devices taking on added features. For example, *multimedia messaging*, as opposed to *voice transmissions*, being delivered to cell phones has rendered such mobile devices an integral part of people's lives and a core part of how they conduct their daily business rather than an add on tool (Buckingham, 2001).

The *3G mobile phone* system aims at unifying the disparate standards of current second generation *wireless systems*. The idea is to eliminate the different types of *global networks* being adopted with a single standard network. This will allow for the delivery of multimedia content and propagation through the network without the need for conversion from one standard to another. 3G systems need smaller cells thus the need for more base stations (mostly due to their operating frequency, power requirements, and modulation) and in many cases will not be feasible to install them in areas where population is not so dense (i.e., rural areas) (Garber, 2002). Because of these requirements and conditions, a better way to deliver the communication must be established. However, global access to such mobile devices will create *data delivery* challenges and servers can become clogged with unwanted communication, like that of wired Internet access. The need for moving relevant data to mobile devices in the shortest time possible becomes of utmost importance.

BACKGROUND

As the evolving functionalities of mobile computing take on primary roles at both the individual and the organizational levels, researchers and developers move to further enhance the technology. Bettstetter, Resta and Santi (2003) offer a random waypoint model for wireless ad hoc networks suggesting that the spatial distribution of network nodes movement, according to this model, is in general nonuniform and impairs the accuracy of the current simulation methodology of ad hoc networks. They present an algorithm that looks at the generalization of the model where the pause time of the mobile modes is chosen arbitrarily in each waypoint and a fraction of nodes remain static for the entire simulation time. They further show that the structure of the resulting distribution is the weighted sum of 3 independent components: the static, pause, and mobility (Bettstetter et al., 2003)

Xie and Akyildiz (2002) address the problem of excessive signaling traffic and long signaling delays in mobile IP. They argue that it is possible to have a distributed and dynamic regional location management scheme for Mobile IP where the "signaling burden is evenly distributed and the regional network boundary is dynamically adjusted according to the up-to-date mobility and traffic load for each terminal". This is suggested for minimizing the cost of content delivery over mobile IP networks (Xie & Akyildiz, 2002).

La Porta (2002) describes mobile computing as "a confluence of communication technologies (particularly the Internet), computing devices and their components, and access technologies such as wireless." He argues that a mobile computing environment will include not only real-time mobility of devices, but also mobility of people across devices, stressing the fact that the environment must include a wide range of devices, applications and networks (La Porta, 2002).

Zimmerman (1999) states that "The proliferation of mobile computing devices including laptops, personal digital assistants (PDAs), and wearable computers has created a demand for wireless personal area networks (PANs)" showing at the same time the fact that the mobility of such devices places considerable requirements on PANs not only for connectivity, cross-platform and networks but also for content delivery in minimum time (Zimmerman, 1999). This article further addresses the subject of data and content delivery to mobile devices with a keen interest in time and cost issues.

MOBILE COMMUNICATION SYSTEMS

There are four major categories in which data can be classified. These are real-time data, daily data, occasional data, and junk data:

1. **Real-Time Data (RTD):** Both hard and soft real-time is data that needs to be sent/ received as soon as possible regardless of cost.
2. **Daily Data (DD):** Data that is sent only once or twice a day at a predetermined time (status reports, weather forecasts, etc.).
3. **Occasional Data (OC):** Data that is sent from time to time (software updates, customer service reports, etc.).
4. **Junk Data (JD):** Data that is considered useless (spam).

One way to speed up the data delivery is called data shorthand, where properly configured computers can send chunks of data based on data changes so only the changed data is sent to the mobile device (Ungs, 2002). But this type of data exchange requires mobile devices to store each of the exchange. Caching transmissions can be used successfully for non real-time data communication (like browsing the Internet, checking e-mail, etc.). For real-time message exchanges, caching cannot be used and other methods of speeding up delivery become necessary.

Convergence between broadband wireless mobile devices and access is currently a significant issue in wireless communications. With the recent technological advances in digital signal processing, software-definable radio, intelligent antennas, and others, the next generation of mobile wireless systems is expected to be more compact, with limited hardware and will feature flexible and intelligent software elements (Rao, Bojkovic, Milovanovic, 2002). Wireless mobile Internet (WMI) is a key application of the converged broadband wireless system where the actual device will be compatible with mobile and global access services, including wireless multicasting and wireless trunking. Some of the characteristics of these mobile devices will be: at least 90% of the transmission traffic will be data, voice recognition functions will be operational for every command, the mobile device will support multiple users and various service options, the mobile device will be adaptive and upgradeable, and the entire transmission will be encrypted for ensuring privacy of communication (encryption will be done in hardware for faster processing).

Mobile wireless communication implies support for user's mobility and the overall communication infrastructure needed to handle movements within the home network cell/servers map but also outside the home network in situations where communication is provided by other providers (Agrawal & Zeng, 2003; Rao et al., 2002). A mobile station (MS) should be able to communicate without session interruptions as it travels anywhere using local wireless infrastructure facilities. Because of this, session handoff between cells and mobile switching centers (MFCs) of various wireless service providers should be supported. As a MS travels from a location to another, it has to register itself with the next cell/server that serves that particular area. Each of the servers maintains a visitor location register (VLR) that is an index of the MS IDs that are in its active area. As the MS leaves a cell/server, an entry is made in the home location register (HLR) of the home network so the current location is known at all times. Based on these registers, data can be sent over the network to reach the mobile device. Our work is concerned less with the way the handoff of the communication session takes place, but more with how many times the data has to jump before it reaches the mobile device as is described below.

NETWORK INTERCONNECTION FRAMEWORK

First, we look at a possible N-cube configuration for mobile switching centers/servers. Each imaginary cube will have eight servers (one server in each corner of the cube). The worst-case scenario will be a maximum of three jumps inside a cube. Any server can be reached from any other one with 1, 2, or 3 jumps. The 2^{nd} cube will also have eight servers and so on all the way to N cubes. The total number of servers will be N [cubes] × 8 [servers/cube]. Each of the MSCs will only have knowledge of their neighbors MSCs as well as the corresponding MSCs in the adjacent cubes. If we consider that for the real-time data (RTD) a maximum of 0.001 s propagation time between two MSCs inside the same virtual cube, and considering the propagation speed of the signal to be at 2/3 × C (where C is the speed of light in vacuum=300,000 [Km/s]) then the maximum distance between two adjacent MSCs should not exceed: D = (2/3 × C) x 100 ms = (2/3 × 3 ×10^8 m/s) × 0.001 s = 200 [Km]. This will make the worst-case scenario to be three jumps inside any given virtual cube that means a 3 × 0.001 [s] delay = 0.003 [s].

If the mobile station (MS) is not in the area covered by a cube, then a jump is needed from a cube to the next cube. If the MS is not registered with a cube, all eight servers/switching stations know that from the VRL list, so it will send the transmission to the next adjacent cube (1 jump only). If we consider the adjacent virtual cubes to be with in 200 [km] of each other, then the jump will not take longer than 1 micro second (0.001 s). In the case of N cubes, we have a maximum of Ln (8N) / Ln (2) jumps to reach the MSC that has the MS registered. In that case considering that every jump introduces a 0.001 [s] delay, in the worst-case scenario we will have 0.001 [s] × Ln (8N) / Ln (2). So if, for example, an MS travels, say, 5000 [km], that means that the area can be covered with the maximum 5000 [km] / 200 [km] = 25 virtual cubes.

