Yahoo! Finance Web service (2006a) to store and update stock information in a database. It stores the most recent stock information in the database so that it can reply to the user's requests when connectivity to the Yahoo! Finance Web Service is limited. Although such stored data can be somewhat stale, it allows the user to obtain information whenever the user requests it. The vocabulary of the stocks application grows to match the user's portfolio each time the user adds a new stock.

Appointments and Reminders

The appointments and reminders application manages the user's calendar and allows the user to send reminders to other people. It supports time-based requests of various forms, for example, "Remind me to go to the dentist on Monday," "Remind me to see the dentist on August 15th," and "Remind me to see the dentist a week from today." It displays an easily readable schedule, so that the user can recall what is planned for the day. The appointments and reminders application interacts with other applications, such as the shopping application. For example, the request "Remind John to go shopping on Monday" sends a reminder to John, along with the current shopping list, if the user wishes to forward that information. It also supports

Figure 5. An example graphical user interface for the stocks application



reminders to the user that are location-aware using GPS, for example, if the user is in the vicinity of a supermarket. The appointments and reminders application is an extension of a calendar service. It links to Microsoft Office Outlook®, and updates scheduled appointments and reminders when in the vicinity of the user's desktop.

Program Manager

The program manager evaluates sentence fragments from a user's request, identifies keywords that determine which application or applications should process the request, reparses the sentence using the grammars for those applications, and forwards the parsed request to the appropriate application. If more than one user is involved, the program manager on one user's mobile device sends messages to the program manager on another user's mobile device, which then handles the request.

The program manager leverages DynaSpeak and a weighted keyword recognition algorithm to break down recognized sentences into application-specific fragments. Those fragments are then processed by the appropriate applications, and are subsequently merged to form the final sentence meaning. This process allows the program manager to handle requests that involve more than one application, for example, "Search for a gas station around Paul Green's house." The parsing of this sentence, using the location grammar, requests a search centered on a location that the location grammar cannot itself provide. The program manager must recognize a keyword from the contacts grammar, parse the sentence using that grammar, and query the contacts application for the address of Paul Green's house. The response to the query is then sent to the location application to obtain the location of the gas station nearest his house.

Graphical User Interface

The graphical user interface (GUI) of thepProgram manager, shown in Figure 1, displays the current running application programs and allows the user to select an application by using voice or keyboard

input. The GUI provides buttons that appear gray when an application has not been started and blue after startup. If the user makes a spoken request that requires an application to display a result, the display for that application is topmost and remains topmost until the user issues another request or a timeout occurs. Whenever the GUI is displayed, the user must provide a keyword in a spoken request to wake up the program manager, or click on one of the application-specific buttons on the display.

EVALUATION

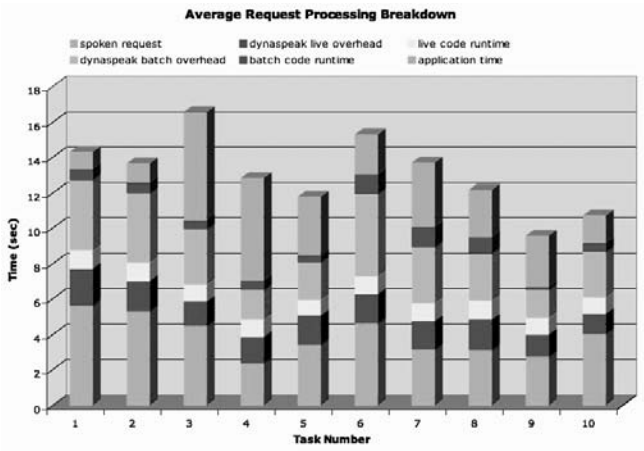
Several experiments were performed to collect qualitative and quantitative data to evaluate the prototype system. Although it is difficult to determine a clear boundary between the user interface and the speech recognizer, it is important to evaluate the user interface and the speech recognizer separately, so that the qualitative and quantitative data gathered from the experiments are not mixed, leading to inconclusive results.

Thus, the experiments were designed as a classical "Don't mind the man behind the curtain" study. In this type of study, the user interacts with a system that is identical to the actual system except that the experiment is being controlled by someone other than the user. The man behind the curtain controls what is spoken as responses to the user's requests and changes the current screen to an appropriate graphical response. This method was used, so that the responses to the qualitative questions would not be biased by the accuracy of the speech recognizer.

To evaluate the system quantitatively, the program manager was instrumented with time segment metrics and data were collected for several performance metrics, including:

- Total time a participant took to complete all tasks
- Overhead of the DynaSpeak speech recognizer during live and batch recognition
- Runtime overhead of the program manager without DynaSpeak
- Spoken length of a request vs. processing time

Figure 6. Processing overhead per task



The results are shown in Figure 6. The time segment metrics represent the runtime complexity of the code associated with the speech recognition and processing. The amount of time taken by each segment adds to the delay associated with the user's request. If any of the time segments has a large duration, the user might become irritated. By measuring each segment separately, the bottleneck in the system can be determined.

The speech processing time increases with the size of the grammar. However, by means of a multiphase procedure that uses keywords organized and weighted by application relevance, the grammar size and the speech processing time can be improved. After live recognition, the system provides a keyword-associated request, which it processes for application weights and then reprocesses using an application-specific grammar, possibly more than once with different grammars. This procedure increases both the speed and the accuracy of the speech recognition, by decreasing the size of the grammar size in the initial phase.

An alternative approach (Kondratova, 2004) is to force the user to make repeated requests, possibly from a menu, with responses by which the device asks for the next step or for more information, so that the device arrives at a better understanding of the user's request. Such an approach introduces navigational complexity for the user. Reducing the speech processing time by creating a complex navigational structure is not the best way to improve usability of the system.

The speech recognizer works better for some speakers than for other speakers. The accuracy of the results can be improved by tuning the speech recognition parameters and enabling learning capabilities. However, the developers of DynaSpeak advise against modification of the speech recognition parameters and use of learning until a relatively high success rate is achieved. For appropriately selected users, quite good speech recognition and understanding can be achieved without using learning capabilities. However, speech recognition accuracy can only improve if voice profiling is combined with learning.

Ambient noise and microphone quality also affect speech recognition accuracy. The internal microphone in the OQO device is of rather poor quality. To ameliorate this problem, a Jabra© Bluetooth headset, was used to provide noise cancellation and reduce the distance between the microphone and the user's mouth. In addition, when the confidence score from DynaSpeak falls below an acceptable threshold, the program manager seeks confirmation from the user or asks for clarification. These mechanisms greatly improve the accuracy of the speech recognizer.

The accuracy of speech recognition is degraded when the grammar contains words that are phonetically similar. During preliminary experiments for the shopping application, we had problems recognizing differences between similar sounding requests like "Add lamb to my shopping list" and "Add ham to my shopping list." These problems arise particularly when users are non-native English speakers or when they have accents. Creating more specific requests can reduce the phonetic similarity, for example, by saying "Add a lamb shank to my shopping list" and "Add a ham hock to my shopping list." However, modifying requests in such a way is undesirable because the requests are then less intuitive and natural.

The location, weather, and stocks applications all use Web Services and require communication over the Internet and, thus, have longer application runtimes than the other Web Services. The location application is written in Java, which runs more slowly than C#. Both the weather application and the stocks application cache data associated with previous requests to take advantage of timing locality. Location requests are different because the caching of maps can involve a large usage of the memory, and users are not inclined to perform the same search twice. Memory is a precious commodity on a handheld device and needs to

be conserved; thus, the location application is coded so that it does not cache maps resulting from previous queries.

To evaluate the qualitative aspects of the system, we performed a user study with participants from diverse backgrounds of education, ethnicity, and sex. The user study was completed with 10 individuals performing 10 tasks resulting in 100 request results. The participants were given a questionnaire that assessed their general impressions about the prototype, with the results shown in Table 1.

After analyzing the averaged responses of the participants, we found several trends. The participants' scores are not strongly correlated with speech recognition accuracy. Participant G gave the system a high score, but was one of the two participants who encountered the most speech recognition problems. Participant B gave the system a low score despite good speech recognition.

The participants agreed that speaking to a mobile handheld device as if it were a human is not comfortable. It is difficult to get used to interacting with a computer that can understand tasks that would be commonplace for humans. The participants were relatively pleased with the GUI interface design and felt the system is relatively easy to use. However, the ease-of-use metric needs to be taken lightly. Ease of use can be assessed more concretely by measuring the number of times a user must repeat a command.

The scores for response appropriateness and relevance are high, indicating that the spoken responses of the applications were well crafted. The scores related to recommending the service to friends and daily life helpfulness are relatively high, from which one might infer that the participants would purchase a device providing the speech-enabled applications. However, this conclusion is not necessarily justified. The participants were not enthusiastic about having to pay for such a device or for such services. However, most participants in the study were quite pleased with the prototype system and found the user interface helpful and easy to use.

Table 1. Responses to the questionnaire

Questions	A	B	C	D	E	F	G	H	I	J	Mean
Was it comfortable talking to the device as if it were a human?	3	3	4	3	4	3	4	5	3	5	3.7
Was the GUI aesthetically pleasing?	5	4	4	5	5	5	5	5	5	4	4.7
Were the request responses appropriate and easy to understand?	3	3	5	5	5	4	4	5	4	4	4.2
Were the spoken responses relevant to your requests?	5	4	5	5	5	3	4	5	4	5	4.5
Was the system easy to use?	4	5	3	4	4	5	4	5	4	5	4.3
Do you think the services would be helpful in your daily life?	4	4	4	5	4	4	4	4	4	5	4.2
Would you recommend a system like this to your friends?	3	3	4	5	4	4	5	5	4	5	4.2
Would you buy the software if it were available for your phone?	3	2	4	5	3	3	5	5	3	5	3.8

FUTURE TRENDS

Integration of multiple applications, and multiple grammars, is not too difficult for a small number of applications that have been designed and programmed to work together, as in our prototype. However, future systems will need to support tens or hundreds of applications, many of which will be designed and programmed independently. Integration of those applications and their grammars will be a challenge.

Currently, speech-enabled applications typically use short commands from the human that are translated into navigational or functional operations. More appropriate is speech recognition technology that supports a more natural, conversational style similar to what humans use to communicate with each other (McTear, 2002).

A mobile device that listens to its owner continuously can provide additional services, such as populating the user's calendar. For example, when a user agrees to an appointment during a conversation with another person, the mobile device might recognize and automatically record the appointment, possibly confirming the appointment later with its user. Similarly, the mobile device might note that the user habitually goes to lunch with the gang at noon on Mondays, or that the user leaves work promptly at 5pm on Fridays. With existing calendar systems, the user often does not record appointments and other commitments, because it is too much bother using the human interfaces of those systems, greatly reducing the value of the calendar.

A useful capability of speech recognition systems for mobile devices is being able to recognize intonation and emotional overtones. "The bus leaves at 6" is, overtly, a simple declaration, but appropriate intonation might convert that declaration into a question or an expression of disapproval. Existing speech recognition systems do not yet recognize and exploit intonation. Similarly, the ability to recognize emotional overtones of impatience, uncertainty, surprise, pleasure, anger, and so forth, is a valuable capability that existing speech recognition systems do not yet provide.

Speech recognition requires a relatively powerful processor. Typical cell phones contain a powerful digital signal processor (DSP) chip and a much less powerful control processor. The control processor operates continuously to maintain communication with the cellular base stations. The DSP processor uses a lot of power and imposes a significant drain on the battery and, thus, analyzes and encodes speech only during calls. The DSP processor is capable of the processing required for speech recognition, although it might need more memory.

For mobile devices, battery life is a problem, particularly when speech recognition or application software requires a powerful processor. The limit of 2 hours of talk time for a cell phone is caused at least as much by the power drain of the DSP processor as by the power needed for wireless transmission. The DSP processor might be needed for speech processing for more than 2 hours per day. There are several possible solutions to this problem, namely, larger batteries, alcohol fuel cells, and DSP processors with higher speeds, reduced power consumption, and better power management.

Background noise remains a problem for speech recognition systems for mobile devices, particularly in noisy environments. The quality of the microphone, and the use of a headset to decrease the distance between the microphone and the speaker's mouth, can improve speech recognition accuracy.

CONCLUSION

The use of voice input and output, in addition to text and graphics and other kinds of audio, video, and tactile interfaces, provides substantial benefits for the users of mobile devices. Such multimodal

interfaces allow individuals to access information, applications, and services from their mobile devices more easily. A user no longer has to put up with the annoyances of a 3-inch keyboard, nested menus, or handwriting recognition, nor does the user need to have a tethered desktop or server computer in order to access information, applications, and services. Providing multiple ways in which the users can interact with the applications on mobile devices brings a new level of convenience to the users of those devices.

KEY TERMS

Global Positioning System (GPS): A system that is used to obtain geographical coordinates, which includes a GPS satellite and a GPS receiver.

Hidden Markov Model (HMM): A technique, based on a finite state machine that associates probabilities with phonemes, and pairs of phonemes, that is used in speech recognition systems, to determine the likelihood of an expression spoken by a user of that system.

Location Aware: An application that is based on a particular physical location, as given by geographical coordinates, physical address, zip code, and so forth, that determines the output of the application.

Mobile Device: For the purposes of this chapter, a handheld device, such as a cell phone or personal digital assistant (PDA), that has an embedded computer and that the user can carry around.

Multimodal Interface: The integration of textual, graphical, video, tactile, speech, and other audio interfaces through the use of mouse, stylus, fingers, keyboard, display, camera, microphone, and/or GPS.

Speech Recognition: The process of interpreting human speech for transcription or as a method of interacting with a computer or a mobile device, using a source of speech input, such as a microphone.

Speech Synthesis: The artificial production of human speech. Speech synthesis technology is also called text-to-speech technology in reference to its ability to convert text into speech.

Web Service: A software application identified by a Uniform Resource Indicator (URI) that is defined, described, and discovered using the eXtensible Markup Language (XML) and that supports direct interactions with other software applications using XML-based messages via an Internet protocol.

Chapter 8.20
Voice Driven Emotion Recognizer Mobile Phone:
Proposal and Evaluations

ABSTRACT

This article proposes an application of emotion recognizer system in telecommunications entitled voice driven emotion recognizer mobile phone (VDERM). The design implements a voice-to-image conversion scheme through a voice-to-image converter that extracts emotion features in the voice, recognizes them, and selects the corresponding facial expression images from image bank. Since it only requires audio transmission, it can support video communication at a much lower bit rate than the conventional videophone. The first prototype of VDERM system has been implemented into a personal computer. The coder, voice-to-image converter, image database, and system interface are preinstalled in the personal computer. In this article, we present and discuss some evaluations that have been conducted in supporting this proposed prototype. The results have shown that both voice and image are important for people to correctly recognize emotion in telecommunications and the proposed solution can provide an alternative to videophone systems. The future works list some modifications that can be done to the proposed prototype in order to make it more practical for mobile applications.

INTRODUCTION AND MOTIVATION

Nonverbal communication plays a very important role in human communications (Komiya, Mohd Arif, Ramliy, Gowri, & Mokhtar, 1999). However,

in telephone systems, only audio information can be exchanged. Thus, using telephony, the transmission of nonverbal information such as one's emotion would depend mostly on the user's conversation skills. Although the importance of nonverbal aspects of communication has been recognized, until now most research on nonverbal information concentrated on image transmission such as transmission of facial expression and gesture using video signal. This has contributed to the emergence of a videophone system, which is one of the most preferred ways to exchange more information in communication. Such services, however, require a wide bandwidth in order to provide real time video that is adequate for a natural conversation. This is often either very expensive to provide or difficult to implement. Besides, in a videophone system, the user has to be fixed in front of the camera at the correct position during the conversation, so that the user's image can be captured and transmitted correctly. This limitation does not happen in the normal telephone system.

Another approach is to use model-based coding (Kidani, 1999). In this approach, instead of transmitting video signals containing an image of the user, only the human action data such as the facial expressions, movement of the mouth, and so on acquired using a microphone, a keypad, and other input devices, are transmitted over the network. When these data are received by the receiver, the polygon coordinate data for each facial feature is recalculated in accordance with the displacement rules and the person's expression is synthesized.

Our approach is similar to the second approach in a sense that a synthesize image is used for the facial expression reconstruction at the receiver side. However, the difference is that only voice is transmitted and the emotion data is extracted from the received voice tone at the receiving side. This is based on the idea that, voice, besides for communication, it is also an indicator of the psychological and physiological state of a speaker. The identification of the pertinent features in the speech signal may therefore allow the evaluation of a person's emotional state. In other words, by extracting the emotion information from the voice of the speaker, it is possible to reconstruct the facial expression of that speaker. Thus, based on this voice-to-image conversion scheme, we propose a new system known as voice driven emotion recognizer mobile phone (VDERM), as seen in Figure 1. This system uses a voice-to-image converter system at the receiver side that identifies the emotional state of the received voice signal and selects the corresponding facial expression of that particular emotion from the image bank to be displayed. Using this approach, only audio transmission is required. Therefore, the existing second generation (2G) mobile phone infrastructures can be used. Another advantage is that the user does not need to be fixed in front of the camera during the conversation because there is no need for image transmission.

VOICE TO IMAGE CONVERSION

Referring to Figure 1, the voice-to-image conversion for this system is done at the receiving side. The conversion scheme can be divided into two parts: the emotion recognition and facial expression reconstructor. These two processes are done by the voice-to-image converter.

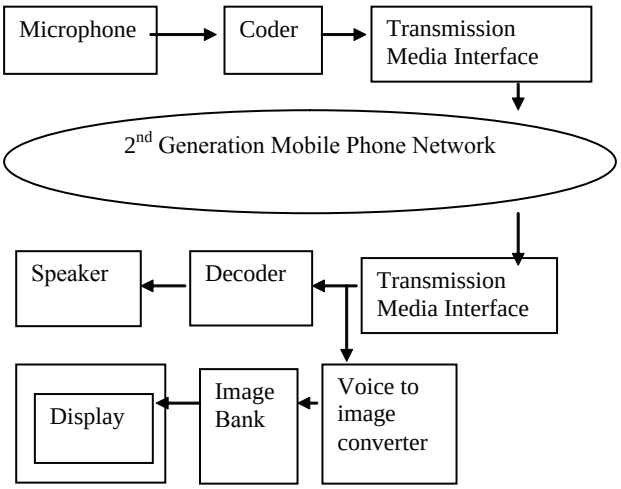
Emotion Recognition

Before we come out with the emotion recognizer design, first we have to deal with these three issues:

1. What kind of emotion to be recognized?

How many and what types of emotional states should be recognized by our system is an interesting yet difficult issue. Besides, there is no widely accepted definition and taxonomy of emotion; it

Figure 1. Basic block diagram of VDERM system



should also be kept in mind that a single emotion can be uttered in different ways. Scherer (1986) distinguishes different categories in a single emotion, for instance, the category "cold anger/ irritation" and the category "hot anger/rage." In our study, we have chosen to consider emotions as discrete categories (Ekman, 1973; Izard & Carroll, 1977; Plutchik, 1980). Six basic emotions defined by Cornelius (1996), that is, happiness, sadness, anger, fear, surprise, and disgust, have been chosen as the emotions to be recognized and reconstructed.

2. What are the features to represent emotion?

Determining emotion features is a crucial issue in the emotion recognizer design. This is because the recognition result is strongly dependant on the emotional features that have been used to represent the emotion. All the studies in this area point to the pitch (fundamental frequency) as the main emotion feature for emotion recognition. Other acoustic features are vocal energy, frequency, spectral features, formants (usually only one or the first two formants F1 and F2 are considered), and temporal features (speech rate and pausing) (Banse & Scherer, 1996). Another approach to feature extraction is to enrich the set of features by considering some derivative features, such as linear predictive coding cepstrum (LPCC) parameters of signal (Tosa & Nakatsu, 1996). Our study has adopted this approach and uses linear predictive analysis (Rabiner & Schafer, 1978) to extract the emotion features. A detailed analysis has been done on selected emotion parameters (Aishah, Izani, & Komiya, 2003a, 2003b, 2003c). Based on these analyses, a total of 18 features (as in Table 1) have been chosen to represent the emotion features. The 18 features are pitch (f_0), jitter (jt), speech energy (e), speech duration (d), and 14 LPC coefficients (a_1- a_{14}). The LPC coefficients are included because we intended to use LPC analysis for the extraction algorithm. Besides,

Table 1. Speech features and description

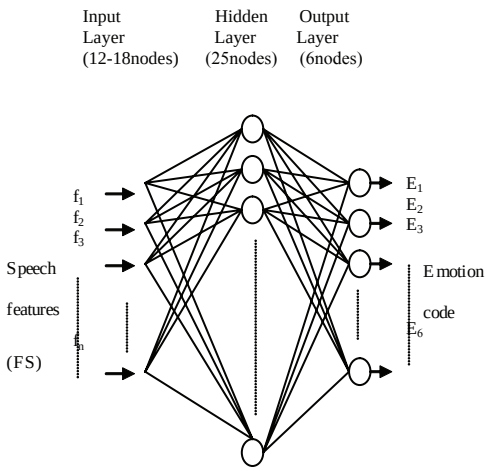
No	Feature	Symbol used	Description
1	Energy	e	Average energy of the speech signal
2	LPC Coefficient	$a_1, a_2, a_3 \ldots a_{14}$	The weighting coefficient used in the linear prediction coding analysis.
3	Duration	d	Duration of the speech signal
4	Pitch	f_0	Fundamental frequency (oscillation frequency) of the glottal oscillation (vibration of the vocal folds).
5	Jitter	jt	Perturbation in the pitch

it represents the phonetic features of speech that are often used in speech recognition

3. What technique to be used for recognition?

There are many methods that have been used for emotion recognition/classification. For instance, Mcgilloway, Cowie, Douglas-Cowie, Gielen, Westerdijk, and Stroeve (2000) have compared and tested three classification algorithms, namely linear discriminant, support vector machine (Schölkopf, Burges, & Smola, 1998), and quantization (Westerdijk & Wiegerinck, 2000). Others are using fuzzy model, K-nearest neighbors, and neural networks (Petrushin, 1999). Among all, perhaps the most common and popular method of emotion recognition is neural network. However, the configuration of the networks differs from one researcher to another, as discussed by Morishima and Harashima (1991), Nakatsu, Nicholson, and Tosa (1999), Petrushin (1999), and Tosa and Nakatsu (1996). In this article we applied neural network configuration as described by NETLAB (Nabney, 2001) for the recognition technique. It uses a 2-layer multilayer perceptron (MLP) architecture with 12-18 elements in the input vector which correspond to the speech features, 25 nodes in the hidden layer, and 6 nodes in the output layer which correspond to the six elements of output vector, the basic emotions. This configuration is illustrated in Figure 2.

Figure 2. The neural network configuration



The weights are drawn from a zero mean, unit variance isotropic Gaussian, with variance scaled by the fan-in of the hidden or output units as appropriate. This makes use of the MATLAB function RANDN and so the seed for the random weight initialization can be set using RANDN ("STATE," S) where S is the seed value. The hidden units use the TANH activation job.

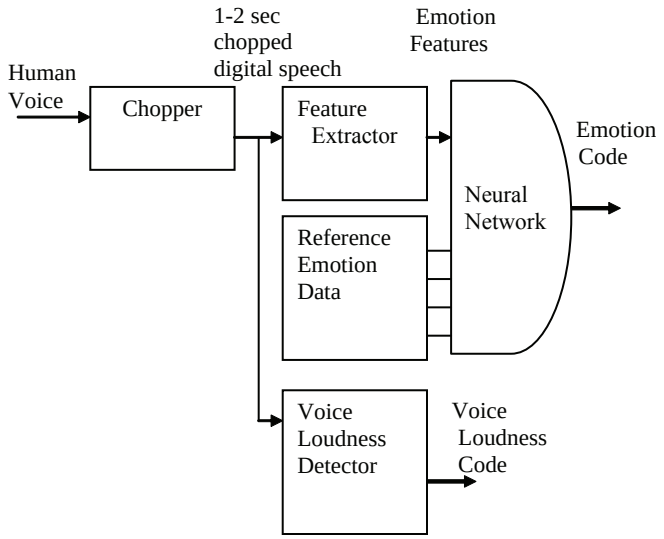
During the training, the weights are adjusted iteratively using a scaled conjugate gradient algorithm (Fodslette, 1993) to minimize the error function, which is the cross-entropy function with softmax as the output activation function. In our experiment, 1,000 iterations are found to be sufficient to achieve an acceptable error rate.

Once our network is trained, we test the network using test samples and calculate the recognition rate. The speech features from test samples are fed into the network and forward propagate through the network to generate the output. Then, the resulted classification performance for the predicted output (output which is recognized by the network) is compared to the target output and displayed in the confusion matrix table. A detail discussion on the result of our experiment using neural network approach is presented by Aishah, Azrulhasni, and Komiya (2004). It is found that an emotion recognition rate of 60% is achievable using the neural network method and this result is sufficient based on a human recognition rate done on the same experiment data.

Once we have dealt with the above issues, we come out with an emotion recognition process as shown in Figure 3. Basically this part extracts the emotion content of the speech received from the transmitting user and recognizes it. In addition to emotion, we also identify the voice loudness level of the speech so that it can be used to control the opening of the mouth shape on the facial images later on.

First, the continuous human voice would be chopped into 2 second speech and undergo preprocessing where it is normalized by its maximum amplitude and the d.c. component is removed.

Figure 3. Block diagram of emotion recognition process



Next, it will go through a feature extractor process where the sample is segmented into 25 msec frames with a 5 msec overlap. LPC analysis is then carried out on these series of frames and the outputs are the 14 LPC coefficients, first reflection coefficient, and energy of the underlying speech segment and energy of the prediction error. Using these outputs, the remaining parameters are determined in the next stage. Speech duration is determined by first classifying the speech frames as voiced or unvoiced using the prediction error signal by simply setting a threshold. The first frame that is classified as voiced will mark the beginning of the speech period. After the beginning of the speech period, if the frame is classified as unvoiced for few consecutive frames, the speech is decided to be ended. The length of the speech period is calculated to get the speech duration. The pitch period for each frame that lies within the speech period is calculated using the cepstrum of the voiced prediction error signal. If an abrupt change in the pitch period is observed, that period is compared to previous pitch periods, and then low-pass filtered (or median filtered) to smooth the abrupt change. With the perturbation in the pitch, jitter is then calculated using pitch perturbation order 1 method, which is obtained by taking the backward and forward differences of perturbation order zero. All the calculation is developed using MATLAB with the use of speech processing and synthesis toolbox (Childers, 1999).

It should be noted that the features extracted so far are based on frame-by-frame basis. As a result, for each sample, it might have many sets of features depending on the number of frames that lie within the speech period of that particular sample. Since we need to standardize the entire sample to have only one feature set, the average of each feature over the frame size is calculated for each sample. The final feature set (FS) for sample n (s_n), consisting of 18 elements is given as

$$\text{FS for } s_n = (e_n, a_{1n}, a_{2n}, a_{3n} \ldots a_{14n}, d_n, f_{0n}, jt_n) \quad (1)$$

On the other hand, a copy of the chopped digital speech will be sent to the voice loudness level detector to detect the loudness level. The outputs of this emotion recognition process are emotion code (from the neural network) and voice loudness code (from the voice loudness detector).

Facial Expression Reconstructor

Figure 4 shows the process involved in facial expression reconstructor. First, the code processor will process the emotion code and voice loudness code and convert it to the equivalent image ID used in the database. The code conversion would also depend on which image the user would like to use represented by the model ID.

For the first prototype of this system, we have used Microsoft Access for the image database and Visual Basic is used as its interface. For each images stored in the database, there is a unique ID tagged to it. The ID is generated sequentially by the system automatically whenever an image is uploaded into the system. Before starting the conversation, the user must first choose which image to be used (for example, male or female model) and once the image is selected, the code processor will make necessary conversions on the received emotion code and voice loudness code to match the ID range for that image. Accordingly, the ID number is sent to the image database, and the image with a matching ID retrieved from the database is then displayed. This image database by default consists of 24 images of female models and 24 images of male models. For each model, the images consist of six basic emotions and each emotion has four levels of voice presented by the opening of mouth shape. In addition we also include different eye shapes which are generated randomly among the four levels.

System Interface

Figure 5 shows the main interface of the facial expression reconstructor system. It consists of a

Figure 4. Block diagram of facial expression reconstructor process

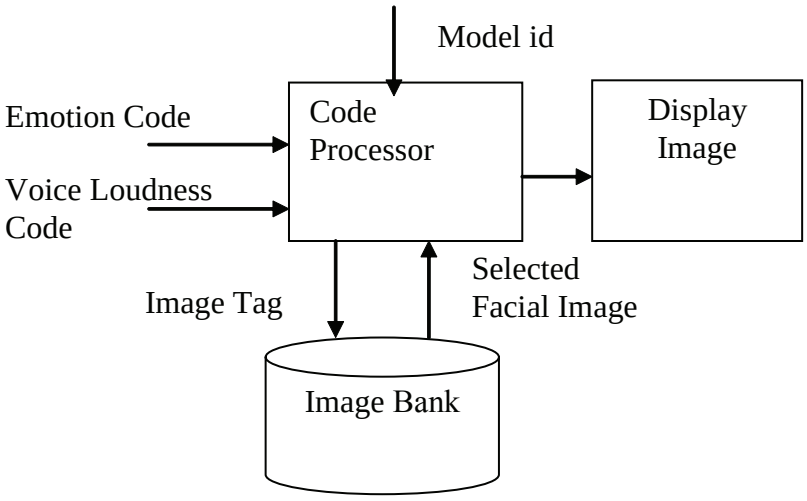


Figure 5. Main interface of facial expression re-constructor

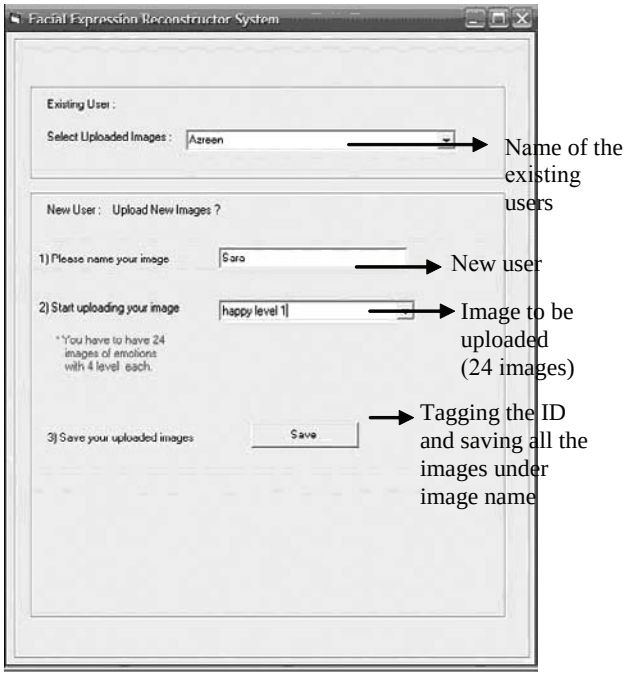
display displaying the facial expression images and buttons for the user to select which model to be used, such as a male or female model. If they click on the "Male" button, the image of male model will be used. Similarly, when they click on the "Female" button, the female image will be displayed, as shown in Figure 5.

In addition to the prestored male and female model, users can also use their own images by using the "Upload own Image" button. When a user clicks on it, a second interface that is shown in Figure 6 will pop up. It has the buttons that show the name of the users that already have their own images uploaded and stored in the system. For new users who want to upload their own image, they can type in their name or any name that will represent them. This will act as the name of the folder which will store all the 24 images of the person. Then users can start to upload their own images which consist of all the six basic emotions which are happiness, sadness, anger, disgust, fear, and surprise with four levels each. The user must have all the 24 images in order to have a complete set of images. At this section, once the user chooses, for example "happy level 1," it will pop up a dialog box and the user will search and upload the appropriate image and save it. Each of the newly uploaded images will

Figure 6. Interface for uploading new image



be tagged accordingly with an image ID. After all the 24 images are completely uploaded, users have to click on the "Save as" button for the final step. This is the part where all the images will be put under the folder that has been created and the image ID range for this image name will be recorded and saved for future use. Once this is done, the user can use it by selecting the name from the "uploaded images" box.

EVALUATIONS

Preliminary Evaluations

There are three preliminary evaluations conducted in the process of completing our first prototype. The details of the evaluations are discussed in the next subsections.

PE I

The main objective of this evaluation are to select good quality of emotional voice samples for our voice database. The samples would later be used for training and testing our neural network model for emotion recognition. The second objective is to see how accurate a person can recognize the emotion content in a speech by just listening to the speech/voice. The result of this human recognition rate will be used as a guide for the recognition rate expected to be achieved by our recognition system later on. The evaluation involves two steps:

1. Collecting voice sample

Four short sentences frequently used in everyday communication that could be expressed in all emotional states without semantic contradictions

are chosen as the utterance. The sentences are: "Itu kereta saya" (In Malay language), "That is my car" (In English), "Sekarang pukul satu" (In Malay language), and "Now is one o'clock" (In English). Two languages are used for the utterance because we want to compare the emotional parameters for both languages and determine how much difference in language could influence the way emotions are expressed. Then, we asked acting students to utter the same utterance 10 times, each for different emotional states and also in neutral voice as a reference.

2. Listening test

The emotionally loaded voice samples are then randomized and each sample is repeated three times within short intervals followed by a 30 second pause. The series of stimuli are presented via headphones to 50 naive listeners to evaluate the emotional state within seven categories: happiness, sadness, anger, fear, disgust, surprise, and not recognizable emotional state.

PE II

The main objective of this evaluation is to detect the most appropriate and highly recognizable facial expressions images that can be used to represent the six basic human emotions for our image database. Another objective is to see how accurate humans can detect emotion based on only the facial expression images, without any audio support. The evaluation also involves two steps:

1. Image collection

For this purpose we have selected three male models and three female models. The facial expressions of the six basic human emotions, which are happy, sad, angry, surprise, disgust, and fear, portrayed by each model are captured, focusing from the neck and above. The background used is a blank white wall with natural daylight so that the model image is clear and focused. The size of images taken are 1000x1600, using a Sony Cyber shot digital camera. The images are then cropped and resized to 6x4 inches size.

2. Viewing test

All the images are randomized and presented to 20 assessors consisting of 10 males and 10 females volunteers. The images are displayed for 2 seconds each with a 3 second gap between images. The assessors are asked to identify the emotion of the given images and then the recognition rates for each image and emotion state are calculated.

PE III

The main objective of this experiment is to verify that the combination of voice and image can improve the capability of humans to correctly recognize an emotion and thus justify the importance of a VDERM system.

For the purpose of this evaluation, we have selected three emotional voice samples for each emotion and matched it with the corresponding images. Around 50 assessors have participated in this evaluation and the recognition rate is calculated and analyzed. They are also asked to answer some questions to reflect the importance of voice and facial expressions in effective communications.

System Evaluation

The main objective behind this system evaluation is to evaluate the reliability and feasibility of the idea of a VDERM system using the developed prototype. This evaluation tries to get some feedback from the user on how efficient the system can improve the message conveyed during a conversation, is the displayed image synchronous with the intended emotion of the speech, and how can the interface be further improved according

to the user's specification. Responses from the assessors on their perception of the VDERM system are important to determine better research direction for the proposed system. For this initial evaluation, the prototype of the VDERM system has been implemented into a personal computer. The coder, voice-to-image converter, image database, and system interface are preinstalled in the personal computer.

Experimental Set-Up

A subjective assessment technique is chosen due to the practicability and suitability. A total of 20 assessors consisting of experts and nonexperts take part in the evaluation test. Assessors first went through a demo on the idea behind a VDERM system and followed with a briefing about the evaluation form contents and the way evaluation must be done. The list of evaluation item is given in Table 2. A sample of a 40 second one-way conversation was played, first using a female model and then a male model with a 15 second gap. The facial expression images switched between different emotions and mouth shapes depending on the emotion content and loudness level of the conversation at every two seconds. Assessors were asked to pretend that they were having a conversation with the model and then they were required to rate the quality of each of the evaluation items based on the scale given in Table 3. Then, they were asked to give comments and suggestions on the grade given for each evaluation item.

Table 2. List of evaluation item for preliminary system evaluation

No.	Item

2	Image accuracy in displaying the facial expression
3	Image synchronization with the speech
4	Features and interface
5	Quality of the images
6	Emotion recognition capability

Table 3. Grading scale

Scale	Quality
0	Worse
1	Average
2	Good
3	Best

RESULTS AND ANALYSIS

PE I

From this evaluation, we have achieved an average recognition rate of 62.33%. The average recognition rate is in line with what has been achieved by other studies using different languages (i.e., around 55-65%) (Morishima & Harashima, 1991; Nakatsu et al., 1999; Petrushin, 1999). This result has proven that even a human is not a perfect emotion recognizer. This is because recognition of emotions is a difficult task due to the fact that there are no standard ways of expressing and decoding emotion. Besides, several emotional states may appear in different scale and have very similar physiological correlates, which result the same acoustic correlates. In an actual situation, people solve the ambiguities by using the context and/or other information. This finding indicates that we shall not try to have our machine to achieve a perfect recognition rate. The human recognition rate is used as a guideline towards achieving the satisfactory rate for computer recognition.

Table 4. Confusion matrix table of PE I

Intended emotion	Response from the assessors					
	Happy	Sad	Anger	Disgust		Surprise
Happy	**68**	2	5	8	12	5
Sad	7	**61**	9	3	18	2
Anger	4	21	**46**	11	7	11
Disgust	4	1	5	**77**	7	6
Fear	9	12	5	15	**54**	5
Surprise	8	1	5	8	10	**68**

Table 4 shows the confusion matrix table that is achieved in PE I. The confusion matrix table of PE I suggests how successful the actors were in expressing the intended emotion and which emotions are easy or difficult to realize. We see that the most easily recognizable emotion based on this experiment is disgust (77%) and the least easily recognizable category is anger (46%). A high percentage of confusion occurs in sad-fear (18%) and anger-sad (21%).

A total of 200 samples which have the highest recognition rate are selected for each emotion. This has resulted in 1,200 samples for the whole voice database.

PE II

From the results in Table 5, it is concluded that among all the facial expression images of emotion, the easiest expressions detected by assessors is happy. This is due to the fact that happiness is the most common emotion shown publicly by humans and it is usually expressed with a smile and bright eyes. Thus it is not difficult to identify

Table 5. Confusion matrix table of PE II

Intended emotion	Response from the assessors					
	Happy	Sad	Anger	Disgust	Fear	Surprise
Happy	**90**	0	0	0	0	10
Sad	0	**80**	0	5	15	0
Anger	0	0	**60**	35	0	5
Disgust	0	0	35	**40**	0	15
Fear	0	5	0	5	**60**	30
Surprise	10	0	0	0	30	**60**

Table 6. Summary of facial gestures according to emotions

EMO-TION	FACIAL GESTURES
Happy	Smile, laughter
Sad	Down turned mouth and eyes, tears
Angry	Eyes bulging, mouth tighten
Disgust	Wrinkled nose, lowered eyelids and eyebrow, raised upper lip
Fear	Eyes squinting
Surprise	Eyes bulging, raised eyebrows, mouth shaped "O"

a happy face even without an audio support. The least recognizable emotion is found to be disgust (40%) and it is often confused with anger (35%). This is because the expressions for both of these emotions are very similar, shown through the "hostile" face; the tight line of the mouth and the squinting eyes. Another thing to note is that based on image, the diversification of confusion in a particular emotion is less compared to recognition based on voice only.

We have also done some analysis on the images which are highly recognizable, and together with the feedback from the assessors, we have identified some main facial gestures which significantly contribute to the recognition of certain emotion. This is summarized in Table 6. Based on the results of Human Evaluation II, we have identified 1 male and 1 female model which have the highest recognizable images to be our model. Then the images of six emotions are recaptured according to the significant facial gestures and each emotion is further developed into four levels of mouth shape, resulting in 24 images for each models.

PE III

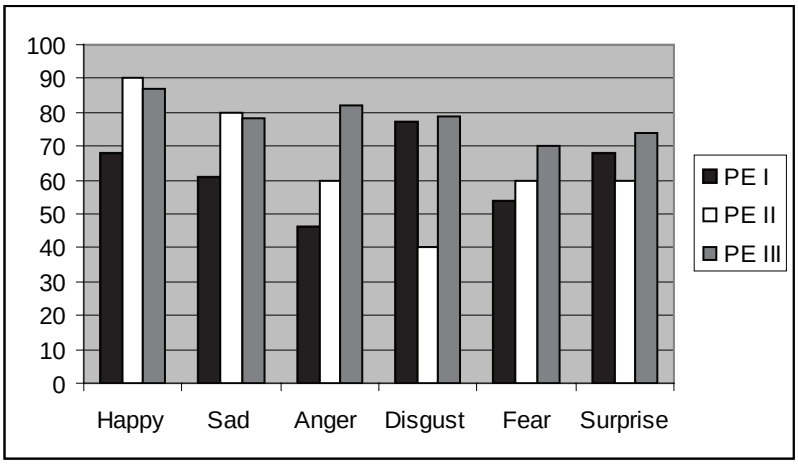
From the confusion matrix Table 7, it is illustrated that the recognition rate for all emotions are quite high (70%-87%). According to assessors, fear is difficult to recognize (70%) compared to other emotions as the expression accompanying the voice of fear can be confused or sad. The most easily recognizable emotion is happy (87%), as the cheerful voice is supported by the smiling face.

Figure 7 compares the recognition rate achievable in all the three preliminary evaluations. On average, PE I achieved an average recognition rate of 62.33% with individual recognition rates ranging between 46% and 77%. PE II shows a slightly higher average recognition rate (65%) compared to PE I with a wider range of individual recognition rate (between 40% and 90%). A significant increase in average and individual recognition is clearly seen in PE III with an average recognition of 78.3% and individual recognition concentration between 70% and 87%. The results have clearly illustrated that PE III has the most percentage of correctness in emotion identification by assessors. This shows that combination of both what we hear (voice) and what we see (image) can greatly improve human capability of identifying the emotions. Thus, this result has justified the importance of the proposed system, which is to combine the image and voice to improve the naturalness and efficiency of telecommunication.

Table 7. Confusion matrix table of PE III

Intended emotion	Response from the assessors					
	Happy		Anger	Disgust		Surprise
Happy	**87**	0	0	0	0	13
Sad	0	**78**	0	0	22	0
Anger	0	0	**82**	18	0	0
Disgust	0	6	15	**79**	0	0
Fear	0	16	7	0	**70**	7
Surprise	26	0	0	0	0	**74**

Figure 7. Comparison between recognition rate achieved in PE I, II and III



On top of the recognition rate presented above, below we have summarized the findings that were collected from the asessors feedback.

1. Comfortable way to express and detect emotion

For emotion expression (Figure 8), 45% agreed that facial expression is the most comfortable way to express emotion, followed by voice tone (34%), and body gesture (21%).

The pattern is also the same for emotion detection (Figure 9) but the percentage for emotion

detection by facial expression is higher at 64%. This is followed by voice tone at 30% and body gesture at 6%.

2. Medium of communication

The results in Figure 10 show that telephone/ mobile phones are the most popular medium of communication nowadays with 48% as the majority, followed by Internet instant messenger (40%) and short messages service (SMS) (12%). This is because telephones are the most convenient and widely available medium of communication.

3. Importance of audio (voice tone) and video (facial expression) information for effective communication

The result in Figure 11 show that 98% agreed that both audio and video information are important for effective communication.

4. Reliability of emotion extraction from voice

The result in Figure 12 show that 64% have agreed that it is reliable to extract emotion from voice.

The result of human emotion recognition based on audio, video, and both highlights two important points. The first one is that emotion recognition is a difficult task and humans can never perfectly recognize emotion. This is because the way people express and interpret emotion might differ from one another, even though some researches have found that it does follow some standard pattern (Cosmides, 1983). The second point is that the ability of humans to correctly recognize emotion is increased to more than 70% when both audio and video information of the speaker are present.

It is also found that facial expression is the most comfortable way for people to express and detect emotion during communication. Thus the presence of facial expressions is very important in communication.

Figure 8. Comfortable way to express emotion

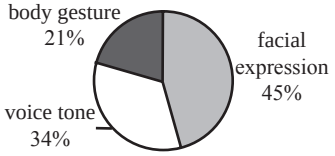


Figure 9. Preferable way to detect emotion

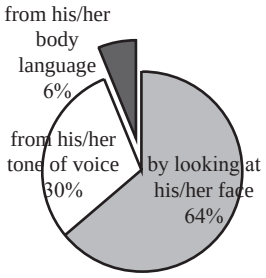

Figure 10. Popular medium of communication

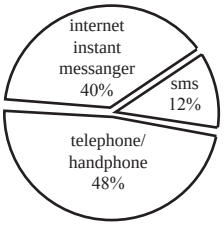

Figure 11. Importance of audio (voice tone) and video (facial expression) information for effective communication

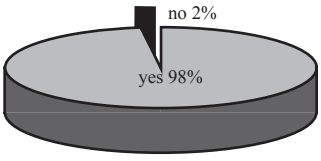

Figure 12. Reliability of emotion extraction from voice

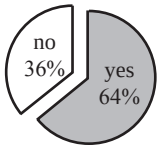


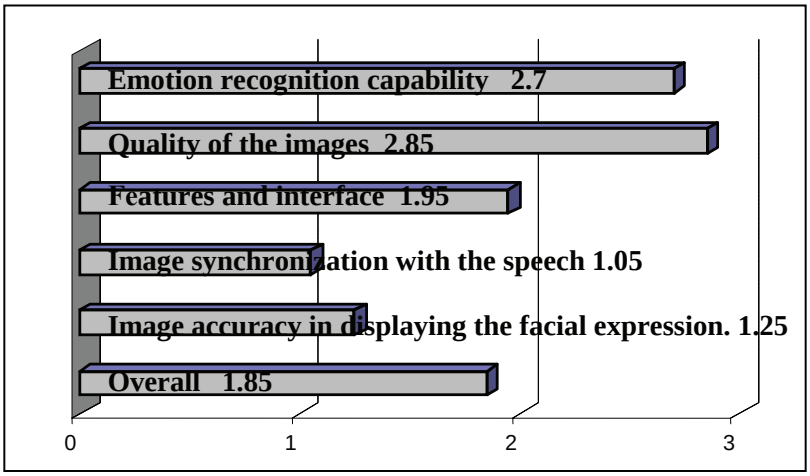
Overall, the results of the preliminery evalutions highlight the importance of facial expressions in providing effective communication, and thus, it is very important to incorporate facial expressions in today's telephone system, as proposed in the VDERM system.

System Evaluation

An average score of each evaluation item was calculated and a bar chart was plotted to represent the results. The preliminary evaluation results are illustrated in Figure 13. From the chart, it is shown that the quality of the images used have the highest scale average with value of 2.85. This shows that the assessors are happy with the quality of the images used, which are clear and focused. This level of quality is not achievable when using a videophone system because the image is transmitted real time and thus subject to transmission quality and the position of the user during the conversation. The next highest scale average is on the emotion recognition capability. This is expected because this system provides both audio and visual information of the speaker which help the assessors to recognize the emotion more easily compared to just having the audio information, as in the case of normal phone conversation.

The third highest score item goes to features and interface design. Overall the assessors think that the system is user friendly because the system has a straight forward design that does not confuse a user, even if the user is not familiar with a computer system. Another point is that the interface buttons have direct and clear instructions to be followed by the user. Moreover, most of the assessors find that the feature to upload their own image is very interesting because it gives the user customization to make the system personal to them. However, a few are concerned with the image database size as more images are being uploaded, and the difficulty of having a set of 24 images before can use their own image. Some also suggested that the features can be improved by having interactive interface using JAVA and personalized skins for the background.

Figure 13. Result for system evaluation



The average score for overall system performance is 1.85. Many of the assessors agreed that this system can improve the efficiency of telecommunication system because the presence of both audio and visual have given them more clues on the emotions being conveyed. Besides they also found that having both elements made the conversation more fun and interesting. In addition, the automatic detection of emotion from voice is also an interesting attempt because most of the currently available chat/Web cam applications require the user to manually select the emotion to be/being conveyed. However, the assessors believed that the system still has a lot of room for improvement, especially in the aspect of image accuracy and image synchronization.

As shown on the chart, image accuracy in displaying the facial expression and image synchronization with the speech has an average score of less than 1.5. The main reason for this is that the level of image for each emotion currently used is only four, which has resulted in switching between images which seems less smooth and the lip movement does not appear to be synchronized with the speech. This is an important issue to address because if the images and voice do not synchronize, the user might not be able to catch the emotion being conveyed. By having more levels for a particular emotion, switching between different emotion states can be smoother, thus the user can have more time to identify the emotion of the images.

FUTURE DESIGN ISSUES

The main improvement in the system is concerned with the accuracy of the images being displayed. Since our intention is to provide real time visual images as in video conferencing, it is very important that the image switching appears to be smooth and synchronized with the speech and emotion content of the speech. One simple modification is to have more levels to represent the voice loudness. However, increasing the level means increasing the number of images needed and consequently can increase the size of our database, which is not desirable.

One possible solution to this is to have the personal images of the user deleted after the call is terminated. However, the problem with this is that the user might need to upload their image every time before the user can start a conversation, which can be time consuming and not practical.

The other advanced alternative for facial expression reconstruction is to use a 3D artificial face model, which can generate facial expressions based on the coded emotion, instead of switching between still pictures. This method is more advanced and complicated but it can provide a more natural facial expressions. For this method, software will be used to convert a person's photo into a face model and a program will be developed to generate the facial expressions on the model based on the emotion code and voice loudness. Using this technique, there is no need for a large image database, which might be more appropriate for application on a mobile phone.

CONCLUSION

In general, based on the results, the system has achieved its main objective, that is, to improve telecommunication by providing voice together with facial expressions and provide an alternative to videophone systems. However it still has a lot of room for improvement in the aspect of interface design and the accuracy of the images being displayed. The evaluation that we have conducted so far was tested on a personal computer. In order to apply the system on a mobile phone, the issues pertaining to the image database size should be thoroughly dealt with.

ABSTRACT

Aphasia is a speech disorder usually caused by stroke or head injury (Armstrong, 1993). Related communication difficulties can include word finding, speaking, listening, writing, and using numbers (FAST, 2004). It is most commonly acquired by people at middle age or older, as a result of stroke or other brain injury. Speech and language therapy is "the process of enabling people to communicate to the best of their ability" (RCSLT, 2004). Treatment, advice, and support are provided based on assessment and monitoring activities that conventionally are carried out in face-to-face sessions. This chapter considers issues in providing technology to continue to support aphasic patients between therapy sessions, through multimedia applications for drill-and-practice in vocalizing speech sounds. Existing paper therapy aids are generally designed to be used under the guidance of a therapist. Multimedia applications enable people with aphasia to practise spoken language skills independently between sessions, and mobile multimedia speech and language therapy devices offer still greater promise for blending treatment and support into an aphasic person's daily life.

INTRODUCTION

Current trends in the demography of the developed world suggest that increased longevity will lead to a larger population of patients needing rehabilitation services after a stroke (Andrews & Turner-Stokes, 2005). An essential part of these services is speech and language therapy (SLT) (NHS, 2004) to enable the patient with aphasia to return to the community and live as independently as possible. At present, even in countries where SLT is a well-developed profession, resources in terms of staff and mobile communication devices for loan are limited (Harris, 2004). Therapy generally cannot offer a "cure" for aphasia; instead, the goals of therapy are to support the person in capitalizing on remaining language ability, regaining as much of their prior language skills as possible, and learning to use compensatory methods of communication.

This chapter describes the existing therapy methods based on paper materials and mobile electronic devices commonly called augmentative and alternative communication (AAC) devices and proposes the development of software solutions which could be delivered flexibly via readily available mobile devices such as personal digital assistants (PDA) used in a stand alone mode or via Internet delivered services. These could be designed to suit the needs of not only the patients and their carers, but also those of the professional speech and language therapists (SLTs) who could tailor and monitor the treatment more regularly than presently possible. The process of creating and evaluating prototype applications with SLTs is described and recommendations are made for the direction of future research and development.

CONVENTIONAL SPEECH AND LANGUAGE THERAPY AIDS

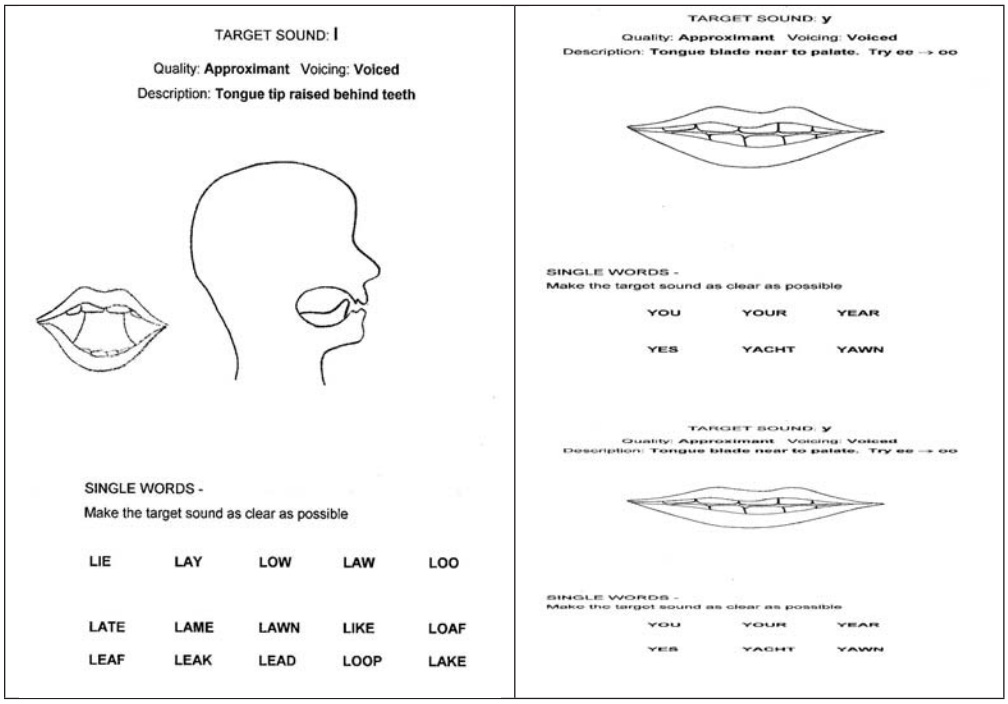
Paper-based representations of lip and tongue positions for sounds are a venerable and common speech and language therapy aid. These are generally provided as line drawings, illustrating how specific sounds are made; the aids are intended for use both during therapy and in practice sessions outside of therapy. Figure 1 is typical of this type of therapy material.