If data needs to propagate from the HS (home station) to the position where the MS station is (5000 Km away), then the total number of jumps (in the worst-case) will be given by: Ln (8 × 25)/Ln (2) = 7.65 → 8 jumps. At 0.001 (s) delay for each jump, then the MS will be reached in minimum 8 × 0.001 s = 0.008 (s). Of course this would represent the best-case scenario ignoring the overhead and delays introduced by the switching equipment itself. If we use a safety factor of 2 (to cover the overhead delays) then in the worst-case scenario the MS at 5000 km away will receive the data 0.016 (s) after it was sent. This would apply to real-time data (RTD) that cannot be cached and needs to reach the MS the fastest way possible. For the data that is not real time and/or has smaller priorities, if channels in MSCs are available, it can be sent the same way as real-time data. But if the MSCs are busy routing real time transmissions, the lower priority data will be cached and put in a FIFO queue for later delivery.

Another possible interconnection of MSCs would be having the servers in a grid type network. Keeping the same constraints like for the virtual N-cube configuration, then the distance between each of the servers would be 200 [km]. Considering that each of the MSCs/servers can only communicate with a maximum of two other MSCs (no diagonal communication), and the grid has a square profile (m × m) with n number of MSCs, then the total number of jumps inside the grid would be 2(m-1). Considering the same example as above, with the MS traveling at 5000 [km] away. That distance can be covered by a 25 × 25 grid with each located at MSC at 200 [km] away from its neighbors. That would imply a number of jumps equal to 2(25-1) = 48. At 0.001 [s] delay per jump, the total delay in the case of a grid network would be 0.001 [s] × 48 jumps = 0.048 [s]. If we consider that the system has some residual delays, and if we use the same safety factor as in the N cube network, then we have a delay of 0.096 [s] which is six times worse than the virtual N cube configuration delay.

For the case when the MS travels outside an area covered by any of these two types of interconnections, a satellite service (MSAT-mobile satellite service) must be used to relay the data. MSAT are communication satellites in geostationary (Keplerian) orbits (35,786 km) and operate in the frequency range of 1626.5-1660.5 [MHz] for uplink and 1550-1559 [MHz] for downlink and currently serve only the US and Canada (Roddy, 2001). The periodicity of such satellite is 23 hr 56 min 4 sec which matches the Earth's periodicity. Some relevant points regarding this type of satellite: the satellite must move Eastward at the same rotational speed as the Earth, the orbit must be circular (and must maintain the same distance from the Earth), and the inclination of the orbit must be zero degrees (Roddy, 2001). Also, there is only one geosynchronous orbit thus communication via those satellites is still expensive for private use (for a two-way communication).

Satellite communication will introduce an additional delay due to the time it takes for the signal to reach the satellite and come back. At 35,768 [Km] away, a signal takes a time T= 35,768 [km]/300,000 [km/s] = 0.119 [sec] each way (Statica, 2002). So the round trip delay would be 2 × 0.119 [s] = 0.238 [s]. If we use the same safety factor of 2 (for delays due to sending acknowledgments, control signals, etc.), then the delay introduced by the satellite would be 0.238 [s] × 2 = 0.476 [s]. This time would be added to the time it takes to propagate through the terrestrial N cube or grid network when the signal arrives from the satellite.

Because the home location register (HLR) knows the exact location of the MS when is registered with any of the VLRs, when the value for a particular MS is not known by the HLR, two possibilities are considered: the MS is turned off (thus unable to communicate with any of the MSCs and register itself in a VLR) and the MS traveled outside an area covered by the terrestrial MSCs. At that point, if communication arrives at the HS for a MS that doesn't have the position known (registered) with any VLRs, then the HS must buffer the communication. When the MS comes on line and registers with a local MSC, even if that MSC is not directly connected to any N cube or grid network (for example is in another country where the HS is located), the MSC that has registered the MS will send a registration request via the satellite to the HS. At that time, the HS will know where to send the data for that MS and the transmission is relayed via the geosynchronous satellite. Of course satellite communication is not suitable for real-time data, due to the delays it introduces, but the MS can still get the data if needed (but not in real time).

FUTURE TRENDS

The push for advanced technology and the high demand for reliable, secure, low cost, high speed wireless connections as well as the high demand for access of data anywhere and anytime has revolutionized the wireless industry and moved the wireless systems from the secondary means of communications to a primary means crossing the line and merging at the same time the personal communication systems with business systems. Third generation (3G) wireless systems are in place, but there are already faster systems that will make the 3G network technically obsolete. Also, the fact that smaller cells are required for 3G systems would create a disadvantage when the technology is deployed over large and less populated rural areas. These systems considered to be the 4^{th} generation (4G) aim at delivering high-definition video signals at rates 10 times faster than the 3G systems (and also cheaper). 4G systems will focus on integrating wireless networks and become the platform for mobile systems. Also, 4G systems will be IP-based multimedia services in a seamlessly integrated network that will allow users to us any system at anytime and anywhere.

The new generation of wireless communication will be multi-everything (multi-mode, multi-band, multi-functional) and is aiming to provide the best connection to users (Kim et al., 2003). 4G systems will also incorporate automatic switching functions for mobile networks, mobility control, fast hand-offs and rapid routing of packets. Because of these capabilities, it is estimated that the 4G systems will improve the coverage in highly populated areas and it will carry more traffic by utilizing various technologies and methodologies to deliver the best possible services in the most efficient way. Important advantages of 4G over 3G are higher transmission rate (almost double), higher capacity, higher frequency band (higher than 3GHz), single mobile device, increased area of coverage, and lower system cost.

As these new systems continue to be developed and improved, the need to be able to deliver data as fast as possible (with minimum delays) becomes a major factor that needs to be incorporated so the new systems live up to their promise of delivering real-time video and data to mobile units.

CONCLUSION

As the integration trend of voice and data transmissions and making them available on the same mobile device grows, it becomes important to route data from the home station (HS) to the mobile station (MS) in the shortest time possible. Moreover, real-time data (RTD) must have the highest priority, should not be queued, and ought to be delivered to the MS also in the shortest time possible. The framework discussed in this article presents a possible N cube configuration and a grid type interconnection of the Mobile Switching Centers (MSCs), which are actually data servers, so the data can jump a minimum amount of servers and reach the MS as quickly as possible. In the case when the HS does not have a direct connection with the network that the MS is registered with (while traveling), a possible satellite communication is suggested using a mobile satellite service (MSAT) network.

In an N cube configuration, it is shown that the worst-case delay would be given by the equation: 0.001 [s] × Ln (8N) / Ln (2), where N is the number of cubes the data has to jump. The number of cubes N is calculated based on the distance the MS is at, considering a distance of maximum 200 [km] between cubes (and between each of the MSCs inside a cube). In the square grid configuration it is shown that the worst-case delay is given by the equation: 0.001 [s] × 2(m-1), where m is the side of the square. Using the MSAT satellite will introduce a minimum of 0.476 [s] delay, only due to the propagation of the signal.