While useful, this paper-based material has obvious limitations. The line drawings are static, and fail to accurately represent the movements necessary to make speech sounds (Harris, 2004). No spoken explanation or auditory reinforcement is possible—this would be provided by the speech therapist, during a session or by a carer. The latter would be untrained and may in certain circumstances reinforce errors. Aphasia frequently includes impairments in processing written language. Notice that these sheets include a relatively large amount of text—some of it possibly redundant ("Make the target sound as clear as possible"), some echoing in a less accessible form the line drawings ("Tongue tip raised behind teeth"), some vocabulary that is highly technical and likely to be unintelligible without training in speech therapy ("Quality: Approximant"). These issues can put off users from practising on their own, or can diminish the effectiveness of their practice.

The problem of confining effective therapy to formal, therapist-facilitated sessions is significant. A meta-analysis of evaluations of aphasia therapy (covering 864 individuals) concluded that concentrated therapy over a shorter period of time has a greater positive impact on recovery than less concentrated therapy over a longer period (Bhogal, Teasell, & Speechley, 2003). Clearly, face-to-face therapy with a trained therapist is the ideal, but availability is a bottleneck for aphasia treatment. Even in an economically well-developed country such as the UK, there are only, on average, 0.6 SLTs per 10 beds in rehabilitation units (Andrews & Turner-Stokes, 2005)

Early attempts at software support for SLT have had variable and limited success (Burton, Meeks, & Wright, 1991), in part because of hardware and

Figure 1. Sample paper-based therapy material



development environment limitations, and in part because there was a limited body of knowledge about the accessibility and usability for aphasic users. As will be discussed next, these barriers are less significant today.

MOBILE DIGITAL COMMUNICATION AND THERAPY TOOLS

Two broad categories of software speech and language therapy applications exist for use by people with aphasia:

- **Drill-and-practice software** that offer instruction and the opportunity to practise language skills. A typical application contains a variety of standard instructional material, and also allows the therapist to record additional words, phrases, or other utterances for playback and practice by the patient.
- **Compensatory software** that provides alternative means for the user to communicate, for example by producing audio, image-based, or written messages for the user. The user selects an appropriate message for playback or display in situations where communication is required—for example, when dealing with commercial organizations or government departments.

Both types of software now commonly include multimedia facilities. Earlier applications were severely limited in scope by tiny (by today's standards) storage available with standard PCs. Larger hard drives, DVD storage, and high-bandwidth Internet connections now support applications that can include video and audio display of large practice sets, audio recording of user practice sessions (for both immediate feedback to the user, and for later evaluation by the therapist), icons for navigating the interface, and speech generation facilities to reduce the need for pre-recording messages used to communicate with others.

Both application categories also have potential to increase their effectiveness by moving to mobile devices. Compensatory communication devices, or AAC devices, would obviously be more useful if they were small and light enough to be easily carried along into conversational situations—so that the user does not have to struggle with a laptop while shopping. Similarly, portable drill-and-practice devices would allow users to practise frequently during the odd breaks that are inevitably sprinkled through the day, and would allow patients to continue therapy when away from home for more extended periods such as vacations (Glykas & Chytas, 2004). However, current commercially-available portable AAC devices are special-purpose pieces of equipment; as such, they are considerably more expensive than standard PDAs and mobiles, even with monochrome screens. As a consequence, portable AAC tools are not widely used at present.

Moving implementations of AAC tools from special-purpose hardware to standard, general purpose devices holds promise for supporting the development of cheaper, more readily available devices. Recent PDA models are now viable platforms for speech and language therapy applications. Screens, while small, now have a high enough resolution to provide a crisp display of images and line drawings. Memory remains relatively small but is sufficient to store a selection of drill exercises and common conversational phrases and sentences. Indeed, there is evidence that including smaller datasets makes these applications more, rather than less, usable. Experience with information display for non-literate (Deo, Nichols, Cunningham, Witten, & Trujillo, 2004) and communication impaired users (Dunlop, Cunningham, & Jones, 2002) emphasizes that these users primarily depend on browsing rather than search to navigate the application. Browsing forces the user to rely on memory to find, and return to, desired documents or exercises, and a too-rich set of options to select from can quickly lead to frustration when the user cannot remember the location of a previously retrieved item or cannot efficiently navigate to a new item. For this type of application, it appears that the limitation is the capacity of the user's memory, rather than the device's storage. Some patients with aphasia have short-term memory problems so the retrieval issue is even more important.

ACCESSIBILITY ISSUES

Funding is one significant accessibility issue for speech and language therapy tools. The cost of a device, software, and training often puts these applications out of reach for many individuals, and local health authorities have extremely limited supplies, if any, for loan (Harris, 2004).

It is clear, however, that the provision of a mobile speech and communication aid is not sufficient in and of itself to ensure that it will be used, and useful, in everyday settings. One study in the UK and the Netherlands demonstrated that, for carefully selected patients, these applications can effectively support therapy—however, 11 of the 28 patients did not choose to use the device in non-clinical settings (van de Sandt-Koenderman, Wiegers, & Hardy, 2005).

Accessibility can also be limited by interface and interaction design. People with aphasia often experience difficulties with reading and understanding text, and may experience a related visual

problem that makes reading tiring and error-prone. Investigations into accessibility and usability of software for people with aphasia have produced several recommendations for effective applications (FAST, 2004; Queensland Aphasia Groups, 2001a, 2001b):

- Interfaces should include few, and simple, words, in large print.
- White space should dominate—text should be as widely spaced as possible.
- When possible, include images and icons to explain the words, or to serve as substitutes/reminders of the words.
- Text, images, and functionality should be pertinent to the needs and interests of people with aphasia—not to therapists, caregivers, or members of the medical community. Note that a separate interface may be required for these other potential users of the application (for example, to allow therapists to create new drill exercises).
- Interaction should not be keyboard dependent, and should be designed for ease of use with alternative input/output devices such as screen readers and switches. Aphasia frequently makes construction of text via the keyboard difficult or impossible, and the condition causing the aphasia (for example, a stroke) may also create physical disabilities that hamper keyboarding.
- Applications should be interactive rather than static information displays, and if possible should support the user in expressing his/her own thoughts (rather than literally putting words into the user's mouth with a standard set of utterances).

DEVELOPMENT OF MULTIMEDIA PROTOTYPES

Two prototypes of a speech therapy tool, SoundHelper, were developed. The tool is intended to support drill and practice in phonetic sounds. In both versions, the user selects a sound for practice, and the sound is represented both through audio and through a demonstration of mouth placement for producing that sound. The design of these prototypes was informed by a speech and language therapist and by an expert in interaction design. On the advice of the therapist the prototypes focus on vowel sounds, as these are the first sounds which are usually addressed in therapy for a person newly aphasic after a stroke or other brain injury.

The SoundHelper interface is organized around the familiar and common "folder" metaphor. The top level of the system presents the folder "containing" all of the exercises (Figure 2a). At the next level, folders are also used to organize and group different classes of sound—for example, exercises pertaining to vowels (Figure 2b).

The two demonstration displays implemented are an animated line drawing (Figure 3a) and a short video clip (Figure 3b). The prototypes were developed using Adobe Premiere to capture the video and Macromedia Flash MX to compress the video clips. Macromedia Flash was then used to rotoscope or motion capture the lip and facial movements, to produce the animated line drawings. The vector graphics produced will automatically rescale to fit a browser window. On a PC monitor, this allows a life-size representation of the animation, creating a "mirror" effect for the user. Automatic scaling also allows the display to be easily ported to a smaller screen such as that of a PDA or other mobile device (Figure 4).

Simplicity and limited use of text are the guiding principles of the interface design, in conformity to interface design principles for users with aphasia. No text or keyboard input is required to use the system. The circular buttons are labelled with speech utterances—in this case, vowel sounds. When the user clicks on a button, an audio recording of the sound is played in synch with the video or animation. If the user cannot read even this limited amount of text, then the

Figure 2a. Top level of SoundHelper

Figure 2b. A second-level folder, organizing exercises based on vowel sounds

small number of options helps the user to rely on memory to locate the desired sound. The feedback from selecting a sound is immediate—the audio and visual demonstration—and so this high degree of interactivity supports learning and exploring the application. A black circle around the selected button highlights the current sound, and the appropriate phonetic text is displayed on the folder tab in large font (here, "ay") to provide emphatic feedback. The pause button allows user to develop their understanding and practise the different stages of making the sound.

Note that the video and animation only include the lower part of the face. This further reduces the cognitive load for users by eliminating distracting elements such as the expression of the eyes (Bulthoff, Graf, Scholkopt, Simoncelli, & Wichmann, 2004).

A more complex exercise or interface would require additional support for the user. One possibility is to provide audio "mouseover" help—that is, for mouse pointer contact with screen elements to trigger the playing of an audio file containing spoken help or reading out button labels, rather than the conventional display of help text (Deo et al., 2004). Textual mouseover displays are unlikely to be useful for users with aphasia—the text is by default displayed in a small font, and users with aphasia frequently find it difficult to interpret text.

The audio in the prototypes was recorded by a female speaker of a similar age to the median age of the intended evaluators of the prototypes (female speech and language therapists). The video prototype is based on a native English speaker of the same gender, race, and median age as the intended evaluators. The importance of matching audio and visual display to the intended user is discussed in the next section.

The prototypes were evaluated in an empirical study with 20 professional speech and language therapists in the southwest region of England. The evaluators rated both prototypes as very easy to use and as potentially more helpful to their patients than conventional paper-based handouts. Eighteen of the evaluators (90%) could identify current patients who might benefit from using this type of application—but only if it were to be made available on a portable device (17 evaluators; 85%). This study was part of an action research

Figure 3a. Prototype line drawing, pronouncing "ay"

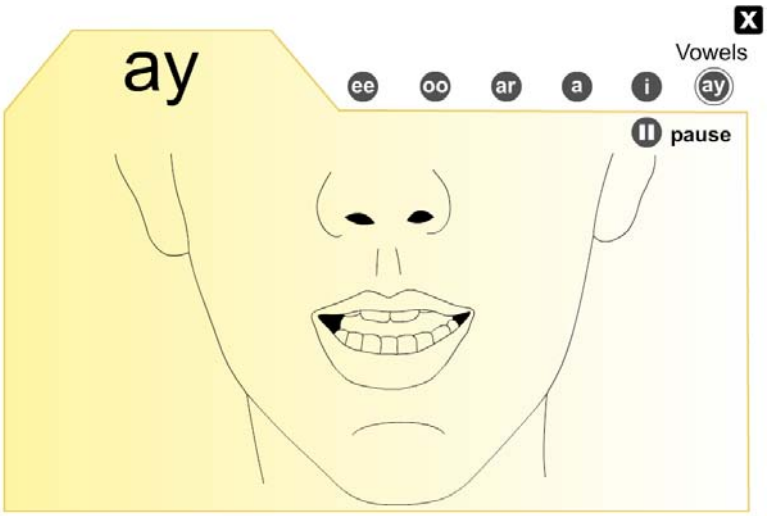


Figure 3b. Prototype video, pronouncing "ay"

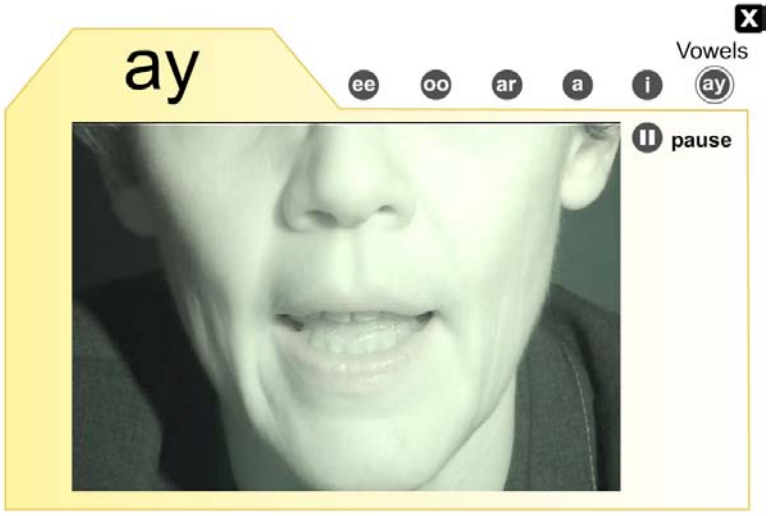
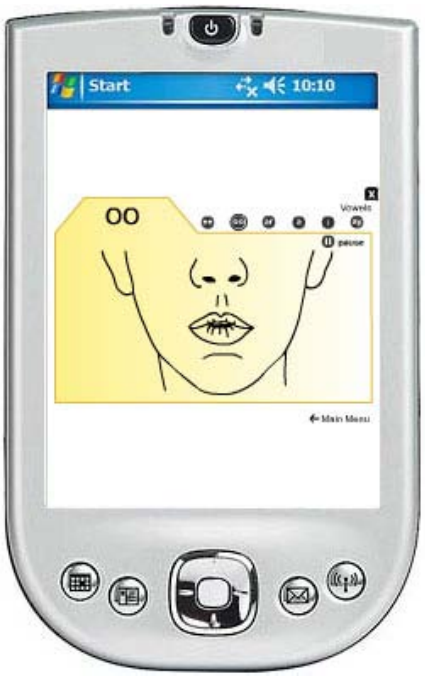


project with the next stage being a refinement of the application to include 3D representations of the formation of sounds made inside the mouth and, provided ethical approval is granted, evaluation with a set of case studies is planned.

Figure 4. Sample display as a PDA application



SOCIO-CULTURAL ISSUES IN SPEECH AND LANGUAGE THERAPY APPLICATION DESIGN

Voice characteristics of the speaker featured in speech and language therapy software should ideally match those of the user in significant factors such as age, cultural group, and sex, as it is commonplace for users of communication aids to adopt the intonation and accent of the recorded voice (Harris, 2004). Recording the voice of a family member or friend is therefore usually avoided, as this can cause confusion for the patient.

The user's cultural membership can also have a significant effect on the choice of voice for a speech and language therapy tool of this type—it is important that the user be able to understand and identify with the accent of the audio. The user's nationality or culture can also affect the example sounds and words to include in the application. New Zealand English provides extreme examples of the accommodations in the exercises that must be possible; for instance, for a New Zealand user the phrase "fish and chips" would be a poor choice for practice in the short i sound as the Kiwi accent usually renders that as "fush and chups", and vowel neutralisation causes word pairs such as "full" and "fill" to be indistinguishable when spoken. Alternative pronunciations are generally seen by individuals as incorrect, with their own pronunciation viewed as the only correct way to speak (Maclagan, 2000). Users are unlikely to accept software that uses pronunciation they regard as "not speaking properly".

The user should also be able to identify with the speaker images, or at the very least should not feel excluded or offended by them. Again, this points to the need to tailor this type of speech and language therapy software to groups of users. A system based on realistic videos, such as the prototype in Figure 3b, obviously would require a greater degree of customisation. The line drawings of Figure 3a are suitable for a broader intended target audience—the animation is less identifiable by gender, race, and age (though not entirely generic). The creation of icons and representations of humans that are completely culturally neutral is not possible, but guidelines exist to reduce the level of cultural bias (del Galdo & Nielsen, 1996).

Note that these problems with providing appropriate matches to the user in voice and appearance exist for face-to-face therapy as well. Again, New Zealand provides an extreme case in point: New Zealand speech is so distinctive that it can be difficult for New Zealand born therapists to work in other English-speaking countries, and conversely New Zealand born clients report difficulties in understanding non-New Zealand therapists (Maclagan, 2000). The creation of multimedia therapy tools offers the chance to provide tailored examples and exercises to an

extent rarely possible in conventional therapy, where the number and age/sex/cultural distribution of therapists is rarely large enough to allow a patient to choose a therapist exactly matching his or her own background.

INTERNET-ENABLED THERAPY

The Internet has been suggested for use with speech and language applications in two ways: for delivering therapy and for monitoring therapy. Internet delivery of exercises is highly appealing for the use of the prototypes on mobile devices, as this could address the problem of relatively small memory availability on PDAs and other mobiles: exercises could be streamed in on demand. This solution may be too financially costly for many users, however. Alternatively, selected exercises might be periodically uploaded via a "sync" with a PC or other larger storage device. Remote monitoring possibilities include storing logs or summaries of user sessions in central database, for therapists to later examine (Glykas & Chytas, 2004). This type of monitoring does not provide the capacity for the immediate feedback that is available in a face-to-face session, but does allow the therapist to maintain awareness of the user's progress between sessions. Therapist feedback could be delivered via the Internet, or the monitoring could be used to inform the next face-to-face session.

The potential of Internet-enabled therapy devices for supporting between-session monitoring or care raises several concerns—most notably, that the increased use of technology in therapy could raise barriers between the therapist and patient, and could lead to the dehumanisation of the professional-patient relationship. Issues of legal liability for the efficacy of this more attenuated version of treatment have yet to be fully resolved. There is also a perceived risk that other areas of care could suffer if scarce health funds are diverted to this potentially costly form of telemedicine (including cost of devices, development of multimedia therapy software, tailoring of software to individual patients, Internet transmission costs, therapist time devoted to remote monitoring, and so forth) (Rosenberg, 2004).

A more general anxiety voiced by the therapists evaluating the prototypes of the earlier section, *Development of Multimedia Prototypes*, is that of the ability of therapists to customize therapies as delivered via the Internet, or for that matter through any multimedia application or device. Therapists perceive that therapy as delivered conventionally is tailored to an individual's needs, although it is difficult to see how the current generic paper-based materials are personalized to any great extent. Clearly these new technologies have raised expectations, and any system deployed would have to provide facilities for therapists to inspect, approve, and modify the therapy support being offered.

FURTHER DIRECTIONS FOR RESEARCH AND DEVELOPMENT

The preliminary evaluation with SLTs illustrated that although they were positive about the application, there are clear limitations to the prototypes already developed. In particular, SLTs identified the need for context words and illustrations for each phonetic sound and help with the production of sounds involving movements within the mouth. For example, the plosive sound "t" where the tongue is placed against the front upper palate. There is also a need for an SLT to be able to tailor the learning materials for a particular patient and monitor their progress.

It should be possible to create 3D models of the mouth rather than the vertical sectional drawings currently used. The model could then be rotated by the patient to see different viewpoints. The context words and images could be addressed relatively easily by building up a repository, or digital library, of learning objects which could be chosen by the SLT or added to by them in the

same way that current mobile AAC devices can be tailored for a particular patient. A suitable system for this needs to be developed in a cooperative design project with SLT users which will allow the SLT to create drill and practice exercises, capture video and audio together with a further system to allow a patient to upload video of their progress for the SLT to monitor. The technical problems of suitable codecs to compress video need to be addressed although some of this work has already been done in the context of British Sign Language learning (Andrews, 2005). The advent of full 3G services on mobile devices could be utilised to develop a fully mobile therapy service. However, the ergonomics of the devices used will need careful design as it is widely accepted that current mobile phones are unsuitable for use by elderly users due to the small size of their interaction buttons (Goodman, Dickinson, & Syme, 2004).

There are, therefore, a range of future directions in which research in mobile multimedia applications to enable people with aphasia to practise spoken language skills independently between sessions could progress. Blended approaches to therapy are likely to be positively received by SLTs to enable them to support patients with aphasia more flexibly than at present.

Chapter 8.22
A Proposed Tool for Mobile Collaborative Reading

Jason T. Black
Florida A&M University, USA

Lois Wright Hawkes
Florida State University, USA

ABSTRACT

This chapter presents a tool for collaborative e-learning using handheld devices that incorporates pair communication via text and speech input. It discusses the current state of e-learning for mobiles and illustrates the lack of such tools in reading comprehension domains. It then describes the tool development as a model for interface design, communication strategies, and data manipulation across mobile platforms. It is argued that such a tool can enhance e-learning among children, due to freedom of movement and variety of input (text and speech). The design is centered on a proven paper-based collaborative learning methodology which should strengthen its effectiveness. A paper prototype test that assisted in determining optimum interface layout and confirming that speech input was preferred among children is described. The system was developed and designed using creative strategies for interface layout and data manipulation. Lessons learned and plans for additional research are discussed.

INTRODUCTION

Collaboration is an important aspect of today's educational learning environment, and the infusion of technology has given rise to various studies in the area of computer-supported collaborative learning (CSCL), computer-supported collaborative work (CSCW), and computer-supported intentional learning environments (CSILE) (Jones, Dircknick-Holmfield, & Lindstrom, 2005; Scardamelia & Bereiter, 1996). The systems developed through these studies have been effectively implemented to produce major gains in comprehension of material in the math and science curriculum, but have yet to explore these benefits when applied

to domains which are not math and science. The investigation of how to efficiently apply emerging technology in such environments is resulting in innovations in a wide range of systems and platforms, including handheld computers and other mobile devices.

One of the disciplines that could benefit significantly from such advancements is reading comprehension. At the present, it is apparent that reading comprehension has emerged as a major problem area in American society (Vaughn, Klingner, & Bryant, 2001). It is important to note that there are several reading comprehension tools available for the desktop platform, but the problem becomes enormous when attempting to transfer such applications to the handheld platform. There are many obstacles that must be overcome, such as limited screen real estate, smaller memory capacity, smaller processing power, and limited and often more difficult input mechanisms (such as stylus and virtual keyboard). These obstacles have led developers to steer away from this handheld platform and instead focus on the more common personal computer environment. Yet, research is indicating that the handheld computer is becoming a more viable and attractive platform due to the smaller cost, portability, durability, and increasing advancements in wireless technology (Soloway & Norris, 1999). Additionally, many scientists are investigating more innovative ways to utilize this technology and make it much more readily available to children from diverse backgrounds (MIT Media Lab, 2006).

Question-answer relationships (QAR) is a very successful learning methodology for developing reading comprehension skills (Royer & Richards, 2005; Outz, 1998; Raphael, 1986). QAR has been beneficial to educational research in that QAR not only has demonstrated the ability to improve comprehension skills of student participants, but has also shown effective implementation of peer-assisted learning strategies. There has not been a significant effort to place QAR in a computerized reading environment, and it is worth investigating whether applying QAR to a handheld learning environment would produce a more efficient reading comprehension software platform.

Thus, this chapter makes the case for collaborative reading comprehension on a mobile platform by illustrating the absence of current research in this area, describes a paper-prototype study for an interface model for collaborative reading comprehension, and then presents a handheld tool supporting collaborative reading using text and speech communication. The tool is designed using QAR as a foundation, and presents a model for development of such systems on mobile platforms. An emphasis is placed on speech input, which can further increase the robustness of user input and collaboration as a result, particularly when implemented for children.

RELATED WORK

Mobile Collaboration in Learning Environments

The explosion of mobile learning (m-learning) in educational environments is largely due to the massive influx of these portable devices in society, and more directly, in the classroom. Mobile learning takes place when users communicate wirelessly via handheld devices (phones, Personal Digital Assistants (PDAs), tablets, etc.) in the process of learning—in other words, learning that takes place with the aid of handhelds (Attewell, 2005). And, since collaboration is a natural and significant extension of a robust learning environment, it is natural to consider ways to facilitate mobile cooperation in learning activities. The mobile environment is rich with a plethora of communication tools (chat, instant messaging, shared workspaces, e-mail, and voice input/out-

put) that make collaborative work a simple and efficient endeavor (Issacs, 2002). It is essential for researchers to explore a wide range of scenarios employing these tools in an effort to improve student learning outcomes. This research takes a look at one such endeavor.

Question-Answer Relationships

Several programs have been implemented that have shown significant development in reading comprehension skills. Among the most successful is Question-Answer Relationships (Royer & Richards, 2005; McIntosh & Draper, 1996; Raphael, 1986), which has been shown to be a particularly effective supplement to a classroom reading program. Question-Answer Relationship teaches students to read by recognizing relationships between questions and possible sources of information, either in the text or in the reader's background. In this technique, readers are asked to read a passage and answer questions about what was read. Then, readers are required to identify the category to which each question belongs: Right There Questions (answer is explicitly in the text), Think-and-Search Questions (answer is implicitly in the text), the Author and You Questions (the answer requires you to use inference to arrive at the answer), and On Your Own Questions (the answer is entirely based on your background knowledge). Several studies have shown that students were capable of generating and answering questions that enhanced their comprehension and led to independent processing and development of knowledge (Royer & Richards, 2005; Outz, 1998). Yet, these approaches have not been incorporated in a desktop or handheld reading comprehension learning environment. It is worth investigating whether doing so will create an electronic comprehension tool which can reinforce through practice, techniques introduced by a human teacher, and hence address these issues (Vaughn, Klingner & Bryant, 2001).

Speech Recognition in Mobile Environments

This increase in the use of mobile devices has created an environment where various types of users are interacting, and as a result, researchers must utilize the full suite of modalities (or modes of input) to facilitate communication (Nanavati, Rajput, Rudnicky, & Siconni, 2006). Almost all mobile devices are equipped for voice input, making speech recognition a viable means of capturing data. In many cases, to compensate for the limited memory and power on these smaller devices, a form of *distributed speech recognition* is implemented (Schmandt, Lee, Kim, & Ackerman, 2004). In such an environment, speech is captured on the mobile device and sent across a wireless network to a server, where processing is done. The translated text is then returned to the device for use. While there are many issues to consider when utilizing this strategy (such as quality of speech, network traffic, noise, etc.), the scope of this work is to present an interface mechanism for facilitating voice input in a mobile collaborative learning session.

OVERVIEW OF SYSTEM DEVELOPMENT

Discussion of Paper Prototype Testing

Paper (also called "low-fidelity" or "lo-fi") prototyping is an interface development strategy that utilizes paper-based designs of the system and interactions with potential users with such system to arrive at an optimum design plan (Snyder, 2003). In paper prototype testing, users are asked to interact with the paper-based interface on a series of popular system tasks, with a designer playing the role of "Computer." The "Computer" mimics the actions and sounds of the system while

the user progresses through these tasks, and user choices and behavior are recorded. After the session, the user is questioned in order to learn his or her cognitive processes in making decisions and the results of these answers are used to design and implement the user interface, complete with modifications indicated in the test. The attempt here is to create a "living" prototype—one that is changing to better fit the designs and recommendations of the testers involved—in order to eventually obtain the optimum design methodology for all involved. Researchers have demonstrated the benefits seen in the application of paper prototype testing—preemptive user feedback (changes are suggested before development has begun), rapid iterative development (changes can be incorporated "on the fly"), and enhanced developer/user communication (Snyder, 2003).

Participants in Paper Prototype Test

To obtain a model for interface development, a paper prototype study was conducted (Black, Hawkes, Jean-Pierre, Johnson, & Lee, 2004) involving elementary school students from a local after-school center. Five students were selected based on their background with computers (two had had experience with handhelds, one had moderate experience, and two had no experience), and age (two were in grade 2, two were in grade 3, and one in grade 4). This number of subjects is consistent with Snyder's recommendations of effective numbers of subjects in such tests, which is recommended to be between five and seven (Snyder, 2003; Nielson and Landauer, 1993). Subject #1 was a fourth grader who was a good and constant reader, and was the only subject that had familiarity with a PDA, though not much exposure. Subject #2 was a third grader who had some experience with computers, but was not a strong reader. Subject #3 was the youngest of the group, a second grader with very little computer experience, but was a strong reader. Subject #4 was a third grader who had very little computer experience and was also not a very strong reader. Subject #5 was the oldest of the group, a fourth grader who had computer experience, but was having trouble reading at grade level. All of the students had some exposure to the basic features of a computer application—buttons, passwords, pointers, and so forth—and were eager to participate in the study.

Apparatus

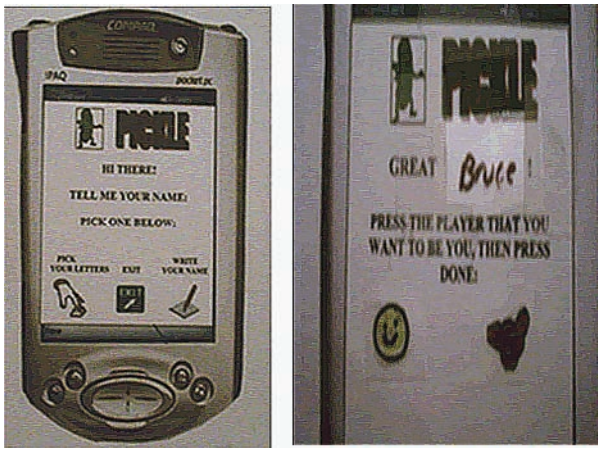
The test was designed using the iPAQ ™ PDA as a model (see Figure 1). A picture of the device was taken, and then scanned and printed, so that the actual size and shape of the PDA could be used in the testing. Then, cut-outs of screens to be presented (as well as buttons, menus, scroll bars, etc.) were designed and used as interchangeable interface components to be presented to subjects during completion of tasks.

Test Design

Screen mock-ups of five basic tasks were created: 1) logging into the system and selecting a partner (for collaboration), 2) reading a story, 3) answering questions, 4) e-mailing the teacher for help, and 5) chatting with their partner. Researchers participated in the test in the roles of the computer (one person transitioned screens as the computer would), and observers (who took notes on user actions and tendencies). Subjects were tested in 30 minute sessions, with two tests conducted on a given day, as recommended by Snyder (2003). During a test session, each subject was introduced to the concept of the test and why it was being conducted. They were then seated at a desk with the "computer" present as well, and the observers looking on.

Each subject was then asked to complete each of the tasks listed, with the question-answer exchanges following each task. After the completion of all five tasks, the subjects were thanked for

Figure 1. Image of mock-up of screen used in Paper Prototype test



their participation and were free to leave. Notes from observers were discussed between tests, and modifications were proposed for future tests.

Test Results

During testing, three of the five subjects preferred writing on the screen for input as opposed to the other presented forms (keypad or speech). This was not surprising, since most of these students had little computer experience, and thus would be more comfortable writing (at least initially) than using the innovative input techniques presented. Of the two subjects that did choose to pick their letters using the keypad, one subject (Subject #4) had trouble navigating the keypad and began pressing buttons on the bottom of the PDA instead of the buttons on the keypad. This action resulted in "beeps" from the "computer" indicating actions that were not allowed by the system, which further confused the subject. But what was gathered from this subject was that he was familiar with the GameBoy™ handheld computer games, which use the directional keypad on the bottom of the device for manipulation of all applications. Research has shown that students' experiences with such gaming devices can be very productive design focuses for scientists developing applications for handhelds. All subjects except Subject #1 had trouble finding the icon during the player selection phase. All subjects had no trouble finding and clicking the "Done" button.

All subjects reported no problem in reading text on the small, handheld-mock up screens, and indicated that the process was enjoyable. Subjects also had no problem transitioning between screens (done by clicking NEXT and BACK buttons presented on the interface). The chat/messaging task perhaps provided the most valuable feedback. All except one subject chose to speak their message instead of the other input features (Subject #4 chose to use the keypad in all writing tasks), indicating that this will likely be a popular feature of the application. The voice input would be very helpful to younger readers, who often do not have the ability to type or write

well, and would prefer an alternative to user input. However, two of the subjects were confused when faced with the submenu that appears with the speak feature, which asks them to click on the microphone to begin speaking and to click send to transmit the message. The two subjects were unsure what buttons to press and when to press send. But once this was explained, the subjects were able to complete the task. The reliance on speech for inputting validated an earlier hypothesis which suggested that due to the age of users and simplicity of the action, speech would be chosen more often by younger users (Black, et. al, 2004). The results of this test were then used as blueprints for actual screen development.

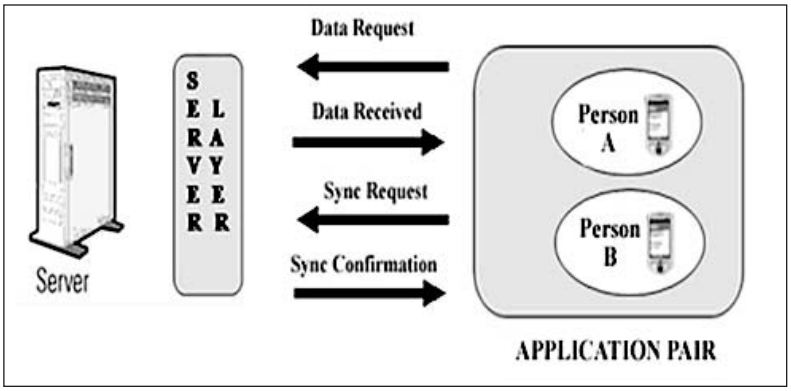
System Overview

The interface layout was developed using an application development toolkit that allows for rapid prototyping of applications for mobile devices and provides a series of emulators that can present a simulation of the application running in or on its intended device platform. Upon completion, the finished application can easily be ported to the actual target device, and run as needed. The prototype uses a client-server approach for wireless communication (SEIR-TEC, 2002), which implies that devices are served by a central access point or base station, and communicate with the central access point through the network (see Figure 2). In this configuration, users will send computation-intensive operations to the more powerful server (such as the speech recognition) for remote processing and then download application-specific tasks to the handhelds (Omojokun, 2002). And, when usage has completed, the handhelds synchronize with the server, uploading user session information back to the server for storage in the database.

System Design

The process flow of the application is constructed on the question-answer relationship collaborative reading model mentioned earlier. In implementing this model, students read a passage on the handheld display and then are asked to answer questions which are downloaded from the server about the text just read. Once questions are answered correctly, students must then identify the type of questions that are presented (Right There, Think and Search, Author and You, or On Your Own), based on Raphael's Taxonomy of Questions

Figure 2. High-level system architecture



(Raphael, 1982). Students work individually on reading and question-answering tasks, but are allowed to collaborate during periods of reaching a consensus on the correct answer (collaboration is "turned on" when questions are answered incorrectly). Students communicate by chatting with their partner as needed, as well as utilizing a shared workspace for group reflection. Students can also record personal notes in the personal journal as they progress through the lessons, as well as interact with the instructor through e-mail. All of the activities will be done on the PDA, with lessons downloaded wirelessly from the server to the PDA as requested, and student progression data being stored on the system server.

The application makes use of the standard high-level interface components—forms for user fill-in, canvases for drawing and painting of both text and images, and checkboxes and radio buttons that register user action. The screen is also touch-sensitive, allowing for stylus input at various points on the interface. Textual input is

Figure 3. Introductory screens for user input

Figure 4. Story and question-answering screens

handled via stylus, keypad, and both the letter recognizer and transcriber (written text using the stylus), and is processed by device standards. The letter recognizer allows users to, after a training period, write letters using the stylus, which are "recognized" by the system and translated to their typed form. The transcriber works similarly, with users writing letters on a text pad, these letters are converted to their typed format. Both have significant learning curves on their usage, but once mastered can serve as very convenient input techniques. Figure 3 shows the initial user login screen (which is essentially a form with text fields and images that behave as buttons), a screen for selecting an icon (which uses images painted on a canvas), and a screen for registering that the user is ready to begin (again, images painted on a canvas).

These screens also make use of the standard mobile menus, which appear at the bottom of the screen just above the device soft buttons. Users can activate these menus either by clicking on them with the stylus or pressing the corresponding soft button.

The story and question screens are similarly done, with images and radio buttons dominating the device display. The user is also presented with icons at the bottom that allow him or her to activate the various system functions (using the *Diary* for personal reflection; sending a message to the instructor, using the *Group Workbook*, etc.). These are illustrated in Figure 4.

Collaboration Components

The collaborative features implemented in the prototype system are shared workspaces, e-mail messaging, personal reflection, and chat services. The shared workspace is implemented as a *group workbook* that is visible to both participants of a team. Each user sees an up-to-the-second image of the workbook and changes made (by entering data in the workbook) are broadcast to each user's device. The system synchronizes access to this feature, locking it while it is being written to so that changes can be implemented before additional writes are allowed. The workbook enables each user to jot down notes that may assist the team in answering questions in later sessions. These notes can be entered either by keypad or writing (textual) or by speaking the text (voice) (see Figure 5).

Figure 5. Workbook and diary screens

The personal journal is used for reflection as the user moves through sessions. Each journal is seen only by that user and is updated upon request. All additional entries into the journal are added to its previous contents, similar to writing in a paper journal. The entries are recorded by being sent to the server for storage upon completion of the session period. Upon the next login, the current contents of the journal are sent to the client should any new entries be desired. As with all other methods of input, the user can provide the journal entry either through textual or voice input (see Figure 5).

The system allows users to send e-mail to the instructor in the event that assistance is needed. The sending of the message is implemented by the client sending a message to the server and the server forwarding that message to the instructor's e-mail address. A record of the transmittal is also stored by the server for reporting purposes. Again, the message can be either in the form of text or voice input (see Figure 6).

Chat Service

The chat service is implemented similar to the standard chat service hosted by any Internet service provider. The system registers that a user wishes to chat and sends a message to the user's partner that he or she wishes to chat. Once a confirmation has been received by the partner, the chat session begins, with users typing in messages (or entering them via voice input) and those messages being displayed on the screen. These messages are also recorded by the server for reporting. When chat is no longer desired, the user indicates this and the session resumes from its previous point. The chat provides the users the opportunity to reach a consensus on certain learning tasks and facilities the peer-tutoring methodology, both techniques present in successful collaborative environments (see Figure 6).

Speech Recognition Strategy

Since the system is designed to be adaptable to a variety of environments, it may be the case that the keypad, recognizer, and transcriber are too complex in a setting of younger users. Thus, the system also allows for Speech Input, where users are allowed to speak their messages into the system, and these messages are converted to text and displayed on the screen (or sent via e-mail if needed). This is done to take into account that

Figure 6. Chat and help screens

younger users may not be good typists or even know how to spell well, but may still wish to enter data.

The ability to provide speech input for users is a major component of the architecture. The current literature does not indicate any use of this feature in studies involving handhelds and collaboration. In the math and science-centered applications, input is often simple, with users asked to select items or to enter numbers as part of equations. This poses a problem in non-science domains, where input may often be sentence-structured and much more verbose. There needs to be an additional method of providing this type of input, and speech or voice input fills this need adequately.

The application environment implements a strategy for dealing with speech input and/or speech output. The system receives the data sent to the server and runs it through a speech recognizer program to produce written text. The written text is then sent back to the application to be displayed on the screen. The server is responsible for handling speech requests sent by the Diary, Help, Journal, Workbook, and Chat applications and funneling them to the appropriate mechanism.

DISCUSSION

It is important to note that while this work demonstrates that this type of interface can indeed be developed for mobile devices, the actual testing of this system in a live classroom will occur in additional studies. The researchers are currently working with school teachers to develop a curriculum model that can incorporate such a system, in an effort to determine if its application would be effective in improving reading skills of younger students. This is a daunting task, but one that holds much promise for both computer scientists and educators as well.

Prior to implementation of a complete system, there are issues to be examined related to data management, data modeling, logging of system and user operations and functions, and server-side management. There are also issues regarding data security and reliability of data to consider. And, while the screen size is likely appropriate for beginning readers and younger users, there may be an issue regarding displaying of material on the device for more advanced users. The current model only displays one page of data at a time, and pages are turned and not scrolled. More advanced users would likely want to remain on a page and simply scroll down or up to view additional material. This would call for some device other than the PDA, or at the very least, in a revision of the type of screen layout. However, the focus of this project is younger children, and thus the designed system is very appropriate.

CONCLUSION AND FUTURE WORK

The development of this collaborative mobile learning system and its implementation on the actual target handheld devices is an indication that this type of architecture is possible and proved both challenging and rewarding. Each of the desired screen designs was capable of being constructed in the chosen language and the interaction between screens was simple to maintain. The communication between devices and between device and server was easily maintained via a wireless network and access to a server machine. Using a Web server allows for testing and demonstration of the system in any environment where wireless Web access is available.

The implementation of QAR in a collaborative platform was also successful. As mentioned earlier, QAR requires individuals to work in pairs, which is accommodated by the interface in this system. QAR also expects students to not only read, but also answer questions and then identify categories of questions. The multiple screens developed in this system also accomplish this task. And, since QAR is an extremely successful

tool (in a paper-based environment) in enhancing reading comprehension skills, it is rewarding to note that the interface presented does not take away from the functionality and robustness of the methodology, but stresses it very well.

Speech input is a very significant feature of any collaborative environment and the tools included in the system provide for that capability. Students are able to speak words of communication with partners, and these words are indeed translated and presented on the screen. This is a major component since mobile devices often have challenging input techniques (using a stylus for large volumes of text can be very cumbersome). This system addresses and solves this issue as well.

The next step is to implement this system in the actual classroom, with the assistance of grade school teachers and administrators, in the effort to study its effect on reading comprehension skills. It is believed that students using this system will become better readers, and that the system's integration into the classroom learning setting will be unobtrusive and seamless. Since most reading comprehension software is developed for the desktop environment, utilization of such a system in this mobile platform could prove very exciting and rewarding, serving to fill a much needed void in the collaborative learning spectrum.

Overall, the system presented in this work provides one possible approach to developing collaborative learning environments on intermittent devices, successfully providing an architecture for modeling interfaces for smaller, more limited machines. This research is just scratching the surface of what is capable for reading comprehension software, showing that tomorrow is promising for addressing the crisis of improving children's reading skills nationally.

KEY TERMS

Collaborative Learning: An environment where students work alone or in groups to complete a set of tasks, usually lessons, where they assist each other in learning.

Computer-Supported Collaborative Learning (CSCL): The study of users collaborating in a computerized environment on learning tasks.

Computer-Supported Intentional Learning Environments (CSILE): Database software that provides tools for organizing and storing knowledge as a means of sharing information and thoughts with peers, supporting both individual and collaborative learning.

Computer-Supported Collaborative Work (CSCW): The study of how people work with computers and how they can work with each other using them.

Distributed Speech Recognition: The process of capturing speech on a mobile device and transporting it via wireless network to a server to be processed ("recognized") or translated, and subsequently returning the translated speech to the mobile device.

Mobile Learning (M-Learning): Users communicating wirelessly via handheld devices in the process of learning.

Question-Answer Relationships (QAR): An instructional methodology for enhancing reading comprehension skills by teaching students to answer questions and generate their own questions based on text.

This work was previously published in Handbook of Research on User Interface Design and Evaluation for Mobile Technology, edited by J. Lumsden, pp. 1068-1078, copyright 2008 by Information Science Reference, formerly known as Idea Group Reference (an imprint of IGI Global).

Chapter 8.23
Mobile Decision Support for Time-Critical Decision Making

F. Burstein
Monash University, Australia

J. Cowie
University of Stirling, UK

INTRODUCTION

The wide availability of advanced information and communication technology has made it possible for users to expect a much wider access to decision support. Since the context of decision making is not necessarily restricted to the office desktop, decision support facilities have to be provided through access to technology anywhere, anytime, and through a variety of mediums. The spread of e-services and wireless devices has increased accessibility to data, and in turn, influenced the way in which users make decisions while on the move, especially in time-critical situations. For example, on site decision support for fire weather forecasting during bushfires can include real-time evaluation of quality of local fire weather forecast in terms of accuracy and reliability. Such decision support can include simulated scenarios indicating the probability of fire spreading over nearby areas that rely on data collected locally at the scene and broader data from the regional and national offices. Decision Support Systems (DSS) available on mobile devices, which triage nurses can rely on for immediate, expert advice based on available information, can minimise delay in actions and errors in triage at emergency departments (Cowie & Godley, 2006).

Time-critical decision making problems require context-dependent metrics for representing expected cost of delaying an action (Greenwald & Dean, 1995), expected value of revealed information, expected value of displayed information (Horvitz, 1995) or expected quality of service (Krishnaswamy, Loke, & Zaslavsky, 2002). Predicting utility or value of information or services is aimed at efficient use of limited decision making time or processing time and limited resources to allow the system to respond to the time-critical situation within the required time frame. Sensitivity analysis (SA) pertains to analysis of changes in output due to changes in inputs (Churilov et al.,

1996). In the context of decision support, traditionally SA includes the analysis of changes in output when some aspect of one or more of the decision model's attributes change, and how these affect the final DSS recommendations (Triantaphyllou & Sanchez, 1997). In time-critical decision making monitoring, the relationship between the changes in the current input data and how these changes will impact on the expected decision outcome can be an important feature of the decision support (Hodgkin, San Pedro, & Burstein, 2004; San Pedro, Burstein, Zaslavsky, & Hodgkin, 2004). Thus, in a time-critical decision making environment, the decision maker requires information pertaining to both the robustness of the current model and ranking of feasible alternatives, and how sensitivity this information is to time; for example, whether in 2, 5, or 10 minutes, a different ranking of proposed solutions may be more relevant. The use of graphical displays to relay the sensitivity of a decision to changes in parameters and the model's sensitivity to time has been shown to be a useful way of inviting the decision maker to fully investigate their decision model and evaluate the risk associated with making a decision now (whilst connectivity is possible), rather than at a later point in time (when perhaps a connection has been lost) (Cowie & Burstein, 2006).

In this article, we present an overview of the available approaches to mobile decision support and specifically highlight the advantages such systems bring to the user in time-critical decision situations. We also identify the challenges that the developers of such systems have to face and resolve to ensure efficient decision support under uncertainty is provided.

MOBILE DECISION SUPPORT

Recent work on mobile decision support focuses on the implementation of knowledge-based services on hand-held computers. Work on mobile clinical support systems, for example, addresses different forms of intelligent decision support such as knowledge delivery on demand, medication consultant, therapy reminder (Spreckelsen et al., 2000), preliminary clinical assessment for classifying treatment categories (Michalowski, Rubin, Slowinski, & Wilk, 2003; San Pedro, Burstein, Cao, Churilov, Zaslavsky, & Wassertheil, 2004), and providing alerts of potential drugs interactions and active linking to relevant medical conditions (Chan, 2000). These systems also address mobility by providing intelligent assistance on demand, at the patient's bedside or on-site.

Research on location-based mobile support systems uses search, matching, and retrieval algorithms to identify resources that are in proximity to the location of the mobile users and that satisfy multi-attribute preferences of the users and the e-service providers. Examples of such location-based systems are those that recommend best dining options to mobile users (Tewari et al., 2001), locate automatic teller machines nearby (Roto, 2003), and locate nearest speed cameras and intersections using GPS-enabled mobile devices. Most of these mobile decision support systems use intelligent technologies and soft computing methodologies (e.g., rule-based reasoning, rough sets theory, fuzzy sets theory, multi-attribute utility theory) as background frameworks for intelligent decision support. However, none of these systems address the issue of quality of data or quality of decision support while connected or disconnected from the network or consider a comprehensive measure of reliability of data as part of supporting time-critical decision-making.

It should be noted that not all real-time decision situations, which could benefit from mobile DSS, are also constringed by the period of time, in which this decision support should be provided. For example, if a decision problem is more of a strategic, rather than operation nature, the time factor could be less critical, hence, more time can be devoted to improve the quality of data before the final decision has to be accepted by the user. In this article, we mainly address the needs of

operational decision making, when time before the final choice is made is limited. In such situations an aggregate measure of quality of data (QoD) is particularly important when aiming to enhance a level of user's confidence and trust.

In recent papers (Hodgkin et al., 2004; San Pedro, Burstein, & Sharp, 2003) the issue of QoD has been addressed. A framework has been proposed for assessing QoD as an indicator of the impact of mobility in decision-making (Burstein, Cowie, Zaslavsky, & San Pedro, 2007; Cowie & Burstein, 2006; Hodgkin et al., 2004; San Pedro et al., 2003). QoD is based on multiple parameters which measure user-specific factors, current technology-related factors, and some factors which can be learned based on past experiences with similar problem situations. By providing a QoD alerting service from the mobile device, the mobile decision maker can be warned against making decisions when QoD falls below a predetermined threshold or when QoD becomes critically low. The assumption made is that a decision maker should feel more confident with a decision when QoD is high, or be alerted when QoD becomes lower than acceptable.

In mobile DSS, QoD can be calculated incrementally at every stage of the decision making process, as the mechanism for alerting the user when more data and/or resources are needed before the best option can be selected. For example, following Simon's classical decision making principal phases (Simon, 1960), when describing a decision situation, QoD can be used to judge how accurate the set of data collected is at the Intelligence phase; when designing alternative actions, QoD can assist in making sure the user is satisfied with the range of possibilities the user is presented with for a choice; when a model is applied for selecting the best alternative, the final output includes a full and explicit representation of the QoD, which is derived as an aggregate of the ones used in the previous stages (Burstein et al., 2007).

Providing the user with a measure of QoD is extremely important in a mobile decision making environment as the focus of decision support moves from strategic long term decision analysis to just-in-time operational decision support (Hodgkin et al., 2004; Malah, 2000). In addition, in a mobile environment, data timeliness, completeness, reliability, and relevance have to be considered as contributing factors of QoD metrics. For example, in the area of contingency management a "good enough" feasible decision achievable "on the spot," anytime, anywhere is often preferable to a perfect solution that may require extensive additional computational resources as well as time.

Further important issues to consider in time-critical DSS are diversity and heterogeneity of data both at the input and output points of the system. For example, in a medical emergency, context DSS needs to meet the varying information and resource needs of the personnel at the site and yet be able to support their physical mobility requirements. The mobile computing approaches seem to provide an ideal environment to reconcile varying data sources while identifying the best form of delivery of time-critical information. For example, aiding ambulance staff involving in the transfer of patients to the most appropriate hospital in the minimal amount of time (Burstein, Zaslavsky, & Arora, 2005; Cowie & Godley, 2006).

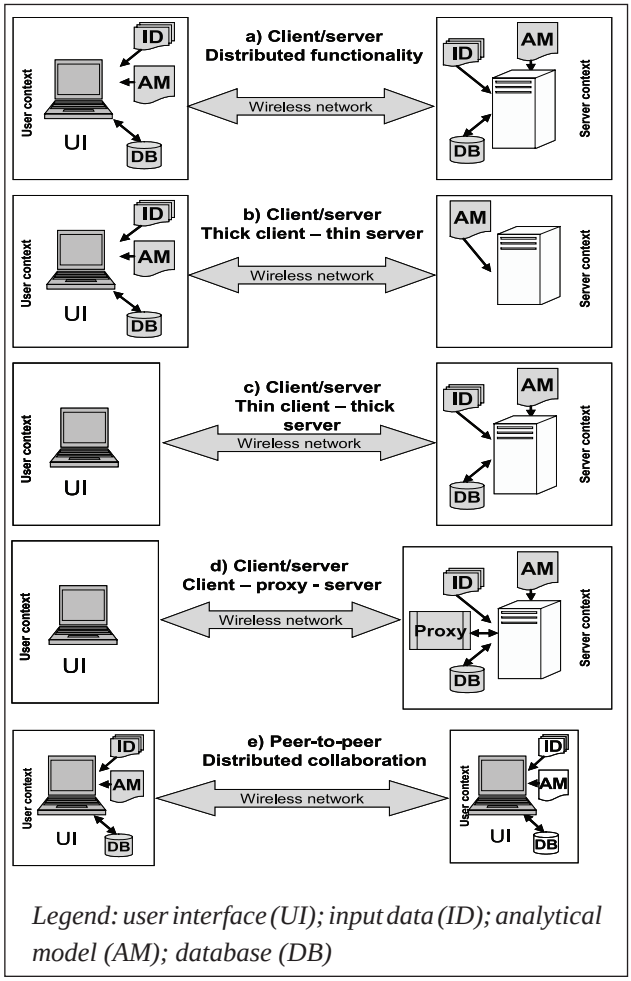
APPROACHES TO AND REQUIREMENTS OF TIME-CRITICAL DECISION SUPPORT

Mobile decision support systems can be implemented in a number of ways, depending on user requirements, available technological resources, frequency of data access, urgency of data retrieval, and so forth. Most of these mobile support systems use intelligent technologies and soft computing

methodologies, for example, multicriteria decision analysis, rule-based reasoning, rough sets theory (Michalowski et al., 2003; San Pedro et al., 2003), fuzzy sets theory (Zadeh, 1994), and multi-attribute utility theory (Keeney, 1992) as background frameworks for being able to learn about the environment in which the decision is taking place and decide upon appropriate support. Location-based decision support is one of many context-aware applications in which systems "can discover or take advantage of contextual information (such as user location, time of day, nearby people and devices, and user activity" (Chen & Kotz, 2000, p. 1).

Time-critical decision making problems require establishing system architectures for such systems that allow infrastructure for fault handling and system recovery (Saksena, da Silva, & Agrawala, 1994), for supporting wireless connectivity (Ahlund & Zaslavsky, 2002),

Figure 1. Mobile decision support architectures (Burstein et al., 2008)



Legend: user interface (UI); input data (ID); analytical model (AM); database (DB)

and provision of network security (Ghosh, 1998; Reis, Hoye, Gilbert, & Ryumae, 2003). Such infrastructures are essential for developing systems that can handle uncertainties due to unreliable communications, possible disconnections from the network, and other technical difficulties that might delay the action or response to a time-critical situation.

As research into such technology is relatively new, optimal architectures for various decision contexts, design configurations, and potential future applications are yet to be investigated. Some generic architectures are proposed and described, for example, by Burstein et al. (2007). They consider how standard DSS component, that is, database (DB), user interface (UI), and analytical model (AM) (Aronson, Liang, & Turban, 2005) can be arranged in mobile decision support architecture. Burstein et al. (2007) describe five possible types of mobile DSS implementation architectures as illustrated in Figure 1.