We found that having an N cube interconnection of MSCs will give the smallest time in data delivery to a MS. With relatively small number of cubes, we can cover a relatively large area of service. For example, for a 5000 [km] travel of MS we need around 25 cubes. The proposed topology fits well in the design of the 4G systems and will help in achieving the design parameters of the 4th generation wireless networks by allowing data to reach the end user the fastest (and cheapest) way possible.

KEY TERMS

Antenna: The part of a transmitting or receiving device that radiates or receives electromagnetic radiation (electromagnetic waves).

Bandwidth: The difference in Hertz between the limiting (upper and lower) frequencies of a spectrum.

Broadband: Refers to systems that provide the user with data rates in excess of 2MBps and up to 100 Mbps.

Cellular Network: A wireless communication network in which fixed antennas are arranged in a special pattern (hexagonal pattern) and mobile stations communicate through nearby fixed antennas.

Channel Capacity: The maximum possible information rate through a channel subject to the constraints of that channel.

Downlink: The communication link from a satellite to an Earth station.

Frequency: Rate of signal oscillation in Hertz.

Geostationary: Refers to geosynchronous satellite angle with zero inclination. So the satellite appears to hover over one spot on the Earth's equator.

Packet: A group of bits that includes data (payload) plus source, destination address and other routing information (in the header).

Transmission Medium: The physical path between a transmitter and receiver (can be wired (guided medium) or wireless (un-guided medium).

Uplink: The communication link from an Earth station to a satellite.

Wireless: Refers to transmission through air, vacuum or water by the means on an antenna.

ABSTRACT

An appropriate control architecture is a crucial premise for successfully achieving truly autonomous mobile robots. The architecture should allow for a robust control of the robot in complex tasks, while it should be flexible in order to operate in different environments pursuing different tasks. This chapter presents a control framework that is able to control an autonomous robot in complex real-world tasks. The key features of the framework are a hybrid control paradigm that incorporates reactive, planning and reasoning capabilities, a flexible software architecture that enables easy adaptation to new tasks and a robust task execution that makes reaction to unforeseen changes in the task and environment possible. Finally, the framework allows for detection of internal failures in the robot and includes self-healing properties. The framework was successfully deployed in the domain of robotic soccer and service robots. The chapter presents the requirements for such a framework, how the framework tackles the problems arising from the application domains, and results obtained during the deployment of the framework.

INTRODUCTION

An appropriate control architecture is a crucial premise for successfully achieving truly autono-

mous mobile robots. The architecture should allow for a robust control of mobile robots during the execution of a wide range of different tasks. Moreover, it should be flexible enough to facilitate different control strategies and algorithms. In addition, the architecture should be adaptable in order to handle more complex tasks and to be able to operate in different environments.

Finding an appropriate architecture for a specific purpose is a challenging task. In fact, no single architecture can be sufficient for all purposes. There is always a trade-off between general applicability and usability. The issue of determining an appropriate architecture suitable to robustly control an autonomous mobile robot can be divided into several sub-problems:

- The first and easier one is the question of which control paradigm to choose. In this chapter the different control paradigms are introduced. It is then motivated why a hybrid paradigm is the most appropriate for applications where robots carry out complex and non-trivial tasks.
- The second problem is more related to software engineering and concerns the software architecture. The software architecture determines how the functionality of the software is physically organized. Several projects working on an architecture sufficient for the needs of mobile robots are introduced. For an in-depth discussion of the issue of choosing or implementing an appropriate software framework, the reader is referred to Orebäck (2004). Finally, an example of a successful solution to this issue is illustrated.
- A more or less strong, deliberative component is part of every hybrid control paradigm. The use of symbol-based abstract decision making has two major drawbacks. First, in general, planning techniques are insufficiently reactive for unpredictable and highly dynamic environments. A solution to this problem is presented, which enables the deliberative component to react more quickly to such effects. Second, if an abstract deliberative component is used, then some kind of connection between the quantitative world of the sensors and actors and the qualitative world of planning and reasoning is necessary. If sensors and actors are prone to uncertainties, then this abstraction of knowledge is difficult. Unfortunately, such uncertainties are nearly always adherent to sensors and actors. Therefore, a novel symbol grounding mechanism is presented, which significantly relaxes this problem.
- The final problem is especially important in the area of autonomous mobile robots. Tolerance of the robot and its control system against faults is crucial for long-term autonomous operation. It is shown how a model-based fault-diagnosis and repair system improves the overall robustness of the control architecture.

Consideration of all these features and requirements has resulted in a control architecture that serves as a platform for research in several areas in autonomous mobile robots, for example, RoboCup robot soccer and service robots. This robust and flexible architecture will serve as a running example and as a guideline throughout this chapter.

SOFTWARE FRAMEWORKS FOR MOBILE ROBOTS

This section addresses the problem of software frameworks for autonomous mobile robots. For this, the applicable control paradigms are introduced. Control paradigms describe how control is organized. Then, general requirements for software architectures in order to be usable for autonomous robots are identified. Finally, popular publicly available software frameworks are reviewed.

Robot Control Paradigms

A robot control paradigm guides the organization of the control of a mobile robot, which enables the robot to carry out given tasks. It structures how the robot maps its sensor readings to actions via a more or less intelligent decision-making module.

One of the first attempts to structure control was the *sense-plan-act* (SPA) paradigm, depicted in Figure 1. This paradigm was inspired by the research on artificial intelligence (AI) of the late '60s and was first successfully used by Nilsson in the robot *Shakey* (Nilsson, 1984). It was guided by the early view on artificial intelligence. The paradigm divides the control into three different functionalities. *SENSE* is responsible for the perception of the robot's internal state and its environment. The data provided by the robot's sensors are interpreted and combined in a central abstract model of the world. Based on the information contained in the world model, a description of the capabilities of the robot and the goal of the task the *PLAN* module tries to find a plan (i.e., a sequence of actions) that will lead to a given goal. The *ACT* module executes this plan in order to achieve the goal. Although the SPA paradigm is powerful and flexible, it suffers from a set of drawbacks. First of all, planning takes a lot of time even on very powerful computers. Therefore, the reaction to dynamic environments is slow. Another drawback is caused by the fact that planning algorithms generally work on a qualitative and abstract representation of the world. The design of such a representation and the transformation of quantitative sensor data into this representation is far from trivial.

In contrast, the reactive *sense-act* (SA) control paradigm provides a different organization of control. Figure 2 depicts the SA paradigm. The paradigm is biologically inspired by the mechanism of reflexes, which directly couple the sensor input with the actor output. Such a reflex of the robot is commonly called a behavior. More complex behaviors emerge through the combination of different reflexes.

A system that follows this paradigm was first proposed in the mid 1980s with the subsumption architecture by Brooks (1986). This architecture achieved significant progress in the research on mobile robots and is still popular and widely used. Brooks argued that abstract knowledge about the world and reasoning is not necessary for the control of a mobile robot. The paradigm is able to control a robot also in dynamic environments because the reaction time is very quick due to the encoding of the desired behavior into reflexes and the tight coupling of the sensors and actors. Although relatively complex behaviors can be achieved by blending different reflexes, the paradigm is prone to fail for more complex tasks. This arises from the fact that neither explicit information about the internal state of the robot nor about the world, nor additional knowledge about the task, are used. Therefore, for complex tasks a goal-driven approach seems much more appropriate than a simple instinct-driven one.