Portable devices can act as computational platforms for task specific applications, collecting, storing, and providing data for analytical processing. The use of device specific resources or server resources creates a distinction between possible types of DSS that can be provided (Navarro, Schulter, Koch, Assuncao, & Westphall, 2006). Mobile decision support can be client-based, server-oriented, proxy-based, or distributed across an ad hoc network of similar peer devices (Bukhres, Pitoura, & Zaslavsky, 2003). The type of architecture depends on where information is stored and where computations are performed. These varying implementations have associated advantages and disadvantages. The developers can choose between different implementations depending on the user context and technical infrastructure available at the time. A context which requires access to significant amounts of information would be more likely to use a server architecture given the limited processing and information storage capabilities of small portable devices. On the other hand, decision support in situations where some preliminary information processing could be performed based on some aggregated information can be deployed directly onto a portable device. Mobile and distributed decision support improves a system's fault tolerance and reduced support requirements.

Currently, the most popular implementation is where the functionality is distributed across a client-server environment with a user interface (UI) located on the user's portable device. In this case the data is distributed across both client and server; while user-sensitive data resides on the user device, the bulk of the data, including historical databases, are located on a server (Burstein et al., 2008). In this configuration, the Analytical Model (AM) is also distributed across client and server, with the user device performing elementary computations and delegating more complex and resource-intensive computations to the server.

Thick client-thin server and vice-versa represent more extreme cases and therefore more rare configurations. Given the high likelihood of disconnections in the wireless environment, some systems may use the concept of proxy architecture where a proxy process is located on a server-side representing a client and, if connectivity is good, allowing data and computations to be simply channelled between server and client. However, if a client becomes disconnected (e.g., driving through a tunnel), then the proxy assumes full functionality of the client and caches data and results until the client reconnects. With proliferation of peer-to-peer computing, it is now becoming possible to form ad hoc networks of similar devices, discovered at a time of need, in order to consolidate resources and perform the AM in a distributed computing environment in a cost-efficient manner.

These alternative architectural approaches and set up options enable enough flexibility and scalability for any possible DSS application or scenario. For time-critical DSS, any of these configurations should provide adequate assistance as long as the decision can be reached with a reason-

able level of confidence within the required time constraints. Moreover, it is essential to utilize the most current data available while also providing additional information on sensitivity of the selected option to minor variations in context data or more dynamic model characteristics (Cowie & Burstein, 2007)

FUTURE TRENDS

The last decade has seen significant advances in the way humans interact with technology. Users of computers are no longer constrained to the office desktop, but can have much more flexible access to technology almost anywhere, anytime. The spread of e-services and wireless devices has facilitated a new way of using computers, increased accessibility to data, and, in turn, influenced the way in which users make decisions while on the move.

Availability of such an infrastructure coupled with an increase in the demands of users provide new opportunities for developing improved, "just in time" support for decision making. Mobile decision support can be incorporated as an integral component of a mobile commerce infrastructure as a means of an enhanced communication (Carlsson et al., 2006) or as a part of an operational decision support environment for a mobile manager.

Mobile DSS can benefit from storing real-time data and then re-using it at the time of calculating the requested best option (Michalowski et al., 2003). Such systems have been proven to perform well in both stand alone and distributed environments, where they can share historical information to deal with a lack of information when supporting time-critical decisions. Shim, Warkentin, Courtney, Power, Sharda, and Carlsson (2002) suggest that the availability of Web-based and mobile tools within a wireless communication infrastructure will be a driving force in further development of decision support, facilitating decision support for decision makers "wherever they may be" (p. 112).

Financial decisions present a good example of when real-time decision support could be beneficial (Hartmann & Bretzke 1999). Decision makers, who require getting a real-time update on their financial position in order to make the best use of their money, can be supported by mobile DSS, which will utilise new as well as transaction history data in calculating the options (Burstein et al., 2008).

CONCLUSION

The realities of the changing way in which we make decisions and the advances in mobile technology create multiple challenges and opportunities for decision makers and computer system developers alike. Making decisions on the move under uncertainty requires decision support systems that can adequately provide up-to-date, context specific, complete information in a way that is understandable and useful to the decision maker.

Observing the development of DSS for the future, Shim et al. (2002) envisage that use of mobile devises for providing decision support will lead to greater collaboration and allow the achievement of true ubiquitous access to information in a timely manner. We wholeheartedly concur with this opinion and look forward to developers of DSS embracing current and future technologies that facilitate mobile decision support, building on well-founded methodologies to model decision situations with better precision. In addition, we believe that by accommodating a measure of the quality of the information provided, decisions on the move can be supported just as effectively as those made behind the desk.

KEY TERMS

Mobile Decision Support: Providing support for a decision maker who has access to a mobile device for their decision support, is possibly on the move, and is possibly in a time-critical environment.

Mobile Devices: Mobile devices are portable computers that facilitate access to information in much the same way as a desktop computer. Typically such devices use a small visual display for user output and either some form of keypad, keyboard, or touch screen for user input.

Quality of Data: A measure of the quality of the data being used to assist the decision maker in making a decision. The quality of data measure is an aggregate value which encompasses information about technical factors of the mobile device (such as connectivity) as well as information pertaining to the completeness, accuracy of the data provided, reliability and relevance of the data provided.

Time-Critical Decisions: The idea that the context of a decision, its parameters, options, and best outcomes, are dependent on when the decision is made. A good outcome at one point in time is not necessary a good outcome at a later point in time if the decision is time-critical.

Uncertainty: Decision making under uncertainty occurs when the decision maker has no clear view on how different outcomes of a decision fair in comparison to each other. There is no obvious ranking of outcomes from best to worst.

This work was previously published in Encyclopedia of Decision Making and Decision Support Technologies, edited by F. Adam and P. Humphreys, pp. 638-644, copyright 2008 by Information Science Reference, formerly known as Idea Group Reference (an imprint of IGI Global).

Chapter 8.24
OFDM Transmission Technique:
A Strong Candidate for the Next Generation Mobile Communications

Hermann Rohling
Hamburg University of Technology, Germany

ABSTRACT

The orthogonal frequency division multiplexing (OFDM) transmission technique can efficiently deal with multi-path propagation effects especially in broadband radio channels. It also has a high degree of system flexibility in multiple access schemes by combining the conventional TDMA, FDMA, and CDMA approaches with the OFDM modulation procedure, which is especially important in the uplink of a multi-user system. In OFDM-FDMA schemes carrier synchronization and the resulting sub-carrier orthogonality plays an important role to avoid any multiple access interferences (MAI) in the base station receiver. An additional technical challenge in system design is the required amplifier linearity to avoid any non-linear effects caused by a large peak-to-average ratio (PAR) of an OFDM signal. The OFDM transmission technique is used for the time being in some broadcast applications (DVB-T, DAB, DRM) and wireless local loop (WLL) standards (HIPERLAN/2, IEEE 802.11a) but OFDM has not been used so far in cellular communication networks. The general idea of the OFDM scheme is to split the total bandwidth into many narrowband sub-channels which are equidistantly distributed on the frequency axis. The sub-channel spectra overlap each other but the sub-carriers are still orthogonal in the receiver and can therefore be separated by a Fourier transformation. The system flexibility and use of sub-carrier specific adaptive modulation schemes in frequency selective radio channels are some advantages which make the OFDM transmission technique a strong and technically attractive candidate for the next generation of mobile communications. The objective of this chapter is to describe an OFDM-based system concept for the fourth generation (4G) of mobile communications and to discuss all technical details when establishing a cellular network which requires synchronization in time and frequency domain with sufficient accuracy. In this cellular environment a flexible frequency division multiple

access scheme based on OFDM-FDMA is developed and a radio resource management (RRM) employing dynamic channel allocation (DCA) techniques is used. A purely decentralized and self-organized synchronization technique using specific test signals and RRM techniques based on co-channel interference (CCI) measurements has been developed and will be described in this chapter.

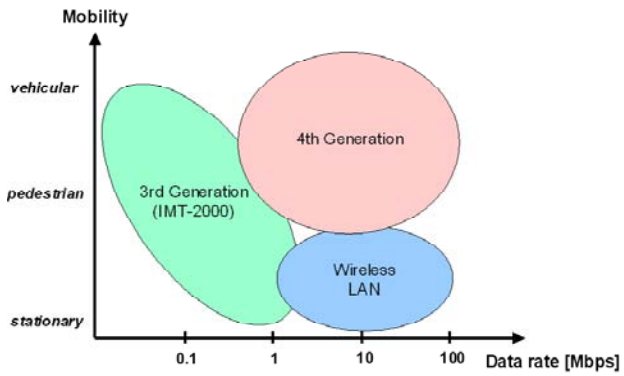
INTRODUCTION

In the evolution of mobile communication systems approximately a 10-year periodicity can be observed between consecutive system generations. Research work for the current 2nd generation of mobile communication systems (GSM) started in Europe in the early 1980s, and the complete system was ready for market in 1990. At that time the first research activities had already been started for the 3rd generation (3G) of mobile communication systems (UMTS, IMT-2000) and the transition from the current second generation (GSM) to the new 3G systems will be observed this year. Compared to today's GSM networks, these new UMTS systems will provide much higher data rates, typically in the range of 64 to 384 kbps, while the peak data rate for low mobility or indoor applications will be 2 Mbps.

The current pace, which can be observed in the mobile communications market, already shows that the 3G systems will not be the ultimate system solution. Consequently, general requirements for a 4G system have to be considered which will mainly be derived from the types of service a user will require in future applications. Generally, it is expected that data services instead of pure voice services will play a predominant role, in particular due to a demand for mobile IP applications. Variable and especially high data rates (20 Mbps and more) will be requested, which should also be available at high mobility in general or high vehicle speeds in particular (see Figure 1). Moreover, asymmetrical data services between up- and downlink are assumed and should be supported by 4G systems in such a scenario where the downlink carries most of the traffic and needs the higher data rate compared with the uplink.

To fulfill all these detailed system requirements the OFDM transmission technique applied in a wide-band radio channel is a strong candidate for an air interface in future 4G cellular systems due to its flexibility and adaptivity in the techni-

Figure 1. General requirements for 4G mobile communication systems



cal system design. From these considerations, it already becomes apparent that a radio transmission system for 4G must provide a great flexibility and adaptivity at different levels, ranging from the highest layer (requirements of the application) to the lowest layer (the transmission medium, the physical layer, that is, the radio channel) in the ISO-OSI stack. Today, the OFDM transmission technique is in a completely matured stage to be applied for wide-band communication systems integrated into a cellular mobile communications environment.

OFDM TRANSMISSION TECHNIQUE

Radio Channel Behaviour

The mobile communication system design is in general always dominated by the radio channel behaviour (Bello, 1963; Pätzold, 2002). In typical radio channel situation, multi-path propagation occurs (Figure 2) due to the reflections of the transmitted signal at several objects and obstacles inside the local environment and inside the observation area. The radio channel is analytically described unambiguously by a linear (quasi) time invariant (LTI) system model and by the related channel impulse response $h(\tau)$ or alternatively by the channel transfer function $H(f)$. An example for these channel characteristics is shown in Figure 3, where $h(\tau)$ and $H(f)$ of a so-called wide-sense stationary, uncorrelated scattering-channel (WSSUS) are given.

Due to the mobility of the mobile terminals the multi-path propagation situation will be continuously but slowly changed over time which is described analytically by a time variant channel impulse response $h(\tau, t)$ or alternatively by a frequency selective and time dependent radio channel transfer function $H(f, t)$ as it is shown in Figure 5 by an example. All signals on the various propagation paths will be received in a superimposed form and are technically characterized by different delays and individual Doppler frequencies which lead finally to a frequency selective behaviour of the radio channel, see Figure 4. The other two system functions, the Delay Doppler function, $v(\tau, f_D)$ and the Frequency Doppler function, $U(f, f_D)$ can be used as an alternative description

Figure 2. Multi-path propagation scenario

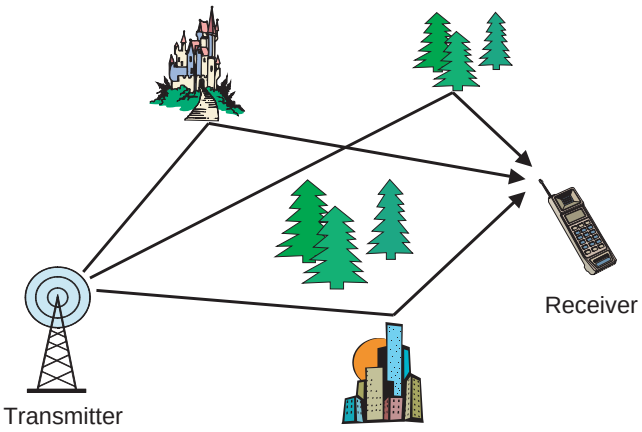


Figure 3. Impulse response and channel transfer function of a WS-SUS channel

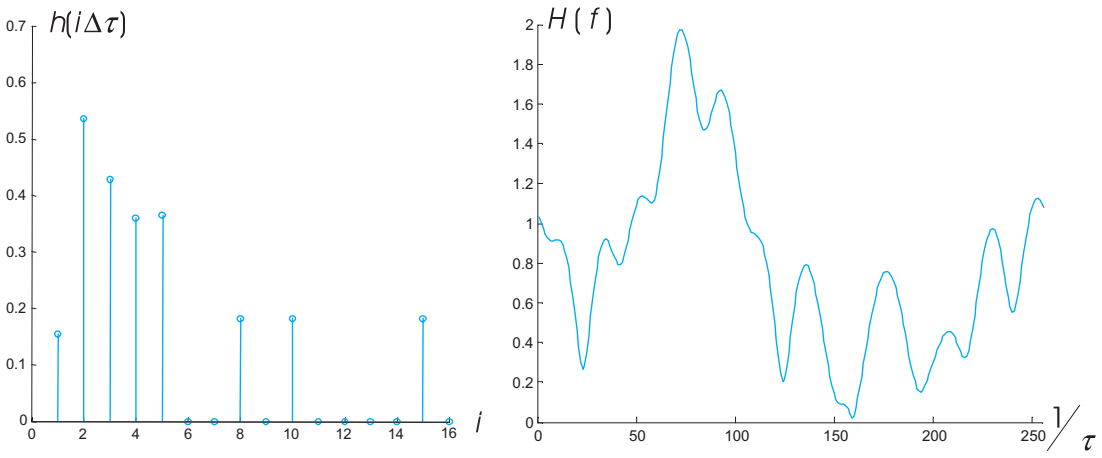

Figure 4. Relationships between different system functions

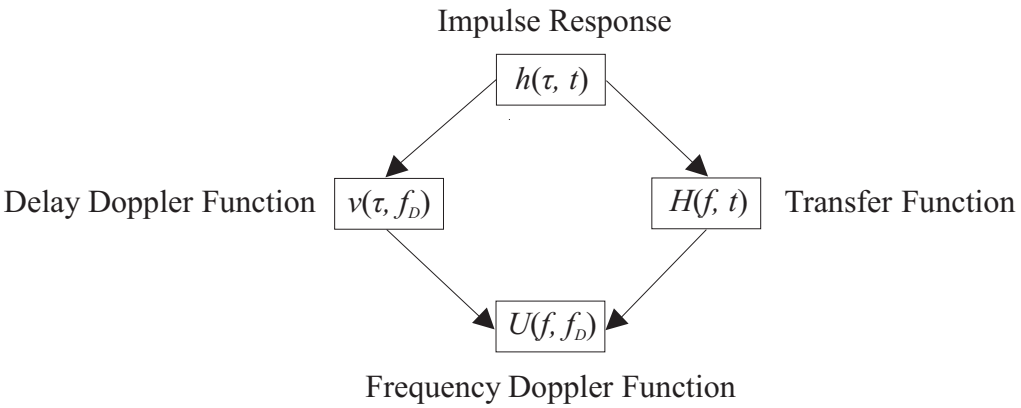
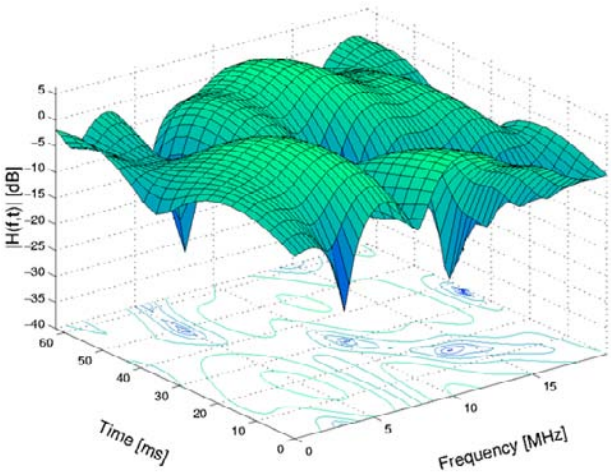


of the radio channel behaviour. The Delay Doppler function $v(\tau, f_D)$ describes the variation of the channel impulse response related to certain values of the Doppler frequency f_D. This means the channel delays change due to alteration of the relative speed between a mobile terminal and the base station. The Frequency Doppler function $U(f, f_D)$ models the same effects for the channel behaviour in the frequency domain.

The radio channel can roughly and briefly be characterised by two important system parameters: the maximum multi-path delay τ_{max} and

Figure 5. Frequency-selective and time-variant radio channel transfer function



the maximum Doppler frequency $f_{D\max}$ which are transferred into the coherence time T_C and the coherence bandwidth B_C of the radio channel:

$$T_C = \frac{1}{f_{D\max}}, \quad B_C = \frac{1}{\mathrm{t}_{\max}} \tag{1}$$

Over time intervals significantly shorter than T_C, the channel transfer function can be assumed to be nearly stationary. Similarly, for frequency intervals significantly smaller than B_C, the channel transfer function can be considered as nearly constant. Therefore it is assumed in this chapter that the coherence time T_C is much larger compared to a single OFDM symbol duration T_S and the coherence bandwidth B_C is much larger than the distance Δf between two adjacent sub-carriers:

$$B_C \gg \Delta f, \quad \Delta f = \frac{1}{T_S}, \quad T_S \ll T_C \tag{2}$$

This condition should be always fulfilled in well-dimensioned OFDM systems and in realistic time variant and frequency selective radio channels.

There are always technical alternatives possible in new system design phases. But future mobile communication systems will in any case require extremely large data rates and therefore large system bandwidth. If conventional single carrier (SC) modulation schemes with the resulting very low symbol durations are applied in this system design, it will be observed that very strong inter-symbol interference (ISI) is caused in wide-band applications due to multi-path propagation situations. This means for high data rate applications the symbol duration in a classical SC transmission system is extremely small compared to the typical values of maximum multi-path delay $\tau_{\max}$ in the considered radio channel. In these strong ISI situations a very powerful equalizer is necessary in each receiver, which needs high computation complexity in a wide-band system.

These constraints should be taken into consideration in the system development phase for a new radio transmission scheme and for a new 4G air interface. The computation complexity for the necessary equalizer techniques to overcome all these strong ISI in a SC modulation scheme increases exponentially for a given radio channel with increasing system bandwidth and can be extremely large in wide-band applications. For that reason alternative transmission techniques for broadband applications are of high interest.

Alternatively, the OFDM transmission technique can efficiently deal with all these ISI effects, which occur in multi-path propagation situations and in broadband radio channels. Simultaneously the OFDM transmission technique needs much less computation complexity in the equalization process inside each receiver. The performance figures for an OFDM based new air interface for the next generation of mobile communications are very promising even in frequency selective and time variant radio channel situations.

Advantages of the OFDM Transmission Technique

If a high data rate is transmitted over a frequency selective radio channel with a large maximum multi-path propagation delay τ_{max} compared to the symbol duration, an alternative to the classical SC approach is given by the OFDM transmission technique. The general idea of the OFDM transmission technique is to split the total available bandwidth B into many narrowband sub-channels at equidistant frequencies. The sub-channel spectra overlap each other but the sub-carrier signals are still orthogonal. The single high-rate data stream is subdivided into many low-rate data streams in the several sub-channels. Each sub-channel is modulated individually and will be transmitted simultaneously in a superimposed and parallel form.

An OFDM transmit signal therefore consists of N adjacent and orthogonal sub-carriers spaced by the frequency distance Δf on the frequency axis. All sub-carrier signals are mutually orthogonal within the symbol duration of length T_S if the sub-carrier distance and the symbol duration are chosen such that $T_S = 1 / \Delta f$. For OFDM-based systems the symbol duration T_S is much larger compared to the maximum multi-path delay τ_{max}. The k-th unmodulated sub-carrier signal is described analytically by a complex valued exponential function with carrier frequency $k\Delta f$, $\tilde{g}_k(t),\ k = 0,\ldots,N-1$.

$$\tilde{g}_k(t) = \begin{cases} e^{j2\pi k\Delta f t} & \forall t \in [0, T_S] \\ 0 & \forall t \notin [0, T_S] \end{cases} \qquad (3)$$

Since the system bandwidth B is subdivided into N narrowband sub-channels, the OFDM symbol duration T_S is N times larger as in the case of an alternative SC transmission system covering the same bandwidth B. Typically, for a given system bandwidth the number of sub-carriers is chosen in a way that the symbol duration T_S is sufficiently large compared to the maximum multi-path delay τ_{max} of the radio channel. On the other hand, in a time-variant radio channel the Doppler spread imposes restrictions on the sub-carrier spacing Δf. In order to keep the resulting inter-carrier interference (ICI) at a tolerable level, the system parameter of sub-carrier spacing Δf must be large enough compared to the maximum Doppler frequency $f_{D\max}$. In Aldinger (1994), the appropriate range for choosing the symbol duration T_S as a rule of thumb in practical systems is given as (compare with Equation (2)):

$$4\tau_{max} \le T_S \le 0.03 \frac{1}{f_{D,\max}}. \qquad (4)$$

The duration T_S as of the sub-carrier signal $\tilde{g}_k(t)$ is additionally extended by a cyclic prefix (so-called guard interval) of length T_G which is larger than the maximum multi-path delay τ_{max}

in order to avoid any ISI completely which could occur in multi-path channels in the transition interval between two adjacent OFDM symbols (Peled & Ruiz, 1980).

$$g_k(t) = \begin{cases} e^{j2\pi k\Delta ft} & \forall t \in [-T_G, T_S] \\ 0 & \forall t \notin [-T_G, T_S] \end{cases} \qquad (5)$$

$$= e^{j2\pi k\Delta ft} rect\left(\frac{2t+(T_G-T_S)}{2T}\right)$$

The guard interval is directly removed in the receiver after the time synchronization procedure. From this point of view the guard interval is a pure system overhead and the total OFDM symbol duration is therefore $T = T_S + T_G$. It is an important advantage of the OFDM transmission technique that ISI can be avoided completely or can be reduced at least considerably by a proper choice of OFDM system parameters.

The orthogonality of all sub-carrier signals is completely preserved in the receiver even in frequency selective radio channels which is an important advantage of the OFDM transmission technique. The radio channel behaves linear and in a short-time interval of a few OFDM symbols even time invariant. Therefore the radio channel behaviour can be described completely by a linear and time invariant (LTI) system model characterized by the impulse response $h(t)$. The LTI system theory gives the reason for this important system behaviour that all sub-carrier signals are orthogonal in the receiver even when transmitting the signal in frequency selective radio channels. All complex valued exponential signals (e.g., all sub-carrier signals) are Eigenfunctions of each LTI system and therefore Eigenfunctions of the considered radio channel which means that only the signal amplitude and phase will be changed if a sub-carrier signal is transmitted in the linear and time invariant radio channel.

The sub-carrier frequency is not affected at all by the radio channel transmission which means that all sub-carrier signals are even orthogonal in the receiver and at the output of a frequency selective radio channel. The radio channel interferes only amplitudes and phases individually but not the sub-carrier frequency of all received sub-channel signals. Therefore all sub-carrier signals are still mutually orthogonal in the receiver. Due to this important property the received signal which is superimposed by all sub-carrier signals can be split directly into the different sub-channel components by a Fourier transformation and each sub-carrier signal can be demodulated individually by a single tap equalizer in the receiver.

At the transmitter side each sub-carrier signal is modulated independently and individually by the complex valued modulation symbol $S_{n,k}$, where the subscript n refers to the time interval and k to the sub-carrier signal number in the considered OFDM symbol. Thus, within the symbol duration time interval T the time continuous signal of the n-th OFDM symbol is formed by a superposition of all N simultaneously modulated sub-carrier signals.

$$s_n(t) = \sum_{k=0}^{N-1} S_{n,k} g_k(t - nT) \qquad (6)$$

The total time continuous transmit signal consisting of all OFDM symbols sequentially transmitted on the time axis is described analytically by the following equation:

$$s(t) = \sum_{n=0}^{\infty} \sum_{k=0}^{N-1} S_{n,k} e^{j2\pi k\Delta f(t-nT)} rect\left(\frac{2(t-nT)+(T_G-T_S)}{2T}\right) \qquad (7)$$

The analytical transmit signal description shows that a rectangular pulse shaping is applied for each sub-carrier signal and each OFDM symbol. But due to the rectangular pulse shaping, the spectra of all the considered sub-carrier signals are sinc-functions which are equidistantly located

on the frequency axis, for example, for the *k*-th sub-carrier signal the spectrum is described in the following equation:

$$G_k(f) = T \cdot \mathrm{sinc}\left[\pi T\left(f - k\Delta f\right)\right] \text{ where}$$
$$\mathrm{sinc}(x) = \frac{\sin(x)}{x} \tag{8}$$

The typical OFDM-Spectrum shown in Figure 6 consists of N adjacent sinc-functions, which are shifted by Δf in the frequency direction.

The spectra of the considered sub-carrier signals overlap on the frequency axis, but the sub-carrier signals are still mutually orthogonal which means the transmitted modulation symbols $S_{n,k}$ can be recovered by a simple correlation technique in each receiver if the radio channel is assumed to be ideal in a first analytical step:

$$\frac{1}{T_s}\int_0^{T_S} g_k(t)\overline{g_l(t)}dt = \begin{cases} 1 & k = l \\ 0 & k \neq l \end{cases} = \delta_{k,l} \tag{9}$$

$$S_{n,k} = \frac{1}{T_S}\int_0^{T_S} s_n(t)\overline{g_k(t)}dt = \frac{1}{T_S}\int_0^{T_S} s_n(t)e^{-j2\pi k\Delta ft}dt \tag{10}$$

where $\overline{g_k(t)}$ is the conjugate complex version of the sub-carrier signal $g_k(t)$. The following equations show the correlation process in detail:

$$Corr = \frac{1}{T_S}\int_0^{T_S} s_n(t)\overline{g_k(t)}dt = \frac{1}{T_S}\int_0^{T_S}\sum_{m=0}^{N-1} S_{n,m}g_m(t)\overline{g_k(t)}dt$$
$$= \sum_{m=0}^{N-1} S_{n,m}\frac{1}{T_S}\int_0^{T_S} g_m(t)\overline{g_k(t)}dt = \sum_{m=0}^{N-1} S_{n,m}\delta_{m,k} = \underline{\underline{S_{n,k}}} \tag{11}$$

In practical applications the OFDM transmit signal $s_n(t)$ is generated in a first step and in the digital baseband signal processing part of the transmitter as a time discrete signal. Using the sampling theorem while considering the OFDM transmit signal inside the bandwidth $B = N\Delta f$, the transmit signal must be sampled with the sampling interval $\Delta t = 1/B = 1/N\Delta f$. The individual samples of the transmit signal are denoted by $s_{n,i}$, $i = 0, 1, \ldots, N-1$ and can be calculated as follows (see Equation (7)):

$$s(t) = \sum_{k=0}^{N-1} S_{n,k}e^{j2\pi k\Delta ft}$$
$$s(i\Delta t) = \sum_{k=0}^{N-1} S_{n,k}e^{j2\pi k\Delta f(i\Delta t)}$$
$$s_{n,i} = \sum_{k=0}^{N-1} S_{n,k}e^{j2\pi ik/N} \tag{12}$$

This Equation (12) describes exactly the inverse discrete Fourier transform (IDFT) applied to the complex valued modulation symbols $S_{n,k}$ of all sub-carrier signals inside a single OFDM symbol.

The individually modulated and superimposed sub-carrier signals are transmitted in a parallel way over many narrowband sub-channels. Thus, in each sub-channel the symbol duration is quite large and can be chosen much larger as compared to the maximum multi-path delay of the radio channel. In this case each sub-channel has the property to be frequency non-selective.

Figure 7 shows the general OFDM system structure in a block diagram. The basic principles of the OFDM transmission technique have already been described in several publications like Bingham (1990) and Weinstein and Ebert (1971). In the very early and classical multi-carrier system considerations like Chang (1966) and Saltzberg (1967), narrowband signals have been generated independently, assigned to various frequency bands, transmitted, and separated by analogue filters at the receiver. The new and modern aspect of the OFDM transmission technique is that the various sub-carrier signals are generated digitally and jointly by an IFFT in the transmitter and that

Figure 6. OFDM spectrum which consists of N equidistant sinc-functions

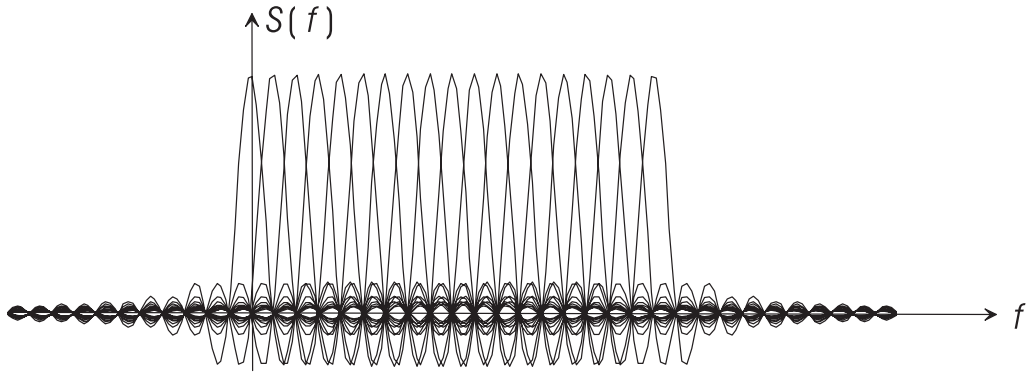


Figure 7. OFDM system structure in a block diagram

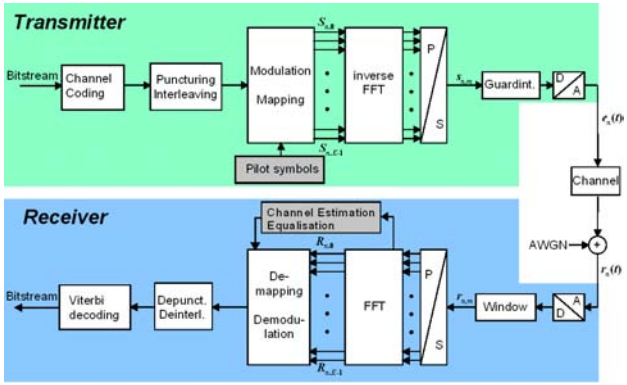


their spectra strongly overlap on the frequency axis. As a result, generating the transmit signal is simplified and the bandwidth efficiency of the system is significantly improved.

The received signal is represented by the convolution of the transmitted time signal with the channel impulse response $h(t)$ and an additive white Gaussian noise term:

$$r_n(t) = s_n(t) * h_n(t) + n_n(t) \quad (13)$$

Due to the assumption, that the coherence time T_C will be much larger than the symbol duration T_S the received time continuous signal $r_n(t)$ can be separated into the orthogonal sub-carrier signal components even in frequency selective fading

situations by applying the correlation technique mentioned in Equation (10):

$$R_{n,k} = \frac{1}{T_S}\int_0^{T_S} r_n(t)e^{-j2\pi k\Delta ft}dt \qquad (14)$$

Equivalently, the correlation process at the receiver side can be applied to the time discrete receive signal at the output of an A/D converter and can be implemented as a DFT, which leads to the following equation:

$$R_{n,k} = \frac{1}{N}\sum_{i=0}^{N-1} r_{n,i}e^{-j2\pi iik/N} \qquad (15)$$

In this case $r_{n,i} = r_n(i\cdot\Delta t)$ describes the *i*-th sample of the received time continuous base-band signal $r_n(t)$ and $R_{n,k}$ is the received complex valued symbol at the DFT output of the *k*-th sub-carrier.

If the OFDM symbol duration T is chosen much smaller than the coherence time T_C of the radio channel, then the time variant transfer function of the radio channel $H(f, t)$ can be considered constant within the time duration T of each modulation symbol $S_{n,k}$ for all sub-carrier signals. In this case, the effect of the radio channel in multi-path propagation situations can be described analytically by only a single multiplication of each sub-carrier signal $g_k(t)$ with the complex transfer factor $H_{n,k} = H(k\Delta f, nT)$. As a result, the received complex valued symbol $R_{n,k}$ at the DFT output can be described analytically as follows:

$$r_n(t) = s_n(t) * h_n(t) + n_n(t)$$
$$r_{n,i} = s_{n,i} * h_{n,i} + n_{n,i}$$

$$R_{n,k} = S_{n,k}H_{n,k} + N_{n,k} \qquad (16)$$

where $N_{n,k}$ describes an additive noise component for each specific sub-carrier generated in the radio channel. This equation shows the most important advantage of applying the OFDM transmission technique in practical applications. Equation (16) describes the complete signal transfer situation of the OFDM block diagram including IDFT, guard interval, D/A conversion, up- and down-conversion in the RF part, frequency selective radio channel, A/D conversion and DFT process in the receiver, neglecting non-ideal behaviour of any system components.

The transmitted Symbol $S_{n,k}$ can be recovered, calculating the quotient of the received complex valued symbol and the estimated channel transfer factor $\tilde{H}_{n,k}$:

$$S_{n,k} = \frac{R_{n,k} - N_{n,k}}{H_{n,k}}, \quad \tilde{S}_{n,k} = R_{n,k}\frac{1}{\tilde{H}_{n,k}} \qquad (17)$$

It is obvious that this one tap equalization step of the received signal is much easier compared to a single carrier system for high data rate applications. The necessary IDFT and DFT calculations can be implemented very efficiently using the Fast-Fourier-Transform (FFT) algorithms such as Radix 2^2, which reduces the system and computation complexity even more.

It should be pointed out that especially the frequency synchronization at the receiver must be very precise in order to avoid any inter-carrier interferences (ICI). Algorithms for time and frequency synchronization in OFDM-based systems are described in Classen and Meyr (1994) and Mizoguchi et al. (1998), for example and will be considered in the section, *Self-Organized Cell Synchronization.*

Besides the complexity aspects, another advantage of the OFDM technique lies in its high degree of flexibility and adaptivity. Division of the available bandwidth into many frequency-non-selective sub-bands gives additional advantages for the OFDM transmission technique. It allows a sub-carrier-specific adaptation of transmit parameters, such as modulation scheme (PHY mode) and transmit power (cp. Water Filling) in

accordance to the observed and measured radio channel status. In a multi-user environment the OFDM structure offers additionally an increased flexibility for resource allocation procedures as compared to SC systems (Hanzo et al., 2003).

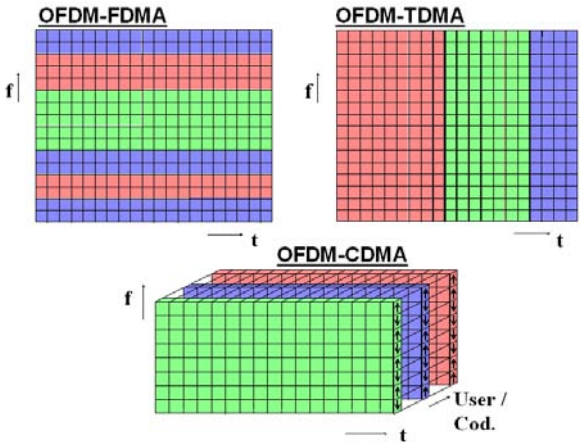
The important system behaviour that all sub-carrier signals are mutually orthogonal in the receiver makes the signal processing and the equalization process realized by a single-tap procedure very simple and leads to a low computation complexity.

OFDM COMBINED WITH MULTIPLE ACCESS SCHEMES

A very high degree of flexibility and adaptivity is required for new mobile communication systems and for the 4G air interface. The combination between multiple access schemes and OFDM transmission technique is an important factor in this respect. In principle, multiple access schemes for the OFDM transmission technique can be categorized according to OFDM-FDMA, OFDM-TDMA, and OFDM-CDMA (Kaiser, 1998; Rohling & Grünheid, 1997). Clearly, hybrid schemes can be applied which are based on a combination of these techniques. The principles of these basic multiple access schemes are summarized in Figure 8, where the time-frequency plane is depicted and the user specific resource allocation is distinguished by different colours.

These access schemes provide a great variety of possibilities for a flexible user specific resource allocation. In the following, one example for OFDM-FDMA is briefly sketched (cf. Galda, Rohling, Costa, Haas, & Schulz, 2002). In the case that the magnitude of the channel transfer function is known for each user the sub-carrier selection for an OFDM-FDMA scheme can be processed in the BS for each user individually which leads to a multi-user diversity (MUD) effect. By allocating a subset of all sub-carriers with the highest SNR to each user the system performance can be improved. This allocation technique based on the knowledge of the channel transfer function shows a large performance advantage and a gain in quality of service (QoS). Nearly the same flexibility in resource allocation is possible in OFDM-CDMA systems. But in

Figure 8. OFDM transmission technique and some multiple access schemes



this case the code orthogonality is destroyed by the frequency selective radio channel resulting in multiple access interferences (MAI), which reduces the system performance.

TECHNICAL PROPOSAL AND EXAMPLE FOR A 4G DOWNLINK INTERFACE

Taking all these important results from the previous sections into consideration, a system design example is considered in this section. OFDM system parameters for a 4G air interface are considered and three different multiple access schemes inside a single cell are compared quantitatively. A bandwidth of 20 MHz in the 5.5 GHz domain is assumed. The assumed multi-path radio channel has a maximum delay of $\tau_{max} = 5$ μs (the coherence bandwidth is therefore $B_C = 200$ kHz). Additionally, a maximum speed of $v_{max} = 200$ km/h is assumed, which yields a maximum Doppler frequency of $f_{Dmax} = 1$ kHz and a coherence time of $T_C = 1$ ms. Table 1 shows an example for the system parameters of a 4G air interface.

For the considered OFDM based system three different multiple access concepts have been analysed and compared. The first proposal is based on a pure OFDM-TDMA structure, while the second one considers an OFDM-FDMA technique with an adaptive sub-carrier selection scheme, as described in the section, *OFDM Transmission Technique Combined with Multiple Access Schemes*. The third one is based on OFDM-CDMA where the user data are spread over a subset of adjacent sub-carriers.

In this case MAI occur and an interference cancellation technique implemented in each MT is useful. To compare the different multiple access schemes, Figure 9 shows the bit error rate (BER) for an OFDM system with the system parameters shown in Table 1.

A single cell situation has been considered in this case with a perfect time and carrier synchronization. As can be seen from this figure, the best performance can be achieved by an OFDM-FDMA system which exploits the frequency selective fading of the mobile radio channel by allocating always the best available sub-carrier to each user. Note that a channel adaptive FDMA scheme requires a good prediction of the channel transfer function which has been considered to be perfect in this comparison. If a non-adaptive FDMA technique was used (i.e., fixed or random

Table 1. Proposal of OFDM system parameters

PARAMETER	VALUE
FFT Length	$N_C = 512$

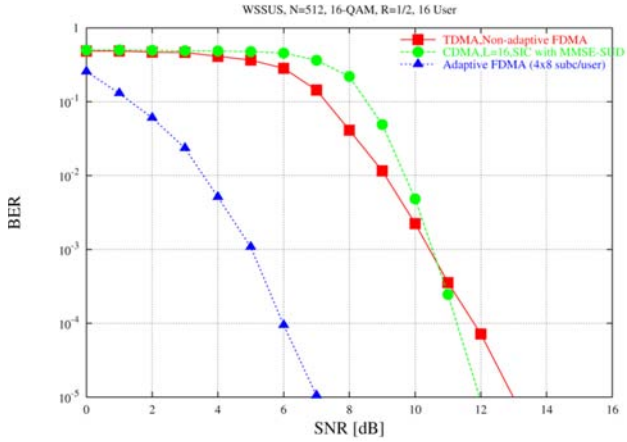
TDMA	
CDMA Spreading matrix	Walsh-Hadamard (L=16)
CDMA detection technique	SUD with MMSE, MUD with soft interference cancellation plus MMSE

Figure 9. BER results for a coded OFDM system employing different multiple access techniques



allocation of sub-carriers), the performance would be comparable to the OFDM-TDMA curve.

In the case of an OFDM-TDMA system the frequency selectivity of the radio channel can be exploited by the Viterbi decoder in conjunction with bit interleaving. A pure coded OFDM-CDMA system which utilizes an orthogonal spreading matrix with minimum mean square error (MMSE) equalization and single user detection (SUD) to exploit the diversity of the channel suffers from MAI due to loss of code orthogonality in frequency selective fading. A performance improvement can be achieved for an OFDM-CDMA scheme applying multi-user detection (MUD) techniques. By successively removing inter-code/-user interference using MUD procedure, a gain of approximately 2 dB can be achieved. But still an OFDM-FDMA system outperforms an optimized OFDM-CDMA system. Additionally, OFDM-CDMA technique has a much higher computational complexity in the MUD scheme.

TECHNICAL PROPOSAL AND EXAMPLE FOR A 4G UPLINK INTERFACE

As shown in the preceding paragraph, there are several system proposals published for an OFDM-based downlink procedure for broadcast and communication systems respectively. But by designing an OFDM uplink transmission scheme some important and additional technical questions will come up. Therefore, OFDM-based uplink systems are still under consideration and research (Rohling, Galda, & Schulz, 2004). As a contribution to this topic, an OFDM-based multi-user uplink system with *M* different users inside a single cell is considered in this section.

Each user shares the entire bandwidth with all other users inside the cell by allocating exclusively a deterministic subset of all available sub-carriers inside the considered OFDM system. This user specific sub-carrier selection process allows to

share the total bandwidth in a very flexible way between all mobile terminals. Hence, as a relevant multiple access scheme an OFDM-FDMA structure is considered in which each user claims the same bandwidth or the same number of sub-carriers inside the total bandwidth respectively. Due to the assumed perfect carrier synchronization and resulting sub-carrier orthogonality in the receiver any multiple access interference (MAI) between different users can be avoided. The sub-carrier allocation process can either be designed to be non-adaptive or adaptive in accordance with the current radio channel state information (CSI).

Since the OFDM transmission signal results from the superposition of a large number of independent data symbols and sub-carrier signals the envelope of the complex valued baseband time signal is in general not constant but has a large peak-to-average ratio (PAR). The largest output power value of the amplifier will therefore limit the maximum amplitude in the transmit signal. Additionally, non-linear distortions due to clipping and amplification effects in the transmit signal will lead to both in-band interferences and out-of-band emissions (Brüninghaus & Rohling, 1997). Therefore, in the downlink case each base station will spend some effort and computation power to control the transmit signal amplitude and to reduce the PAR. The objective is in this case to minimize the resulting non-linear effects or even to avoid any interferences.

But for the uplink case it is especially important to design a transmit signal with low PAR to reduce computation complexity in the mobile terminal and to avoid any interference situation caused by non-linear effects of the amplification process.

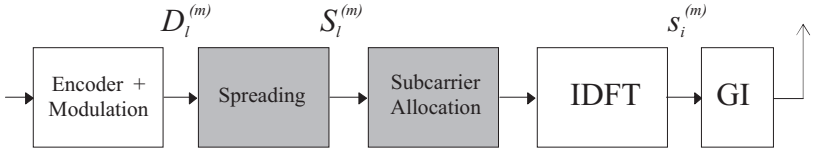
It will be shown in this section that an OFDM-FDMA system based on an equidistant sub-carrier selection procedure combined with an additional sub-carrier spreading technique will reduce the resulting PAR significantly (Brüninghaus & Rohling, 1998) for the uplink procedure. Furthermore, this proposal will lead to a modulation technique which becomes technically very simple and where the transmit signal consists of a periodic extension and multiple repetition of all modulation symbols. This is the result of the duality between multi-carrier CDMA and single carrier transmission technique as described in Brüninghaus and Rohling (1998).

Figure 10 shows the general structure of an OFDM uplink signal processing in the mobile terminal, which will be considered in this section. In this block diagram there are two main components in the OFDM-based modulation scheme which will be treated in the design process of a multi-user uplink system: The sub-carrier selection technique, and a user specific spreading scheme applied to the user's selected sub-carrier subset, respectively.

The last two blocks in the block diagram show the characteristic IDFT processing and the guard interval (GI) insertion, that are common in all OFDM-based transmitter schemes.

In the uplink system model of a multi-user, OFDM-FDMA based scheme, an arbitrary num-

Figure 10. Block diagram of a multi-user OFDM-FDMA uplink system

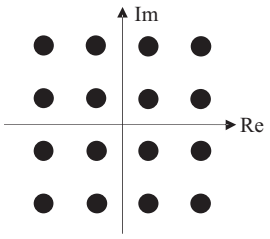


ber of M different users are considered inside a single cell and each user allocates exclusively L different sub-carriers which are considered inside the entire system bandwidth for data transmission. The total number of all considered sub-carriers inside the system bandwidth of the transmission scheme is therefore $N_C = L \cdot M$.

The input data stream for each mobile user terminal m, $m = 0, \ldots, M-1$, is convolutionally encoded in a first step. Afterwards, the bit sequence is mapped onto a modulation symbol vector $\vec{D}^{(m)} = \left(D_0^{(m)}, D_1^{(m)}, \ldots, D_{L-1}^{(m)}\right)$ of L complex valued symbols $D_l^{(m)}$ from a given modulation alphabet with 2^Q different modulation symbols inside the constellation diagram. An example for such a modulation alphabet is given in Figure 11 for a 16-QAM.

In this section, a non-differential, higher level modulation scheme is assumed for the uplink case.

Figure 11. 16-QAM as an exemplary alphabet with modulation symbols $D_l^{(m)}$



Each user transmits $L \cdot Q$ bits per OFDM symbol. It is assumed in this section without any loss of generality that each user transmits the same data rate or the same number of modulation symbols per OFDM signal respectively.

Sub-Carrier Allocation Process

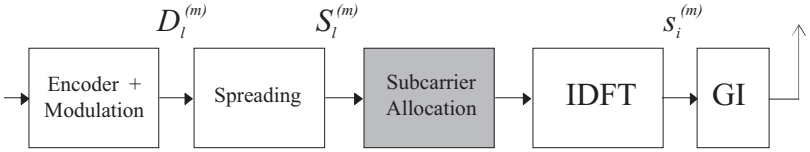
The first important question in the OFDM-FDMA multi-user uplink system design is the user specific sub-carrier selection scheme. This process is responsible for sharing the bandwidth between M different users, see Figure 12.

There is a large degree of freedom in this system design step to allocate exclusively a subset of L specific sub-carriers to each user. This can either be done by a random or a deterministic allocation scheme. Alternatively there are proposals made for adaptive sub-carrier selection schemes to increase the resulting system capacity (Gross, Karl, Fitzek, & Wolisz, 2003; Shen, Li, & Liu, 2004; Toufik & Knopp, 2004).

In this paragraph a very specific non-adaptive sub-carrier selection procedure is proposed. In this case the allocated sub-carrier subset is equidistantly located on the frequency axis over the entire system bandwidth. This approach is shown in Figure 13 and will be pursued in the following.

In this multi-user uplink system each user m allocates exclusively in total L sub-carriers which are in each case placed in an equidistant way on the frequency axis. The selected L sub-carriers are modulated with L complex valued transmit sym-

Figure 12. Block diagram for an OFDM-FDMA based system with sub-carrier selection process



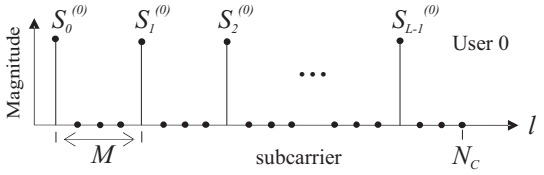
bols $S_l^{(m)}$, described and denoted by the transmit symbol vector $\vec{S}^{(m)}$. The proposed non-adaptive sub-carrier selection and modulation process does not need any radio channel state information (CSI) at the transmitter side.

Due to this specific sub-carrier selection process based on equidistantly located sub-carriers on the frequency axis the resulting OFDM uplink transmit time signal $s_i^{(m)}$ of any user has a periodic structure with period length L and consists in any case of an M-times repetition time signal, see Figure 14.

Equation (18) describes the relation between the sub-carrier transmit symbols $S_l^{(0)}$ and a single period of the resulting OFDM transmit time signal $s_i^{(0)}$ for user 0 analytically.

$$s_i^{(0)} = \frac{1}{\sqrt{L}} \sum_{l=0}^{L-1} S_l^{(0)} e^{j2\pi il/L} \quad \text{for } i = 0,1,\ldots,L-1 \tag{18}$$

Figure 13. Equidistantly allocated subset of L sub-carriers for a single user in a multi-user environment



This relation in equation is simply an IDFT applied to the transmit symbols $S_l^{(0)}$, as shown in Equation (19).

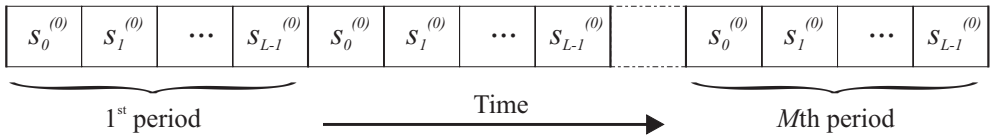
$$\begin{pmatrix} s_0^{(0)} \\ s_1^{(0)} \\ \cdots \\ s_{L-1}^{(0)} \end{pmatrix} = \text{IDFT} \begin{pmatrix} S_0^{(0)} \\ S_1^{(0)} \\ \cdots \\ S_{L-1}^{(0)} \end{pmatrix} \tag{19}$$

Because the sub-carrier subset of a single user is assumed to be allocated equidistantly over all N_C sub-carriers inside the entire bandwidth (Figure 13), it can be shown that an N_C-IDFT processing of the sub-carrier transmit symbols $S_l^{(0)}$ inside the OFDM transmitter leads to the same M-times repetition of the user time signal $s_i^{(0)}$ as shown in Figure 14. The periodicity of the transmit signal is directly related to the selection process of equidistantly located sub-carrier on the frequency axis.

Sub-Carrier Spreading Technique

This paragraph addresses the second design element of an OFDM-FDMA based system: a spreading technique applied to the user's selected sub-carriers, see Figure 15. There are several well-known spreading techniques, which can be integrated into an OFDM-based transmission technique (Kaiser, 2002; Linnartz, 2000). Analo-

Figure 14. OFDM-FDMA based periodic transmit time signal with period length L and M-times repetition



gous to other MC-CDMA systems, described in Kaiser (2002) and Linnartz (2000), the vector $\vec{D}^{(m)}$ of L modulation symbols (see Figure 11) is spread in this case over L sub-carriers which are exclusively allocated to user m applying an unitary spreading matrix [C].

This results in a transmit sub-carrier symbol vector $\vec{S}^{(m)} = \left(S_0^{(m)}, S_1^{(m)}, \ldots, S_{L-1}^{(m)}\right)$ consisting of L complex valued transmit symbols $S_l^{(m)}$, $l = 0,\ldots, L-1$. The spreading operation can be denoted mathematically by the following matrix multiplication where each complex valued transmit symbol $S_l^{(m)}$ is calculated by the sum of L user specific modulation symbols $D_l^{(m)}$ weighted by L orthogonal code vectors $\vec{C}_l = \left(C_{l,0}, C_{l,1}, \ldots, C_{l,L-1}\right)$ with $l = 0,\ldots, L-1$:

$$\begin{pmatrix} S_0^{(m)} \\ S_1^{(m)} \\ \vdots \\ S_{L-1}^{(m)} \end{pmatrix} = \begin{bmatrix} C_{0,0} & C_{0,1} & \cdots & C_{0,L-1} \\ C_{1,0} & \ddots & & C_{1,L-1} \\ \vdots & & & \vdots \\ C_{L-1,0} & \cdots & \cdots & C_{L-1,L-1} \end{bmatrix} \cdot \begin{pmatrix} D_0^{(m)} \\ D_1^{(m)} \\ \vdots \\ D_{L-1}^{(m)} \end{pmatrix} \tag{20}$$

The spreading Matrix [C] consists of L orthogonal spreading codes. It can be designed, for example, by a Walsh-Hadamard matrix like in Kaiser (2002) and Linnartz (2000) or by a DFT matrix as described in Brüninghaus and Rohling (1997, 1998). Both matrix types fulfill the requirements for unity and orthogonality. Examples for these matrices are shown in Figure 16. In the considered multi-user uplink system, only a DFT matrix based spreading technique will be used, because of the resulting benefits in combination with an equidistant sub-carrier allocation scheme.

After the spreading process, the sub-carrier specific transmit symbols $S_l^{(m)}$ are mapped onto L sub-carrier signals which are exclusively allocated to user m. In principle, the user specific sub-carrier subset can be composed of any L out of N_C sub-carriers that have not been assigned to another user.