Even though the choice of an appropriate control paradigm sometimes seems to be rather a question of faith than of science, there is a relatively clear commitment within the robotics research community that the most appropriate architecture is hybrid architecture (see Figure 3). Hybrid systems combine the advantages of the planning approach and the reactive paradigm while avoiding most of their drawbacks. Such systems use reactive behaviors where reactivity is needed (e.g., avoiding a dynamic obstacle)

Figure 1. The sense-plan-act control paradigm

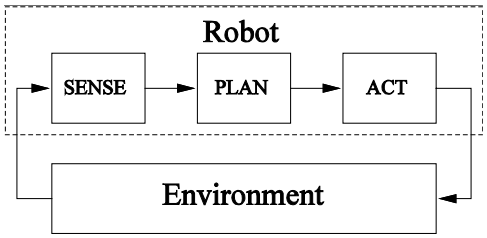

Figure 2. The reactive sense-act control paradigm

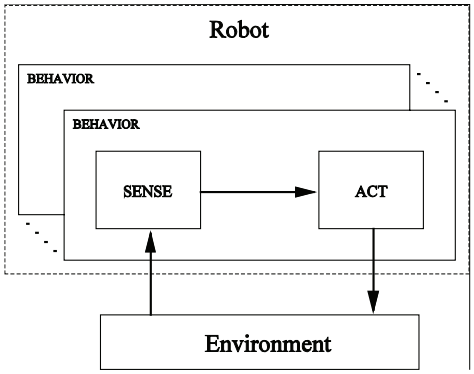
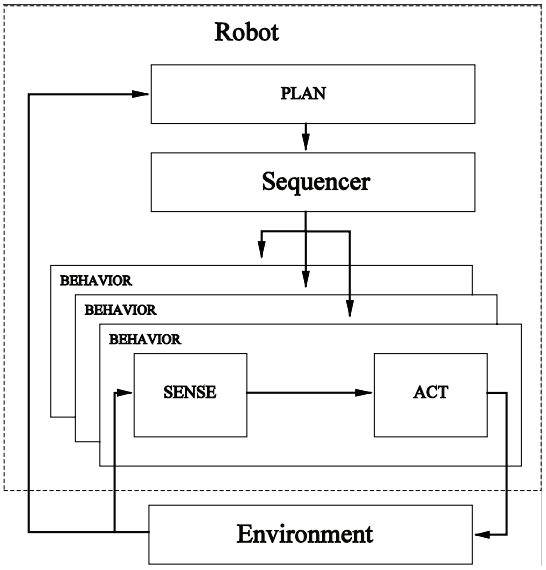


and use planning and reasoning where complex decisions have to be made and a limited amount of delay is not critical.

Commonly, hybrid systems consist of three layers. The *reactive layer* uses reactive behaviors to implement a fast coupling of the sensors and the actors in order to be reactive to a dynamic environment. Often this layer implements the basic skills of a robot, that is, basic movement primitives and obstacle avoidance. The *deliberative layer* has a global view on the robot and its environment, and is responsible for high-level planning in order to achieve a given goal. Typical functionalities that are located in this layer are mission planning, reasoning, localization, path planning, and the interaction with humans or other robots. The *sequence layer* is located between the reactive and the deliberative layer and bridges the different representations of the two layers. The sequencer generates a set of behaviors in order to achieve a sub-goal submitted by the deliberative layer. It is also responsible for the correct execution of such a set of behaviors and should inform the higher layer if the sub-goal was successfully achieved or the execution failed for some reason.

A more detailed introduction to the different control paradigms can be found in the book by Kortenkamp, Bonasso, and Murphy (1998) and the book by Murphy (2002).

Figure 3. The hybrid control paradigm



Requirements for the Software Architecture of an Autonomous Robot

The control paradigm guides the functional decomposition of the robot control on a more abstract view. The software architecture, on the other hand, guides the modular decomposition of the system into different components and the implementation of such components. Furthermore, it concerns the encapsulation of different functionalities into manageable modules.

A well-designed software architecture should provide, among others, the following features:

- Robustness
- Flexibility
- Sensor and actor interface abstraction
- Easy exchange and reuse of components
- Reliable communication between components
- Easy adaptation of the system for new purposes
- Easy portability to other hardware platforms

- Support of a defined development process
- Support for test and evaluation

For a long time the above requirements and principles have been neglected during the development of many prototype control systems. This is because the issue of software architecture design is not tightly coupled to pure robotic research. As a result, most of the research software is hard to maintain and to adapt and therefore lacks general usability. Fortunately, many of the best-practice principles and processes from the software development community are now widely accepted by the robotic research community. These principles are, amongst others, object-oriented design, the incorporation of well-known design patterns, the reuse of established libraries, the compliance to widely accepted standards, and the use of test and evaluation frameworks. This leads to higher quality and to improved adaptability of the software. Furthermore, a great pool of software frameworks for robotic research has been developed. Most of these frameworks can be used out of the shelf and fulfil most of the requirements proposed by robotic research.

Existing Frameworks for Mobile Robots

There exists a number of popular frameworks for mobile robot research. Some of them are more general and flexible than others while some of them are closely related to specific robots or tasks. Examples for such frameworks are: task control architecture (TCA) (Simmons, 1994), Saphira (Konolige & Myers, 1998), *Carnegie Mellon Robot Navigation Toolkit* (Carmen) (Montemerlo, Roy, & Thrun, 2003), and Player/Stage (Gerkey et. al, 2001). A very good overview and a more formal and detailed evaluation of existing frameworks is given in (Orebäck & Christensen, 2003). In the next section, we will discuss the framework named *Middleware for Robots* (Miro), on which our own developments are based.

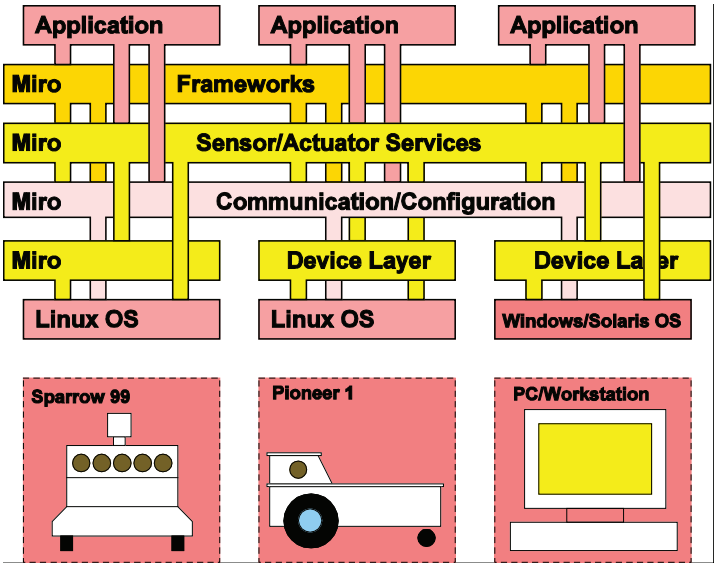
Miro is a distributed object-oriented software framework for robot applications. It has been developed at the Department of Computer Science at the University of Ulm (Utz, 2005; Utz, Sablatnüg, Enderle, & Kraetzschmar, 2002). The aim of the project is to provide an open and flexible software framework for applications on mobile robots. In general, Miro is a software framework and not a ready-to-use robotic application. The goals for the design of Miro are:

- Full object-oriented design
- Client/server system design
- Hardware and operating system abstraction
- Open architecture approach
- Multi-platform support, communication support, and interoperability
- Software design patterns
- Agent technology support

Miro achieves these goals by adopting an architecture that is divided into three layers. Figure 4 depicts the architecture of Miro. The use of the *Adaptive Communication Environment* (ACE) and CORBA for the communication between the layers and other applications enables a flexible, transparent, and platform-independent development. Miro uses *the ACE Object Request Broker* (TAO) (Schmidt, 2000) as CORBA framework. The implementation of this object-oriented framework is completely done in the C^{++} language.

The *Miro device layer* provides object-oriented interface abstractions for all sensory and actuatory facilities of a robot. This is the platform-dependent part of Miro. The *Miro communication and service layer* provides active service abstractions for sensors and actuators via CORBA *interface definition language* (IDL) descriptions and implements these services as network-transparent objects in a platform-independent manner. The programmer uses standard CORBA object protocols to interface to any device, either on the local or a remote robot. Miro provides a number

Figure 4. The architecture of Miro (Figure from Utz, 2005)



of often-used functional modules for mobile robot control, like modules for mapping, self-localization, behaviour generation, path planning, logging and visualization facilities.

A complete description of Miro and many useful examples can be found in The Miro Developer Team (2005). The use of Miro as a basis for further development has the following advantages:

- **Object-oriented design:** The design of the framework is fully object-oriented, elaborated, and easy to understand. Moreover, there are a whole bunch of ready-to-use design patterns that provide, for example, multi-threading, device reactors, and so forth.
- **Multi-platform support and reuse:** Miro comprises a great number of abstract interfaces for numerous different sensors and actors, for example, odometry, bumper, sonar, laser, and differential drives. Moreover, for all of these interfaces Miro already provides implementations for many different robot platforms. Due to the clear design and the use of CORBA and IDL, the implementation of interfaces for a new robot platform and the integration of new interfaces is straightforward. Miro currently supports many different common robot platforms like the B21, the Pioneer family, and some RoboCup MSL (Middle-Size League) robots.
- **Communication:** For the communication between different components of the robot control software, Miro provides two main mechanisms:

Direct CORBA method calls are used in a client/server manner for a 1-1 communication of components. This mechanism is commonly applied to actor and sensor interfaces. Due to the use of CORBA, the user does not have to deal with the internals of such a communication, for example, marshalling or memory management. Furthermore, the communication is completely transparent even if the client and the server run on different computers or use different programming languages.

The *event channel*, on the other hand, provides 1-n communication. The event channel follows the producer/consumer paradigm. The producer

simply pushes an event of a certain type to the channel. All consumers who are subscribed for this event are automatically informed when this specific event is available. Although this mechanism has a lot of advantages, it has to be mentioned that a heavy use of this mechanism leads to a poor run-time performance because of the computational overhead in the event channel.

- **Behaviour engine:** Miro contains a complete module for the modeling and the implementation of reactive behaviours. The *behaviour engine* follows the behavioural control paradigm introduced by Brooks (1986). The module uses a hierarchical decomposition of behaviours. On the base of the hierarchy, there are different atomic *behaviors* like, for example, "dribble ball" for a soccer robot. These behaviors can be grouped in *action patterns*. Such action patterns may be comprised of, for example, a dribble action and a local obstacle avoidance behavior. Different action patterns can be combined to a *policy*.

Once the behaviours are implemented, action patterns and policies are built up by describing them in an XML-file. Therefore, experiments with different action patterns and policies are easy and straightforward.

Unfortunately, Miro does not provide any paradigms and implementations for a deliberative layer. Therefore, extension of the Miro framework by a planning system is described in the third section.

A MODULAR ARCHITECTURE FOR AUTONOMOUS MULTI-PURPOSE ROBOTS

In order to fulfil as many of the requirements for an appropriate framework stated in the second part of the second section as possible, a novel design approach for mobile autonomous robots was developed (Fraser, Steinbauer, & Wotawa, 2004). The approach is based on a consequent modularization of both the robot's software and its hardware.

It is possible to distinguish between the functional view on the software and the software architecture. The functional view provides a decomposition of functionality into layers with increasing levels of abstraction. Therefore, the functionality is organized into different layers ranging from an abstract top layer with planning and reasoning capabilities down to a layer with direct hardware access. The software architecture represents a physical view on the software system.

The framework presented in this section is built upon the Miro framework and was deployed and evaluated in the RoboCup middle-size league team (MSL) of the Graz University of Technology. Besides using the robots for soccer games, the robots are also used for research in the area of service robotics.

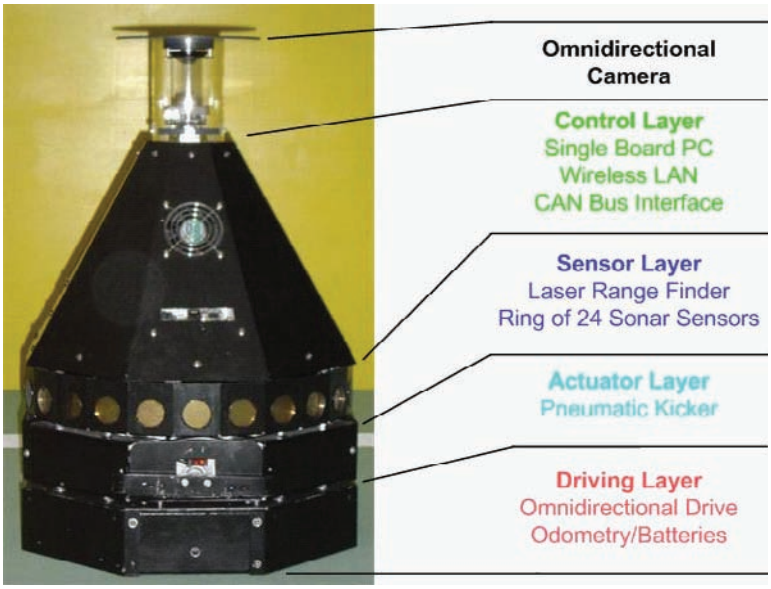
Figure 5 shows the modularized robot platform, which was developed and used as a target system for the proposed control architecture. The hardware of the robot is divided into five layers. Each layer provides one particular skill. The layers are stacked to build up the robot platform.

Functional View on the Software

The functional view on the software is guided by a consequent modularization. The functionality of the software is divided into three layers with an increasing level of abstraction. The layers are shown in Figure 6. Note that the functionality of a layer fully relies on the layer below.