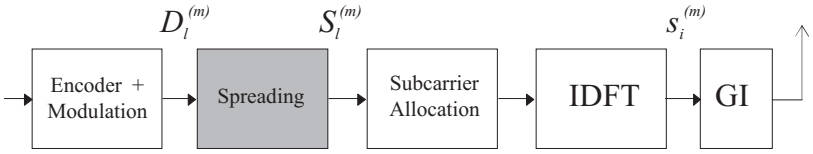
Combination of Spreading and Sub-Carrier Allocation

As explained in the previous paragraph, the spreading technique applied to the modulation symbols

Figure 16. Examples for Walsh-Hadamard (left) and DFT spreading matrix

$$\begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & -1 & 1 & -1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 \end{bmatrix} \qquad \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & e^{-j\pi/2} & e^{-j\pi} & e^{-j\frac{3}{2}\pi} \\ 1 & e^{-j\pi} & e^{-j2\pi} & e^{-j3\pi} \\ 1 & e^{-j\frac{3}{2}\pi} & e^{-j3\pi} & e^{-j\frac{9}{2}\pi} \end{bmatrix}$$

Figure 15. Block diagram of a multi-user OFDM-FDMA uplink system with additional spreading technique



$D_l^{(m)}$ is considered in a way, that a DFT-Matrix can be used as spreading matrix [C]. Therefore, the relation between modulation symbols $D_l^{(0)}$ and sub-carrier transmit symbols $S_l^{(0)}$ are described analytically by Equation (21):

$$\begin{pmatrix} S_0^{(0)} \\ S_1^{(0)} \\ \cdots \\ S_{L-1}^{(0)} \end{pmatrix} = \begin{bmatrix} \\ [C] \\ \\ \end{bmatrix} \cdot \begin{pmatrix} D_0^{(0)} \\ D_1^{(0)} \\ \cdots \\ D_{L-1}^{(0)} \end{pmatrix} = \mathrm{DFT} \begin{pmatrix} D_0^{(0)} \\ D_1^{(0)} \\ \cdots \\ D_{L-1}^{(0)} \end{pmatrix} \tag{21}$$

If this DFT-based spreading technique is combined with the earlier explained, equidistant sub-carrier selection process the transmit time signal $s_i^{(0)}$ can be calculated directly by the M-times repetition of modulation symbol vector $\vec{D}^{(0)}$ which consists of L complex valued modulation symbols, see Figure 17. Therefore, it is needless to process the DFT spreading matrix and the IFFT in the OFDM system structure explicitly, which reduces the computation complexity in the mobile terminal, see Equation (22). Hence, a single period of the resulting time signal $s_i^{(0)}$ is directly given by the calculated modulation symbols $D_l^{(0)}$.

$$\begin{pmatrix} s_0^{(0)} \\ s_1^{(0)} \\ \vdots \\ s_{L-1}^{(0)} \end{pmatrix} = \mathrm{IDFT} \begin{pmatrix} S_0^{(0)} \\ S_1^{(0)} \\ \vdots \\ S_{L-1}^{(0)} \end{pmatrix} = \mathrm{IDFT} \left(\mathrm{DFT} \begin{pmatrix} D_0^{(0)} \\ D_1^{(0)} \\ \vdots \\ D_{L-1}^{(0)} \end{pmatrix} \right) = \begin{pmatrix} D_0^{(0)} \\ D_1^{(0)} \\ \vdots \\ D_{L-1}^{(0)} \end{pmatrix} \tag{22}$$

In almost all OFDM systems, a cyclic prefix of length N_G will be added to the transmit time signal $s_i^{(0)}$ to avoid any ISI. Therefore, the so-called guard interval is also an integral part of the multi-user uplink system described in this paragraph. Thus, the structure of the OFDM-FDMA multi-user uplink system depicted in Figure 18 can be simplified. Figure 18 shows the functionality of the overall system in detail. It becomes clear that because of the cancellation of DFT spreading and IDFT calculation these components can be completely removed in the technical realization. They are replaced by a simple repetition process of the considered user specific modulation symbols $D_l^{(0)}$.

Figure 17. Periodic transmit signal for the multi-user uplink system: Symbols $s_i^{(0)}$ and modulation symbols $D_l^{(0)}$

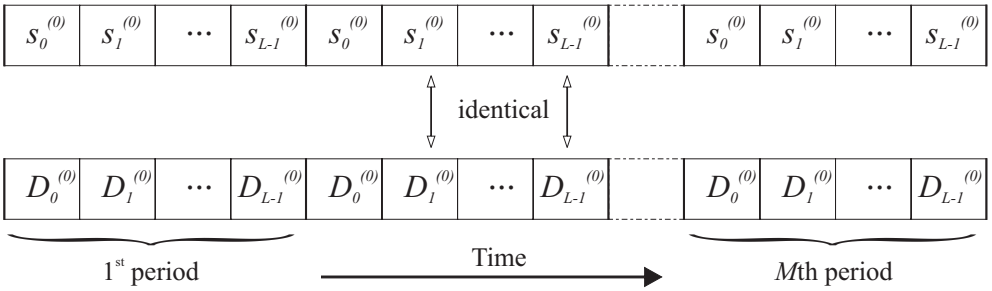


Figure 18. OFDM-FDMA based uplink system including a DFT spreading matrix applied to a set of equidistant sub-carriers

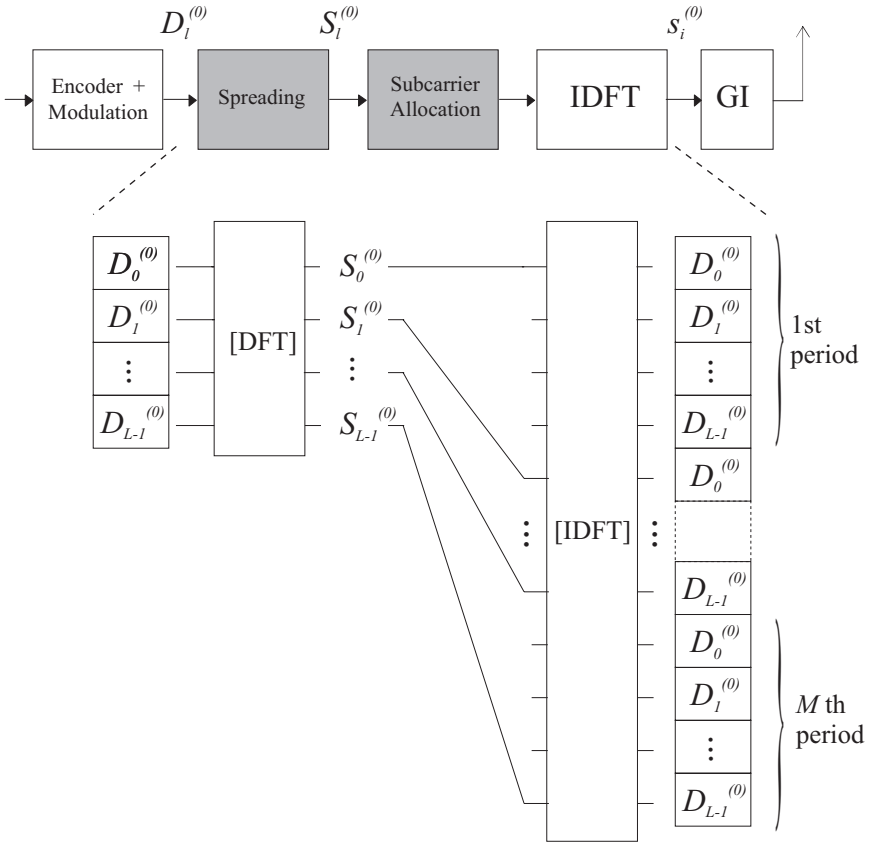

Multi-User Case

The extension from a single to an arbitrary user m is straight forward and will be described in the following. Another user m also allocates an equidistantly spaced subset of all sub-carriers which is shifted in the frequency space by m sub-carriers, see Figure 19.

Any frequency shift results in a multiplication of the transmit time signal $s_i^{(m)}$ with a complex valued signal $e^{j2\pi im/N_C}$, see Equation (23).

Figure 19. Shifting the total sub-carrier subset in a multi-user environment

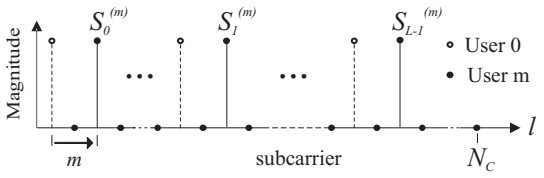

Figure 20. OFDM-FDMA uplink transmit signal for an arbitrary user m

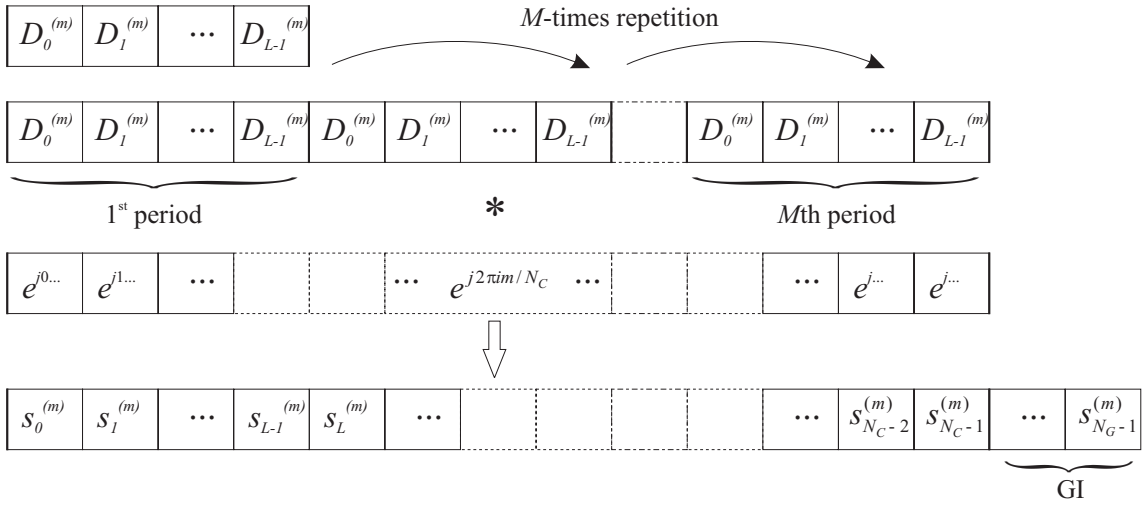


$$S_l^{(m)} \cdot \mathrm{d}(l-m) \quad \bullet\!-\!\circ \quad s_i^{(m)} \cdot e^{j2\pi im/N_C} \qquad (23)$$

This yields a phase rotation of the transmit time symbols $s_i^{(m)}$ with the constant frequency $f_0 = m / N_C$. But this has no significant impact on the complexity of the transmitter structure. Also, the signal envelope of a single OFDM symbol is still constant. The simplified synthesis of the transmit time signal for the multi-user case is depicted in Figure 20. First, the vector of L modulation symbols $\vec{D}^{(m)}$ is calculated and repeated M-times on the time axis. Then, the time sequence is elementwise multiplied by the user-specific, phase rotating sequence $e^{j2\pi im/N_C}$. In the last step, the guard interval is added. Figure 20 describes the simple transmit signal processing and the low computation complexity at the transmitter side and in the mobile terminal for the uplink case.

Figure 19 and Figure 20 show that the time signal of the OFDM-FDMA based uplink scheme with DFT spreading can be considered as a blockwise single carrier periodic transmission system where a cyclic prefix is integrated into a single block as a guard interval. Therefore, the signal envelope is nearly constant and additional techniques like $\pi / 4$ – QPSK can be employed to even reduce the resulting small PAR for this single carrier system. An additional advantage of this OFDM-FDMA based uplink system is the flexible use of sub-carrier allocation process and data rate adaptation for a certain user.

OFDM-BASED AND SYNCHRONIZED CELLULAR NETWORK

In the preceding sections, several uplink- and downlink-schemes for the connection between mobile terminals and base stations were discussed. In this section, the focus will be broadened from

individual links to the overall cellular network. In this context, resource allocation and synchronization of the network play an important role.

As before, the OFDM receiver in a cell has to deal with ISI effects, which occur in multi-path propagation situations in broadband radio channels. In a sufficiently designed OFDM system, these effects can be completely avoided.

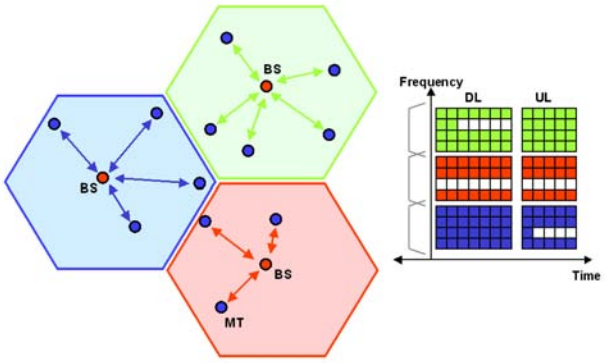
Consequently, the OFDM receiver can also deal with superimposed signals which have been transmitted by several distinct and adjacent base stations (BS) in a cellular environment, if the cellular network is synchronized in time and carrier frequency. All adjacent BS operate simultaneously in the same frequency band which leads to a reuse factor of 1.

In current cellular radio networks each base station assigns resources independently and exclusively to its users. To be able to use a TDMA or FDMA multiple access scheme in a cellular environment, an off-line radio resource planning is required to avoid co-channel interference situations between adjacent cells. As a consequence only a small fraction of the available resource determined by the spatial reuse is assigned to each cell which can dynamically be accessed by its users (Zander & Kim, 2001). However, due to this fixed resource distribution among adjacent cells, a dynamic and flexible shift of resources between cells is technically difficult. Such a conventional cellular network with a fixed frequency planning is shown in Figure 21 for a time division duplex (TDD) system as an example.

By introducing the OFDM transmission technique in such a cellular environment, the limitations of fixed resource allocation can be overcome. Since the OFDM transmission technique is robust in multi-path propagation situations, a synchronized network can be established. All BS and MT are synchronized in this case and the signals from adjacent BS will be received with a mutual relative delay no longer than the guard interval. Under these synchronized network conditions each BS can use all available resources simultaneously. With this technique at hand it is possible to add an additional "macro" diversity to a cellular environment by transmitting the same signal from synchronized BS.

Synchronized networks have been intensively studied, for example, for DVB-T broadcast systems as a single frequency network (SFN). In this case the same information signal is transmitted

Figure 21. Conventional cellular network with fixed resource allocation



on the same resources from different BS. In the communication case and in a synchronized network different information signals are transmitted by the adjacent BS but all received signals can be considered as co-sub-carrier interferer which allows in general the allocation of all available resources for each BS.

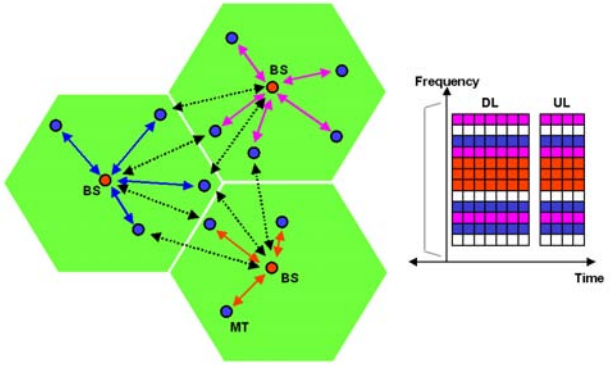
A synchronized network will also be considered to implement a dynamic resource allocation scheme by assigning different sub-carriers of an OFDM-FDMA multiple access scheme to users in adjacent cells. Since the OFDM sub-carriers remain orthogonal in a synchronized network, no MAI between different user in adjacent cells will occur as long as the sub-carriers have been allocated in an exclusive way.

All resources can be accessed in this case by the MT inside a cellular network. Synchronized networks can be used to provide the needed flexibility inside a cellular environment to allocate system resources in those cells where this bandwidth is needed. Especially for non-uniformly distributed users inside a cellular environment or for hot spot situations the system capacity can be largely increased in synchronized networks. The synchronization concept is shown in Figure 22 for an OFDM-FDMA and TDD system as an example. In this case the resource management could be based on co-channel interference (CCI) measurements processed in each BS.

Self-Organized Cell Synchronization

The dynamic sharing of all available resources between adjacent cells requires a tight time and frequency synchronization of all BS and all MT inside the cellular environment. All MTs are synchronized to a single BS using a specific test signal which is transmitted in a downlink preamble. It is assumed in this paragraph that the required network synchronization is achieved without any assistance of a central controller but in a totally decentralized and self-organized way. Furthermore a TDD system is assumed. Synchronization between adjacent BS can be achieved not in a direct way but indirectly if all MT inside a single cell transmit a specific test signal at the end of each frame (or super frame) in an uplink postamble. These different test signals transmitted from all MT in adjacent cells will be received in all BS inside a local environment. Each BS can process this information to synchronize

Figure 22. Flexible radio resource management by making all resources available to all BS in a synchronized OFDM-based cellular environment



clock and carrier simultaneously to establish a synchronized network.

Test signals will therefore be used in the down- and uplink to synchronize all BS in a local environment and all MT inside a single cell, see Figure 23. The test signal itself is designed to allow an almost interference-free time and frequency offset estimation.

To generate the test signal structure, each BS selects a single pair of two adjacent sub-carriers for each frame inside the preamble as it is shown in Figure 24. The sub-carriers inside the test signal are chosen randomly and independently by each BS from a set of allowed sub-carrier pairs placed equidistantly in the frequency band and separated by a guard band of unused sub-carriers to reduce interference in a non-synchronized situation. During the downlink preamble each BS transmits the specific test signal on the individually selected pair of sub-carriers.

In the uplink all MT inside a single cell transmit a test signal which is identical to that one they have received in the preamble at the beginning of the data frame. Each BS receives these test signals in

Figure 23. Test signal structure which is used for the synchronization of MT to a single BS during downlink and between all BS during the uplink phase

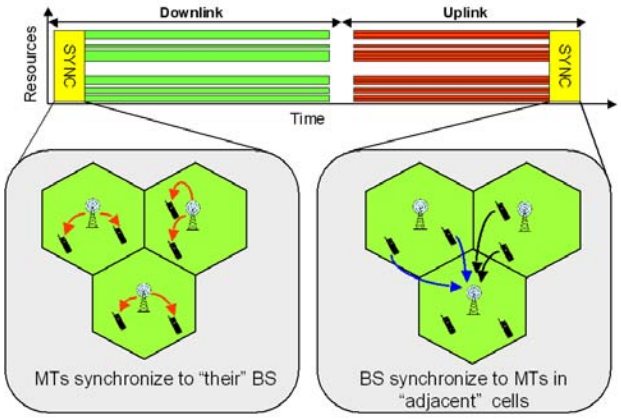


Figure 24. Sub-carrier allocation of test signals

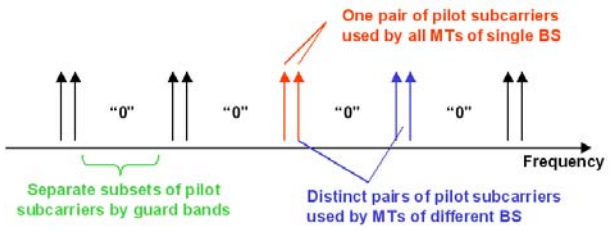


a superimposed form from all MT inside the cell on the same sub-carrier pair. Test signals from MT in adjacent cells will be observed by the BS on distinct pairs of sub-carriers and can therefore be distinguished and processed separately. Each BS selects randomly the sub-carrier pair for the test signal in the preamble of each data frame. Therefore data collisions between test signals of adjacent BS will only occur rarely but do not influence the synchronization process at all. All received test signals are evaluated in the frequency domain as shown in Figure 25.

The signal processing and test signal evaluation is identical in the downlink and uplink. To avoid ISI and ICI during the fine synchronization procedure the test signals are designed to be phase continuous for the duration of N_p consecutive OFDM symbols as it is shown in Figure 25.

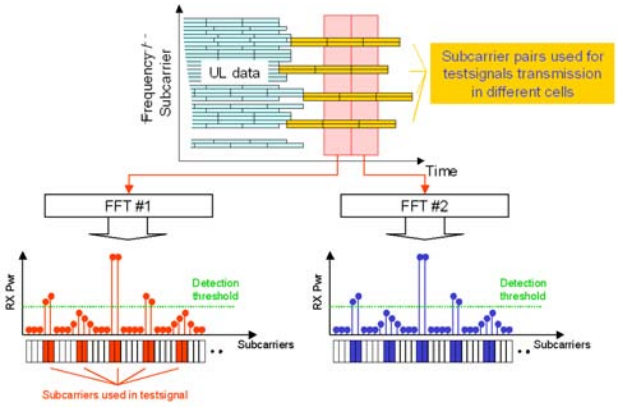
In the downlink case and in the MT synchronization phase a single FFT output signal already contains the time offset information between BS and MT in a certain phase rotation between the two considered adjacent sub-carriers. The carrier frequency offset between BS and MT is given by the phase rotation between the FFT output signals of the same sub-carrier but the two consecutive FFT.

Using this synchronization technique in each BS and MT which is based on phase difference measurements the time and frequency offset estimates are obtained simultaneously for each possible received sub-carrier pair. But only those measurements which exceed a certain amplitude threshold will be used for the subsequent adjustment of the BS time and frequency offsets.

Self-Organized Resource Management

One additional important design aspect for a 4G system is the capability to serve the time-varying data rate demands of all MT efficiently, incorporating high traffic peaks at isolated BS. Therefore dynamic channel allocation (DCA) is considered as an important feature for future networks. Centralized resource management schemes in which a central unit has the complete knowledge about the resource allocation in all cells have been

Figure 25. Time interval free of ISI and ICI between different test signals is used for the estimation of fine time and frequency offsets



investigated with respect to OFDM systems in Wahlqvist et al. (1997) and Wang et al. (2003), for example.

In the following, however, it is assumed that each BS decides in the radio resource management (RRM) procedure and in the sub-carrier allocation process in a self-organizing (SO) way without any cooperation and communication between adjacent cells and without a central management unit. Therefore, the proposed system concept is termed SO-DCA.

The assumed OFDM-FDMA and TDD scheme shown in Figure 22 is only one possible way of arranging the resource management. The SO-DCA concept can be applied for any orthogonal multiple access scheme with a TDMA and/or an

Figure 26. Each BS determines the resource allocation process by measuring the signal power on all sub-carriers inside the available bandwidth

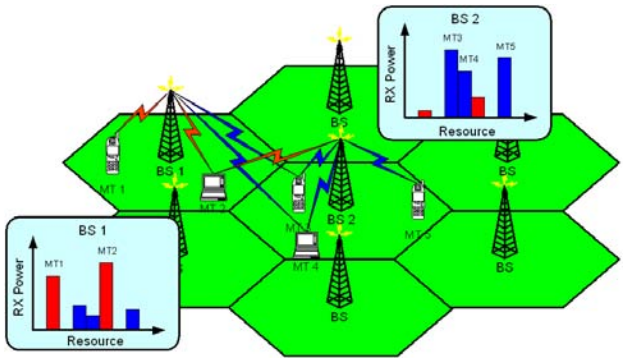


Figure 27. Resource allocation and PHY Mode selection based on the interference measurements at the MT and BS

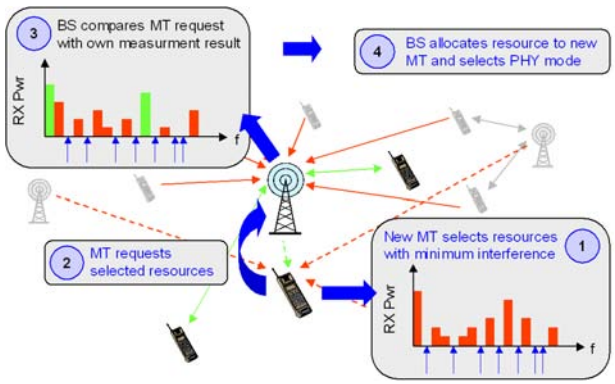

FDMA component. A MAC frame consists of one down link (DL) and one uplink (UL) period and has a total duration of $T_F = T_{UL} + T_{DL}$.

This paragraph introduces a suitable DCA algorithm which strongly benefits from the tight synchronization between all BS and MT inside the cellular environment. The RRM process is mainly based on continuous CCI measurements in each frame. Based on the available CCI measurements (see Figure 26), each BS decides independently of other BS which resources will be covered for a new MT.

In order to increase the system throughput, a link adaptation (LA) procedure is further introduced. Each BS makes decisions about the modulation scheme and channel code rate (PHY mode) which can be used currently on the individual link. The choice of the applied PHY mode is derived from the radio channel measurement. The main task for the DCA algorithm is to assign a sufficient number of sub-carrier resources to a specific user (MT) to satisfy the current quality of service (QoS) demand. The sub-carrier selection process in the DCA procedure is important to allocate those sub-carriers which are less attenuated by the radio channel. This selection process is mainly based on CCI measurements in the MT and BS. The resource allocation process is summarized in Figure 27.

CONCLUSION

Some aspects for future mobile communication networks have been considered in this chapter. The OFDM transmission technique itself has a large potential due to the robust behaviour in wideband frequency selective and time variant radio channels. The combination with multiple access schemes showed good performance under realistic channel assumptions. A system proposal for an air interface structure for downlink and uplink has been discussed. Future cellular networks require high flexibility for data sources with different and time variant data rate in multi-path propagation environments. Therefore a synchronized cellular network has been proposed and the completely decentralized and self-organized time and carrier synchronization aspects have been discussed. Finally, a self-organized RRM has been proposed to establish a totally decentralized organization inside each BS. All these different techniques and technical concepts can be combined in a way to establish a future powerful and flexible mobile communications network for the 4G.

Chapter 8.25
Malicious Software in Mobile Devices

Thomas M. Chen
Southern Methodist University, USA

Cyrus Peikari
Airscanner Mobile Security Corporation, USA

ABSTRACT

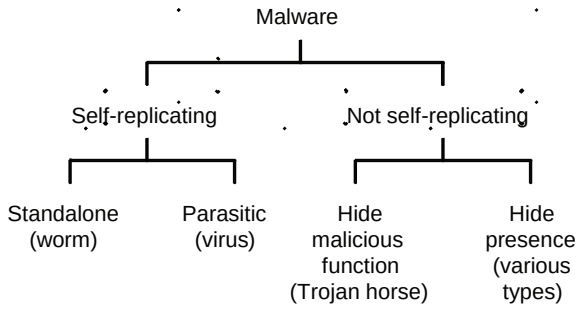
This chapter examines the scope of malicious software (malware) threats to mobile devices. The stakes for the wireless industry are high. While malware is rampant among 1 billion PCs, approximately twice as many mobile users currently enjoy a malware-free experience. However, since the appearance of the Cabir worm in 2004, malware for mobile devices has evolved relatively quickly, targeted mostly at the popular Symbian smartphone platform. Significant highlights in malware evolution are pointed out that suggest that mobile devices are attracting more sophisticated malware attacks. Fortunately, a range of host-based and network-based defenses have been developed from decades of experience with PC malware. Activities are underway to improve protection of mobile devices before the malware problem becomes catastrophic, but developers are limited by the capabilities of handheld devices.

INTRODUCTION

Most people are aware that malicious software (malware) is an ongoing widespread problem with Internet-connected PCs. Statistics about the prevalence of malware, as well as personal anecdotes from affected PC users, are easy to find. PC malware can be traced back to at least the Brain virus in 1986 and the Robert Morris Jr. worm in 1988. Many variants of malware have evolved over 20 years. The October 2006 WildList (www.wildlist.org) contained 780 viruses and worms found to be spreading "in the wild" (on real users' PCs), but this list is known to comprise a small subset of the total number of existing viruses. The prevalence of malware was evident in a 2006 CSI/FBI survey where 65% of the organizations reported being hit by malware, the single most common type of attack.

A taxonomy to introduce definitions of malware is shown in Figure 1, but classification is

Figure 1. A taxonomy of malicious software



sometimes difficult because a piece of malware often combines multiple characteristics. Viruses and worms are characterized by the capability to self-replicate, but they differ in their methods (Nazario, 2004; Szor, 2005). A virus is a piece of software code (set of instructions but not a complete program) attached to a normal program or file. The virus depends on the execution of the host program. At some point in the execution, the virus code hijacks control of the program execution to make copies of itself and attach these copies to more programs or files. In contrast, a worm is a stand-alone automated program that seeks vulnerable computers through a network and copies itself to compromised victims.

Non-replicating malware typically hide their presence on a computer or at least hide their malicious function. Malware that hides a malicious function but not necessarily its presence is called a Trojan horse (Skoudis, 2004). Typically, Trojan horses pose as a legitimate program (such as a game or device driver) and generally rely on social engineering (deception) because they are not able to self-replicate. Trojan horses are used for various purposes, often theft of confidential data, destruction, backdoor for remote access, or installation of other malware. Besides Trojan horses, many types of non-replicating malware hide their presence in order to carry out a malicious function on a victim host without detection and removal by the user. Common examples include bots and spyware. Bots are covertly installed software that secretly listen for remote commands, usually sent through Internet relay chat (IRC) channels, and execute them on compromised computers. A group of compromised computers under remote control of a single "bot herder" constitute a bot net. Bot nets are often used for spam, data theft, and distributed denial of service attacks. Spyware collects personal user information from a victim computer and transmits the data across the network, often for advertising purposes but possibly for data theft. Spyware is often bundled with shareware or installed covertly through social engineering.

Since 2004, malware has been observed to spread among smartphones and other mobile devices through wireless networks. According to F-Secure, the number of malware known to target smartphones is approximately 100 (Hypponen, 2006). However, some believe that malware will inevitably grow into a serious problem (Dagon, Martin, & Starner, 2004). There have already been complex, blended malware threats on mobile

devices. Within a few years, mobile viruses have grown in sophistication in a way reminiscent of 20 years of PC malware evolution. Unfortunately, mobile devices were not designed for security, and they have limited defenses against continually evolving attacks.

If the current trend continues, malware spreading through wireless networks could consume valuable radio resources and substantially degrade the experience of wireless subscribers. In the worst case, malware could become as commonplace in wireless networks as in the Internet with all its attendant risks of data loss, identity theft, and worse. The wireless market is growing quickly, but negative experiences with malware on mobile devices could discourage subscribers and inhibit market growth. The concern is serious because wireless services are currently bound to accounting and charging mechanisms; usage of wireless services, whether for legitimate purposes or malware, will result in subscriber charges. Thus, a victimized subscriber will not only suffer the experience of malware but may also get billed extra service charges. This usage-based charging arrangement contrasts with PCs which typically have flat charges for Internet communications.

This chapter examines historical examples of malware and the current environment for mobile devices. Potential infection vectors are explored. Finally, existing defenses are identified and described.

BACKGROUND

Mobile devices are attractive targets for several reasons (Hypponen, 2006). First, mobile devices have clearly progressed far in terms of hardware and communications. PDAs have grown from simple organizers to miniature computers with their own operating systems (such as Palm or Windows Pocket PC/Windows Mobile) that can download and install a variety of applications. Smartphones combine the communications capabilities of cell phones with PDA functions. According to Gartner, almost 1 billion cell phones will be sold in 2006. Currently, smartphones are a small fraction of the overall cell phone market. According to the *Computer Industry Almanac*, 69 million smartphones will be sold in 2006. However, their shipments are growing rapidly, and IDC predicts smartphones will become 15% of all mobile phones by 2009. Approximately 70% of all smartphones run the Symbian operating system, made by various manufacturers, according to Canalys. Symbian is jointly owned by Sony Ericsson, Nokia, Panasonic, Samsung, and Siemens AG. Symbian is prevalent in Europe and Southeast Asia but less common in North America, Japan, and South Korea. The Japanese and Korean markets have been dominated by Linux-based phones. The North American market has a diversity of cellular platforms.

Nearly all of the malware for smartphones has targeted the Symbian operating system. Descended from Psion Software's EPOC, it is structured similar to desktop operating systems. Traditional cell phones have proprietary embedded operating systems which generally accept only Java applications. In contrast, Symbian application programming interfaces (APIs) are publicly documented so that anyone can develop applications. Applications packaged in SIS file format can be installed at any time, which makes Symbian devices more attractive to both consumers and malware writers.

Mobile devices are attractive targets because they are well connected, often incorporating various means of wireless communications. They are typically capable of Internet access for Web browsing, e-mail, instant messaging, and applications similar to those on PCs. They may also communicate by cellular, IEEE 802.11 wireless LAN, short range Bluetooth, and short/multimedia messaging service (SMS/MMS).

Another reason for their appeal to malware writers is the size of the target population. There were more than 900 million PCs in use worldwide

in 2005 and will climb past 1 billion PCs in 2007, according to the *Computer Industry Almanac*. In comparison, there were around 2 billion cellular subscribers in 2005. Such a large target population is attractive for malware writers who want to maximize their impact.

Malware is relatively unknown for mobile devices today. At this time, only a small number of families of malware have been seen for wireless devices, and malware is not a prominent threat in wireless networks. Because of the low threat risk, mobile devices have minimal security defenses. Another reason is the limited processing capacity of mobile devices. Whereas desktop PCs have fast processors and plug into virtually unlimited power, mobile devices have less computing power and limited battery power. Protection such as antivirus software and host-based intrusion detection would incur a relatively high cost in processing and energy consumption. In addition, mobile devices were never designed for security. For example, they lack an encrypting file system, Kerberos authentication, and so on. In short, they are missing all the components required to secure a modern, network-connected computing device.

There is a risk that mobile users may have a false sense of security. Physically, mobile devices feel more personal because they are carried everywhere. Users have complete physical control of them, and hence they feel less accessible to intruders. This sense of security may lead users to trust the devices with more personal data, increasing the risk of loss and appeal to attackers. Also, the sense of security may lead users to neglect security precautions such as changing default security configurations.

Although mobile devices might be appealing targets, there are certain drawbacks to malware for mobile devices. First, mobile devices usually have intermittent connectivity to the network or other devices, in order to save power. This fact limits the ability of malware to spread quickly. Second, if malware is intended to spread by Bluetooth, Bluetooth connections are short range. Moreover, Bluetooth devices can be turned off or put into hidden mode. Third, there is a diversity of mobile device platforms, in contrast to PCs that are dominated by Windows. Some have argued that the Windows monoculture in PCs has made PCs more vulnerable to malware. To reach a majority of mobile devices, malware writers must create separate pieces of malware code for different platforms (Leavitt, 2005).

EVOLUTION OF MALWARE

Malware has already appeared on mobile devices over the past few years (Peikari & Fogie, 2003). While the number is still small compared to the malware families known for PCs, an examination of prominent examples shows that malware is evolving steadily. The intention here is not to exhaustively list all examples of known malware but to highlight how malware has been developing.

Palm Pilots and Windows Pocket PCs were common before smartphones, and malware appeared first for the Palm operating system. Liberty Crack was a Trojan horse related to Liberty, a program emulating the Nintendo Game Boy on the Palm, reported in August 2000 (Foley & Dumigan, 2001). As a Trojan, it did not spread by self-replication but depended on being installed from a PC that had the "liberty_1_1_crack.prc" file. Once installed on a Palm, it appears on the display as an application, Crack. When executed, it deletes all applications from the Palm (www.f-secure.com/v-descs/lib_palm.shtml).

Discovered in September 2000, Phage was the first virus to target Palm PDAs (Peikari & Fogie, 2003). When executed, the virus infects all third-party applications by overwriting them (http://www.f-secure.com/v-descs/phage.shtml). When a program's icon is selected, the display turns gray and the selected program exits. The virus can spread directly to other Palms by infrared beaming or indirectly through PC synchronization.

Another Trojan horse discovered around the same time, Vapor is installed on a Palm as the application "vapor.prc" (www.f-secure.com/v-descs/vapor.shtml). When executed, it changes the file attributes of other applications, making them invisible (but not actually deleting them). It does not self-replicate.

In July 2004, Duts was a proof-of-concept virus, the first to target Windows Pocket PCs. It asks the user for permission to install. If installed, it attempts to infect all EXE files larger than 4096 bytes in the current directory.

Later in 2004, Brador was a backdoor for Pocket PCs (www.f-secure.com/v-descs/brador.shtml). It installs the file "svchost.exe" in the Startup directory so that it will automatically start during the device bootup. Then it will read the local host IP address and e-mail that to the author. After e-mailing its IP address, the backdoor opens a TCP port and starts listening for commands. The backdoor is capable of uploading and downloading files, executing arbitrary commands, and displaying messages to the PDA user.

The Cabir worm discovered in June 2004 was a milestone marking the trend away from PDAs and towards smartphones running the Symbian operating system. Cabir was a proof-of-concept worm, the first for Symbian, written by a member of a virus writing group 29A (www.f-secure.com/v-descs/cabir.shtml). The worm is carried in a file "caribe.sis" (Caribe is Spanish for the Caribbean). The SIS file contains autostart settings that will automatically execute the worm after the SIS file is installed. When the Cabir worm is activated, it will start looking for other (discoverable) Bluetooth devices within range. Upon finding another device, it will try to send the caribe.sis file. Reception and installation of the file requires user approval after a notification message is displayed. It does not cause any damage.

Cabir was not only one of the first malware for Symbian, but it was also one of the first to use Bluetooth (Gostev, 2006). Malware is more commonly spread by e-mail. The choice of Bluetooth meant that Cabir would spread slowly in the wild. An infected smartphone would have to discover another smartphone within Bluetooth range and the target's user would have to willingly accept the transmission of the worm file while the devices are within range of each other.

In August 2004, the first Trojan horse for smartphones was discovered. It appeared to be a cracked version of a Symbian game Mosquitos. The Trojan made infected phones send SMS text messages to phone numbers resulting in charges to the phones' owners.

In November 2004, the Trojan horse—Skuller—was found to infect Symbian Series 60 smartphones (www.f-secure.com/v-descs/skulls.shtml). The Trojan is a file named "Extended theme.SIS," a theme manager for Nokia 7610 smartphones. If executed, it disables all applications on the phone and replaces their icons with a skull and crossbones. The phone can be used to make calls and answer calls. However, all system applications such as SMS, MMS, Web browsing, and camera do not work.

In December 2004, Skuller and Cabir were merged to form Metal Gear, a Trojan horse that masquerades as the game of the same name. Metal Gear uses Skulls to deactivate a device's antivirus. This was the first malware to attack antivirus on Symbian smartphones. The malware also drops a file "SEXXXY.SIS," an installer that adds code to disable the handset menu button. It then uses Cabir to send itself to other devices.

Locknut was a Trojan horse discovered in February 2005 that pretended to be a patch for Symbian Series 60 phones. When installed, it drops a program that will crash a critical system service component, preventing any application from launching.

In March 2005, ComWar or CommWarrior was the first worm to spread by MMS among Symbian Series 60 smartphones. Like Cabir, it was also capable of spreading by Bluetooth. Infected phones will search for discoverable Bluetooth devices within range; if found, the infected phone

will try to send the worm in a randomly named SIS file. But Bluetooth is limited to devices within 10 meters or so. MMS messages can be sent to anywhere in the world. The worm tries to spread by MMS messaging to other phone owners found in the victim's address book. MMS has the unfortunate side effect of incurring charges for the phone owner.

Drever was a Trojan horse that attacked antivirus software on Symbian smartphones. It drops non-functional copies of the bootloaders used by Simworks Antivirus and Kaspersky Symbian Antivirus, preventing these programs from loading automatically during the phone bootup.

In April 2005, the Mabir worm was similar to Cabir in its ability to spread by Bluetooth. It had the additional capability to spread by MMS messaging. It listens for any arriving MMS or SMS message and will respond with a copy of itself in a file named "info.sis."

Found in September 2005, the Cardtrap Trojan horse targeted Symbian 60 smartphones and was one of the first examples of smartphone malware capable of infecting a PC (www.f-secure.com/v-descs/cardtrap_a.shtml). When it is installed on the smartphone, it disables several applications by overwriting their main executable files. More interestingly, it also installs two Windows worms, Padobot.Z and Rays, to the phone's memory card. An autorun file is copied with the Padobot.Z worm, so that if the memory card is inserted into a PC, the autorun file will attempt to execute the Padobot worm. The Rays worm is a file named "system.exe" which has the same icon as the system folder in the memory card. The evident intention was to trick a user reading the contents of the card on a PC into executing the Rays worm.

Crossover was a proof-of-concept Trojan horse found in February 2006. It was reportedly the first malware capable of spreading from a PC to a Windows Mobile Pocket PC by means of ActiveSync. On the PC, the Trojan checks the version of the host operating system. If it is not Windows CE or Windows Mobile, the virus makes a copy of itself on the PC and adds a registry entry to execute the virus during PC rebooting. A new virus copy is made with a random file name at each reboot. When executed, the Trojan waits for an ActiveSync connection, when it copies itself to the handheld, documents on the handheld will be deleted.

In August 2006, the Mobler worm for Windows PCs was discovered (www.f-secure.com/v-descs/mobler.shtml). It is not a real threat but is suggestive of how future malware might evolve. When a PC is infected, the worm copies itself to different folders on local hard drives and writable media (such as a memory card). Among its various actions, the worm creates a SIS archiver program "makesis.exe" and a copy of itself named "system.exe" in the Windows system folder. It also creates a Symbian installation package named "Black_Symbian.SIS." It is believed to be capable of spreading from a PC to smartphone, another example of cross-platform malware.

At the current time, it is unknown whether Crossover and Mobler signal the start of a new trend towards cross-platform malware that spread equally well among PCs and mobile devices. The combined potential target population would be nearly 3 billion. The trend is not obvious yet but Crossover and Mobler suggest that cross-platform malware could become possible in the near future.

INFECTION VECTORS

Infection vectors for PC malware have changed over the years as PC technology evolved. Viruses initially spread by floppy disks. After floppy disks disappeared and Internet connectivity became ubiquitous, worms spread by mass e-mailing. Similarly, infection vectors used by malware for mobile devices have changed over the past few years.

Synchronization: Palm and Windows PDAs were popular before smartphones. PDAs install

software by synchronization with PCs (Foley & Dumigan, 2001). For example, Palm applications are packaged as Palm resource (PRC) files installed from PCs. As seen earlier, Palm malware usually relied on social engineering to get installed. This is a slow infection vector for malware to spread between PDAs because it requires synchronization with a PC and then contact with another PC that synchronizes with another PDA. Much faster infection vectors became possible when PDAs and then smartphones started to feature communications directly between mobile devices without having to go through PCs.

E-mail and Web: Internet access from mobile devices allows users away from their desktops to use the most common Internet applications, e-mail and the World Wide Web. Most mobile devices can send and receive e-mail with attachments. In addition, many can access the Web through a microbrowser designed to render Web content on the small displays of mobile devices. Current microbrowsers are similar in features to regular Web browsers, capable of HTML, WML, CSS, Ajax, and plug-ins. Although e-mail and the Web are common vectors for PC malware, they have not been used as vectors to infect mobile devices thus far.

SMS/MMS messaging: Commonly called text messaging, SMS is available on most mobile phones and Pocket PCs. It is most popular in Europe, Asia (excluding Japan), Australia, and New Zealand, but has not been as popular in the U.S. as other types of messaging. Text messaging is often used to interact with automated systems, for example to order products or services or participate in contests. Short messages are limited to 140 bytes of data, but longer content can be segmented and sent in multiple messages. The receiving phone is responsible for reassembling the complete message. Short messages can also be used to send binary content such as ringtones or logos. While SMS is largely limited to text, MMS is a more advanced messaging service allowing transmission of multimedia objects—video, images, audio, and rich text. The ComWar worm was the first to spread by MMS (among Symbian Series 60 smartphones). MMS has the potential to spread quickly. ComWar increased its chances by targeting other phone owners found in the victim's address book. By appearing to come from an acquaintance, an incoming message is more likely to be accepted by a recipient. MMS will likely continue to be an infection vector in the future.

Bluetooth: Bluetooth is a short-range radio communication protocol that allows Bluetooth-enabled devices (which could be mobile or stationary) within 10-100 meters to discover and talk with each other. Up to eight devices can communicate with each other in a piconet, where one device works in the role of "master" and the others in the role of "slaves." The master takes turns to communicate with each slave by round robin. The roles of master and slaves can be changed at any time.

Each Bluetooth device has a unique and permanent 48-bit address as well as a user-chosen Bluetooth name. Any device can search for other nearby devices, and devices configured to respond will give their name, class, list of services, and technical details (e.g., manufacturer, device features). If a device inquires directly at a device's address, it will always respond with the requested information.

In May 2006, F-Secure and Secure Networks conducted a survey of discoverable Bluetooth devices in a variety of places in Italy. They found on average 29 to 154 Bluetooth devices per hour in discoverable mode in the different places. In discoverable mode, the devices are potentially open to attacks. About 24% were found to have visible OBEX push service. This service is normally used for transfer of electronic business cards or similar information, but is known to be vulnerable to a BlueSnarf attack. This attack allows connections to a cellular phone and access to the phone book and agenda without authorization. Another vulnerability is BlueBug, discovered

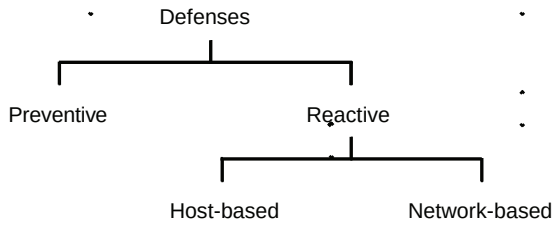
in March 2004, allowing access to the ASCII Terminal (AT) commands of a cell phone. These set of commands are common for configuration and control of telecommunications devices, and give high-level control over call control and SMS messaging. In effect, these can allow an attacker to use the phone services without the victim's knowledge. This includes incoming and outgoing phone calls and SMS messages.

The Cabir worm was the first to use Bluetooth as a vector. Bluetooth is expected to be a slow infection vector. An infected smartphone would have to discover another smartphone within a 10-meter range, and the target's user would have to willingly accept the transmission of the worm file while the devices are within range of each other. Moreover, although phones are usually shipped with Bluetooth in discoverable mode, it is simple to change devices to invisible mode. This simple precaution would make it much more difficult for malware.

MALWARE DEFENSES

Practical security depends on multiple layers of protection instead of a single (hopefully perfect) defense (Skoudis, 2004). Fortunately, various defenses against malware have been developed from decades of experience with PC malware. A taxonomy of malware defenses is shown in Figure 2. Defenses can be first categorized as preventive or reactive (defensive). Preventive techniques help avoid malware infections through identification and remediation of vulnerabilities, strengthening security policies, patching operating systems and applications, updating antivirus signatures, and even educating users about best practices (in this case, for example, turning off Bluetooth except when needed, rejecting installation of unknown software, and blocking SMS/MMS messages from untrusted parties). At this time, simple preventive techniques are likely to be very effective because there are relatively few threats that really spread in the wild. In particular, education to raise user awareness would be effective against social engineering, one of the main infection vectors used by malware for mobile devices so far.

Figure 2. A taxonomy of malware defenses



Host-Based Defenses

Even with the best practices to avoid infections, reactive defenses are still needed to protect mobile devices from actual malware threats. Reactive defenses can operate in hosts (mobile devices) or within the network. Host-based defenses make sense because protection will be close to the targets. However, host-based processes (e.g., antivirus programs) consume processing and power resources that are more critical on mobile devices than desktop PCs. Also, the approach is difficult to scale to large populations if software must be installed, managed, and maintained on every mobile device. Network-based defenses are more scalable in the sense that one router or firewall may protect a group of hosts. Another reason for network-based defenses is the possibility that the network might be able to block malware before it actually reaches a targeted device, which is not possible with host-based defenses. Host-based defenses take effect after contact with the host. In practice, host-based and network-based defenses are both used in combination to realize their complementary benefits.

The most obvious host-based defense is antivirus software (Szor, 2005). Antivirus does auto-

matic analysis of files, communicated messages, and system activities. All commercial antivirus programs depend mainly on malware signatures which are sets of unique characteristics associated with each known piece of malware. The main advantage of signature-based detection is its accuracy in malware identification. If a signature is matched, then the malware is identified exactly and perhaps sufficiently for disinfection. Unfortunately, signature-based detection has two drawbacks. First, antivirus signatures must be regularly updated. Second, there will always be the possibility that new malware could escape detection if it does not have a matching signature. For that case, antivirus programs often include heuristic anomaly detection which detects unusual behavior or activities. Anomaly detection does not usually identify malware exactly, only the suspicion of the presence of malware and the need for further investigation. For that reason, signatures will continue to be the preferred antivirus method for the foreseeable future.

Several antivirus products are available for smartphones and PDAs. In October 2005, Nokia and Symantec arranged for Nokia to offer the option of preloading Symbian Series 60 smartphones with Symantec Mobile Security Antivirus. Other commercial antivirus packages can be installed on Symbian or Windows Mobile smartphones and PDAs.

In recognition that nearly all smartphone malware has targeted Symbian devices, a great amount of attention has focused on the vulnerabilities of that operating system. It might be argued that the system has a low level of application security. For example, Symbian allows any system application to be rewritten without requiring user consent. Also, after an application is installed, it has total control over all functions. In short, applications are totally trusted.

Although Windows CE has not been as popular a target, it has similar vulnerabilities. There are no restrictions on applications; once launched, an application has full access to any system function including sending/receiving files, phone functions, multimedia functions, and so forth. Moreover, Windows CE is an open platform and application development is relatively easy.

Symbian OS version 9 added the feature of code signing. Currently all software must be manually installed. The installation process warns the user if an application has not been signed. Digital signing makes software traceable to the developer and verifies that an application has not been changed since it left the developer. Developers can apply to have their software signed via the Symbian Signed program (www.symbiansigned.com). Developers also have the option of self-signing their programs. Any signed application will install on a Symbian OS phone without showing a security warning. An unsigned application can be installed with user consent, but the operating system will prevent it from doing potentially damaging things by denying access to key system functions and data storage of other applications.

Network-Based Defenses

Network-based defenses depend on network operators monitoring, analyzing, and filtering the traffic going through their networks. Security equipment include firewalls, intrusion detection systems, routers with access control lists (ACLs), and antivirus running in e-mail servers and SMS/MMS messaging service centers. Traffic analysis is typically done by signature-based detection, similar in concept to signature-based antivirus, augmented with heuristic anomaly based detection. Traffic filtering is done by configuring firewall and ACL policies.

An example is Sprint's Mobile Security service announced in September 2006. This is a set of managed security services for mobile devices from handhelds to laptops. The service includes protection against malware attacks. The service can scan mobile devices and remove detected malware automatically without requiring user action.

In the longer term, mobile device security may be driven by one or more vendor groups working to improve the security of wireless systems. For instance, the Trusted Computing Group (TCG) (www.trustedcomputinggroup.org) is an organization of more than 100 component manufacturers, software developers, networking companies, and service providers formed in 2003. One subgroup is working on a set of specifications for mobile phone security (TCG, 2006a). Their approach is to develop a Mobile Trusted Module (MTM) specification for hardware to support features similar to those of the Trusted Platform Module (TPM) chip used in computers but with additional functions specifically for mobile devices. The TPM is a tamper-proof chip embedded at the PC board level, serving as the "root of trust" for all system activities. The MTM specification will integrate security into smartphones' core operations instead of adding as applications.

Another subgroup is working on specifications for Trusted Network Connect (TCG, 2006b). All hosts including mobile devices run TNC client software, which collects information about that host's current state of security such as antivirus signature updates, software patching level, results of last security scan, firewall configuration, and any other active security processes. The security state information is sent to a TNC server to check against policies set by network administrators. The server makes a decision to grant or deny access to the network. This ensures that hosts are properly configured and protected before connecting to the network. It is important to verify that hosts are not vulnerable to threats from the network and do not pose a threat to other hosts. Otherwise, they will be effectively quarantined from the network until their security state is remedied. Remedies can include software patching, updating antivirus, or any other changes to bring the host into compliance with security policies.

FUTURE TRENDS

It is easy to see that mobile phones are increasingly attractive as malware targets. The number of smartphones and their percentage of overall mobile devices is growing quickly. Smartphones will continue to increase in functionalities and complexity. Symbian has been the primary target, a trend that will continue as long as it is the predominant smartphone platform. If another platform arises, that will attract the attention of malware writers who want to make the biggest impact.

The review of malware evolution suggests a worrisome trend. Since the first worm, Cabir, only three years ago, malware has advanced steadily to more infection vectors, first Bluetooth and then MMS. Recently malware has shown signs of becoming cross-platform, moving easily between mobile devices and PCs.

Fortunately, mobile security has already drawn the activities of the TCG and other industry organizations. Unlike the malware situation with PCs, the telecommunications industry has decades of experience to apply to wireless networks, and there is time to fortify defenses before malware multiplies into a global epidemic.

CONCLUSION

Malware is a low risk threat for mobile devices today, but the situation is unlikely to stay that way for long. It is evident from this review that mobile phones are starting to attract the attention of malware writers, a trend that will only get worse. At this point, most defenses are common sense practices. The wireless industry realizes that the stakes are high. Two billion mobile users currently enjoy a malware-free experience, but negative experiences with new malware could have a disastrous effect. Fortunately, a range of

host-based and network-based defenses have been developed from experience with PC malware. Activities are underway in the industry to improve protection of mobile devices before the malware problem becomes catastrophic.

KEY TERMS

Antivirus Software: Antivirus software is designed to detect and remove computer viruses and worms and prevent their reoccurrence.

Exploit Software: Exploit software is written to attack and take advantage of a specific vulnerability.

Malware Software: Malware software is any type of software with malicious function, including for example, viruses, worms, Trojan horses, and spyware.

Smartphone: Smartphones are devices with the combined functions of cell phones and PDAs, typically running an operating system such as Symbian OS.

Social Engineering: Social engineering is an attack method taking advantage of human nature.

Trojan Horse: A Trojan horse is any software program containing a covert malicious function.

Virus: A virus is a piece of a software program that attaches to a normal program or file and depends on execution of the host program to self-replicate and infect more programs or files.

Vulnerability: Vulnerability is a security flaw in operating systems or applications that could be exploited to attack the host.

Worm: A worm is a stand-alone malicious program that is capable of automated self-replication.

This work was previously published in Handbook of Research on Wireless Security, edited by Y. Zhang, J. Zheng, and M. Ma, pp. 1-10, copyright 2008 by Information Science Reference, formerly known as Idea Group Reference (an imprint of IGI Global).