The idea of functional layers with different levels of abstraction is similar to the idea of cognitive robotics (Castelpietra, Guidotti, Iocchi, Nardi, & Rosati, 2002). As mentioned above, a combination of reactive behaviors, explicit knowledge representation, planning, and reason-

Figure 5. The modularized robot platform



ing capabilities promises to be more flexible and robust. Furthermore, such an approach will be able to fulfil far more complex tasks. Note that this functional design is inspired by the hybrid control paradigm.

Hardware Layer

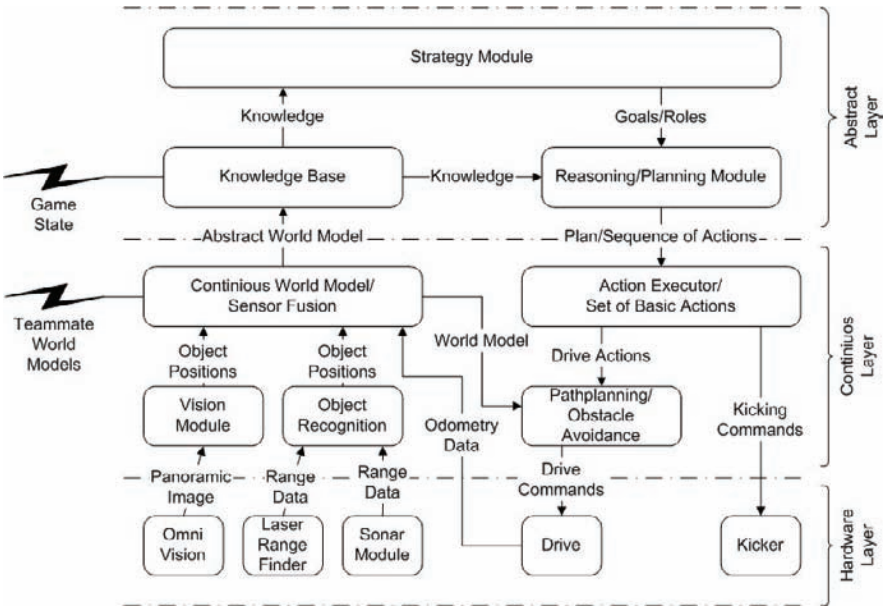
The hardware layer implements the interfaces to the sensors and actuators of the robot. This layer delivers raw continuous sensory data to the next layer and performs a low-level control of the actuators.

Continuous Layer

The continuous layer implements a numerical representation (quantitative view of the world) of the sensing and acting of the robot. This layer performs the processing of range data and the image processing. This processing computes possible positions of objects in the environment, including the robot's own *pose*. A pose consists of position and orientation of an object. These positions, together with the motion information from the odometry, are fused into a continuous world model by Kalman Filters (other objects) (Dietl, Gutmann, & Nebel, 2001) or Monte Carlo methods (own pose) (Fox, Burgard, Dellaert, & Thrun, 1999). Of course, all sensing and acting of a real mobile robot is afflicted with uncertainty. Therefore, sensor fusion is done using the above probabilistic methods. The world model represents the continuous world by estimating the most likely hypothesis for the positions of objects and the position of the robot itself.

Furthermore, this layer is responsible for the low-level execution of actions. Execution is based on a set of actions implemented as patterns of prioritized simple reactive behaviors. To take an example from robot soccer, suppose that the abstract layer (see next section) chooses to execute the high-level action DribbleBall. This action could be implemented by the following reactive behaviors: *dribble*, *kick*, and *obstacle_avoidance* (*oa*). *Dribble* will have the lowest priority, *oa* the highest. That is, if an obstacle is detected, only *oa* is executed in order to avoid a collision with the

Figure 6. Functional view of the software (robot soccer example)



obstacle. However, as long as there is no obstacle, this behavior will be inactive, and so behaviors with lower priorities can be executed. *Kick* is inactive most of the time; it becomes active only when the robot is in a proper distance and angle to the opponent goal. Then this behavior will emit a kick command, which is sent to the hardware layer, and become inactive again. *Dribble* is executed at those times when the other behaviors are inactive. This action execution forms the reactive part of the hybrid control paradigm and is similar to Brooks' subsumption architecture (Brooks, 1986).

Abstract Layer

The abstract layer contains a symbolic representation (qualitative view of the world) about the knowledge of the robot and a planning module for the decision making. A detailed description of the planning system can be found in Fraser et al. (2005). A similar approach also has been proven to work in the RoboCup MSL domain (Dylla, Ferrein, A., Lakemeyer, 2002). The abstract layer allows for an easy implementation of a desired task by specifying the goals, actions, and knowledge as logical sentences.

The core of this layer is the knowledge base. It contains a symbolic representation of the entire high-level knowledge of the robot. This knowledge consists of predefined domain knowledge, of a qualitative world model, which is an abstracted representation of the continuous world model, and of an abstract description of the actions the robot is able to perform.

The qualitative world model is represented by a set of logical propositions. The knowledge about actions is represented using a STRIPS-like representation language (Fikes & Nilsson, 1972) enriched by quantifiers from first-order logic. That is, an action is described by means of a precondition and an effect, where precondition and effect are represented by conjunctions of logical propositions. An action can be executed only if its precondition holds, and the effect states which conditions hold after the action has been executed successfully. Note that those propositions that are not included in the effect are not changed by the action.

Based on the agent's domain knowledge, the strategy module chooses the next goal the robot

has to achieve for fulfilling the long-term task. In a simplified view, the strategic knowledge could be regarded as a set of condition-goal pairs, where the condition is a logical sentence, and the goal can only be chosen if this condition is fulfilled. The planning module generates a plan that is supposed to achieve this goal. Any planning algorithm can be used within the planning module. Currently a simple regression planner (Russell & Norvig, 2003) or the more effective Graphplan is used (Blum & Furst, 1995). It has to be mentioned that the use of planning suffers from two drawbacks. First, planning takes time. Decisions that are made by planning are not feasible for time-critical tasks where a tight schedule have to be maintained. Furthermore, planning needs a significant amount of computational resources. Therefore, planning is only feasible for systems with enough resources or for systems where the time needed for the decision making is not that important.

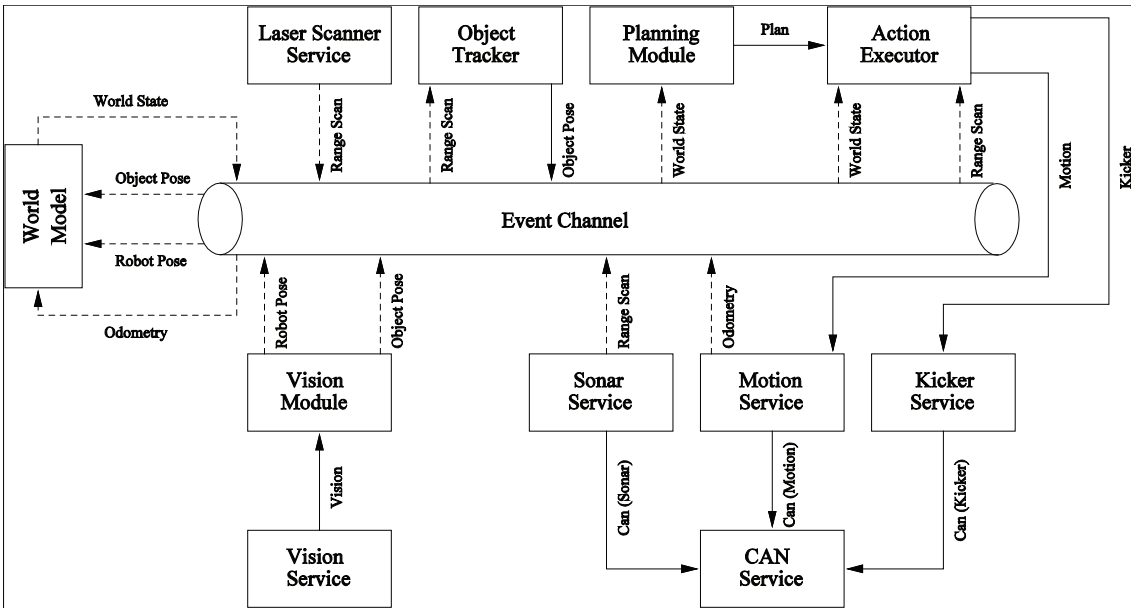
The calculated plan is communicated to the action executor, which implements the actions by means of simple behaviors. Note that a plan is monitored permanently for its validity during execution. The plan is canceled or updated if preconditions or invariants of the plan or its actions are no longer valid. This concept will be explained below.

Software Architecture

The software architecture, which is based on Miro (Utz et al., 2002), is shown in Figure 7. All software modules are implemented as autonomous services. Each service runs as an independent task. The communication between services primarily employs two mechanisms, the CORBA-interfaces and the event channel, which were described in the second section.

Hence, the services are independent of each other and an adaptation of software modules or the integration of new services is very easy and transparent to the rest of the system. It has to be mentioned that the event channel has a major drawback beside its advantages. The problem is that the Event channel needs significantly more

Figure 7. Software architecture. Solid connections represent remote invocations to CORBA IDL interfaces. Dashed connections denote an event-based communication.



computational resources than, for instance, a simple CORBA-interface. This fact is caused by its more complex communication mechanism and results in greater communication delays. Therefore, the use of the event channel is limited to only the necessary communications. Furthermore, time-critical communications like the connection between the action-execution with its behaviours and actuators are implemented by the faster CORBA method-calls.

ROBUST PLAN EXECUTION

In this section, an extension to hybrid architectures is presented that improves the quality of the plan execution in unpredictable and dynamic environments. First, it is illustrated how a plan is created, which fulfils a chosen goal. Then issues related to the plan execution and monitoring are discussed. Finally, it is shown how a quantitative world model can be transformed to a qualitative symbolic representation and which problems arise. Examples in this section are based on a RoboCup scenario, which is the original intent of the architecture presented in the previous section.

A Simple Example

Suppose that the following predicates are used for a qualitative representation of the world:

InReach(*x*)	true iff object *x* is in reach, i.e., within a small distance
KickDistance(*x*)	true iff the object *x* is close enough to be reachable by a ball which is kicked by this robot
HasBall	true iff the robot has the ball
IsAt(*x*,*y*)	true iff object *x* is at position *y*

where *x* and *y* can be one of the object constants *Ball* or *OppGoal* (opponent goal).

A classical AI-planning problem (Fikes & Nilsson, 1972) is defined by an initial state, a goal state, and the available actions. In the example, the initial state refers to the current state of the world, that is, the state of the environment and the robot itself. Suppose that initially all predicates are false and that the agent wants to achieve that a goal is scored. Furthermore, the knowledge base contains four high-level actions described in first-order logic, which the robot is able to perform.

1. Initial state $s_{init} = \neg InReach(Ball) \wedge \neg InReach(OppGoal) \wedge \neg HasBall \wedge \neg \ldots$
2. Goal state $g = IsAt(Ball,OppGoal)$
3. Actions schemas: $\Lambda^A = \{GrabBall, MoveT, Score, DribbleTo\}$. The schema definitions are given below.

As already explained, an action is defined by a precondition and an effect. The precondition denotes which conditions must hold before the action can be started, and the effect states how the qualitative world state is changed by the action. Consider the following example actions, where *target* is a placeholder for object constants. See Box 1.

A planning algorithm (Weld, 1999) searches for a sequence of actions that fulfils a given goal. In this example, the algorithm can find the following plan that achieves the goal *IsAt*(*Ball*,*OppGoal*):

1. *MoveTo*(*Ball*)
2. *GrabBall*
3. *DribbleTo*(*OppGoal*)
4. *Score*

Figure 8 depicts the qualitative states that appear during the execution of this plan. The nodes of the graph represent states, while the labels of the edges are actions. Only those predicates that are true are shown in the states; all other predicates are false. The state on the top of the graph is the initial state, in which all predicates are false. The last state at the bottom satisfies the goal *g*. In the initial state, only the action *MoveTo*(*Ball*) can be executed, as the preconditions of the

Box 1. A set of example actions

action:	precondition:	effect:
GrabBall	$\neg$*HasBall* $\wedge$ *InReach*(*Ball*)	*HasBall*
MoveTo(*target*)	-	*InReach*(*target*)
Score	*HasBall* $\wedge$ *KickDistance*(*OppGoal*)	$\neg$*HasBall* $\wedge$ $\neg$*InReach*(*Ball*) $\wedge$ *IsAt*(Ball,*OppGoal*)
DribbleTo(*target*)	*HasBall*	*KickDistance*(*target*)

other actions are not fulfilled in this state. After the execution of this action, the ball is in reach. Thus, action *GrabBall* can begin. If this action succeeds, *DribbleTo*(OppGoal) can be executed, and finally *Score* is supposed to achieve the goal. Please note that the term "goal" is twofold in the robot soccer domain.

Plan Execution and Monitoring

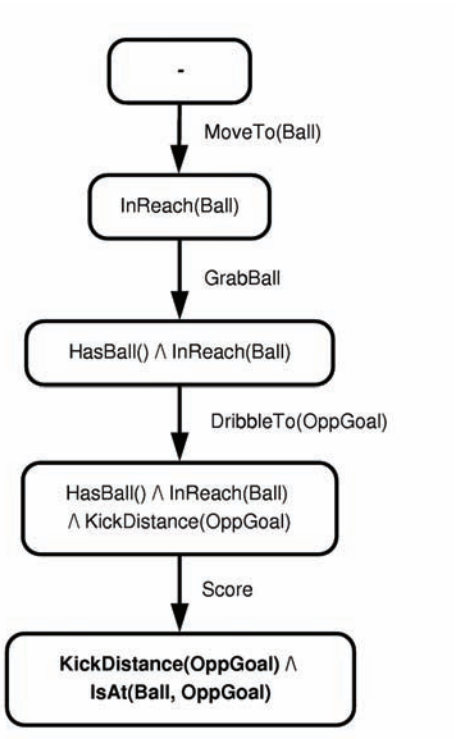
The classical AI planning theory makes some simplifying assumptions. Actions are considered atomic, their effects are deterministic, and they do always succeed. Furthermore, all world changes are caused by actions of this agent only, therefore the environment is fully deterministic. Finally, it is assumed that the environment is fully observable.

While these assumptions are convenient for the planning theory, they often do not hold in real-world applications. In practice, robots operate in dynamic and uncertain environments. Actions are not atomic, as their execution needs time, and unpredictable things can happen during the execution. Thus, actions may fail or their effect may be non-deterministic. Another issue is to determine when an action is finished, that is, when the effect is achieved. Moreover, the world is not only influenced by actions of this agent but also by other agents, for example, by other robots, by humans, or by other influential factors. In addition, due to the limitations of the sensors, the environment is not fully observable.

This discussion shows that permanent execution monitoring is required in real domains. The execution monitoring has to deal, among other things, with the following issues:

- Has the current action already achieved its effect?
- When is it necessary to abort the ongoing action due to unforeseen changes of the environment?
- Can the next action of the plan be executed in the current world state? It might be the

Figure 8. An example plan that aims at scoring a goal



case that its precondition is no longer fulfilled due to a change of the environment.

- Is the plan still valid? Under which conditions is it necessary to abort a plan?

In order to be able to perform a permanent monitoring of the plan execution, the qualitative world state has to be re-computed each time a continuous world state is created. After the computation of the truth values of the predicates, the preconditions and effects of the action in the plan can be re-evaluated. Action invariants are also used, that is, conditions that must hold as long as the action is executed. In most cases, the action invariant is equal to the action precondition. Let us come back to the example plan in Figure 8. Suppose the first action, *MoveTo*(*Ball*), has succeeded, and therefore the robot executes *GrabBall*. The invariant and the effect of this action are permanently re-evaluated.

Traditional approaches to plan execution and monitoring only take the preconditions of actions into account. In Fraser, Steinbauer, and Wotawa (2005), the use of plan invariants is proposed as a means to supervise plan execution. When a violation of the plan invariant is detected, the plan is aborted immediately. A plan invariant is a condition that refers to the plan as a whole and thus can include conditions that are not present in the action preconditions and invariants. The use of plan invariants is proposed in order to define conditions such that a violation indicates that it is no longer desirable to pursue this plan, although the plan is feasible according to the action preconditions and invariants, and its goal could be achieved. This allows the agent to adapt its behaviour to unforeseen changes in the environment.

In Fraser et al. (2005) the *extended planning problem* was defined, which extends the original definition in Fikes and Nilsson (1972). It consists of:

1. An initial state s_{init}
2. A goal state g
3. A set A that contains all possible actions
4. The plan invariant *inv*

A plan invariant can be defined for each goal and thus is assigned to plans that are created for this goal. In the example, one could define that the goal *IsAt*(*Ball*,*OppGoal*) should no longer be pursued when two or more players of the opponent team have moved between the ball and the opponent goal, no matter whether or not this robot already owns the ball. The idea is that in this case it is not reasonable to attempt to score a goal, as the chances of success are low, and that it may be better to change the tactics. Therefore, a new predicate *Blocked*(*Ball*,*OppGoal*) is introduced, and its negation is part of the plan invariant.

This robust method of plan execution has been deployed and successfully evaluated in the RoboCup middle-size league.

From the Quantitative World to a Symbolic Representation

As already explained, the perceptions from different sensors are fused in order to create the most probable continuous model of the real environment. The resulting model contains the robots' own pose and the positions of objects in the world.

This purely quantitative model is transformed to an abstract world model, which consists of logical predicates that are true or false. The example predicate *InReach*(*x*) has already been introduced, which is true if and only if the object *x* is within a certain distance of the robot. The truth value of a predicate is re-computed each time a new quantitative world model is available. For each type of predicate, an evaluation function is defined, which determines the truth value. For example, the value of *InReach*(*x*) is computed as follows:

```
COND_InReach(x, m): boolean
  return (dist(r, x) < t)
```

where *m* is the continuous world model, *r* is the robot, and *t* is a threshold.

This approach has, compared to reasoning based on continuous data, many advantages. Amongst others, a qualitative model has only a finite number of possible states, and qualitative models are implicitly able to cope with uncertain and incomplete knowledge. Another reason is the fact that the programming of the robot is simplified and can also be done by human operators who have no programming skills. The knowledge and the strategy of a robot can be neatly expressed in logical formulas on a more abstract level. Such programming appears more intuitive.

The mapping from a quantitative model to symbolic predicates in a dynamic and uncertain environment leads to two major problems: First, the truth value of predicates is calculated using thresholds, that is, there are sharp boundaries. Thus slight changes of the environment can cause truth value changes and result in abortion of plans due to a violation of the invariant, even if the plan still could be finished successfully. The consequence is instability in the high-level decision-making process. A longer-lasting commitment to a plan, once it is chosen, is desired. Second, sensor data is inherently noisy. Hence, due to the sharp boundaries, sensor noise leads to unstable knowledge, that is, to undesired oscillation of truth values, even if the environment does not change.

In Steinbauer, Weber, and Wotawa (2005a) a predicate hysteresis was proposed as an attempt to reduce the problems described above. The term hysteresis is well known from electrical engineering. It means that the current state is influenced by a decision that has been made previously. This concept was adapted in order to improve the robustness of the decision making process. The basic idea is that once a predicate evaluates to a certain truth value, only significant changes of the environment can cause a change of this truth value.

In an example, an improved evaluation function for *InReach*(*x*) is introduced:

```
COND_InReach(x, m, l): boolean
 if l then
    return (dist(r, x) < t + h
 else
    return (dist(r, x) < t – h
```

where the variable *l* represents the current truth value of *p* and *h* is the hysteresis size.

Such an evaluation function has the advantage that at the boundary only a significant change in the quantitative world causes a change of the truth value. This leads to a stabilization of the evaluation. However, it has to be mentioned that hysteresis is always a trade-off between stability and reactivity.

RUNTIME FAULT DETECTION AND REPAIR

Even if the control software of a mobile robot is carefully designed, implemented, and tested, there is always the possibility of faults in the system. Generally, faults are the deviation of the current behaviour of a system from its desired behaviour. Carlson and Murphy (2003) presented a quantitative evaluation of failures on mobile robots. The situation gets even worse if one thinks about autonomous robots, which operate for a long time without the possibility of human intervention, for example, nuclear inspection robots, space probes, or planetary rovers. Therefore, control architectures that are robust and fault-tolerant are crucial for truly autonomous robots.

Because faults are not totally avoidable, it is desirable that mobile robots are able to autonomously detect and repair such faults. When a permanent fault, that is, a broken hardware component, is identified, then the robot should

at least provide basic functionality or should be able to switch to a safe state. These requirements can be fulfilled if a dedicated diagnosis system is attached to the robot control software. Usually, a diagnosis system is comprised of three modules: (1) a monitoring module, (2) a fault detection and localization module, and (3) a repair module. The first module observes the actual behaviour of the hardware and software of the robot system. The fault detection uses observations and a model of the system's desired behaviour to detect deviations between them. A deviation is equivalent to a detected fault. However, in practice the detection of a fault is not enough. The module should also identify the hardware or software component that caused the fault. If a fault and its location are identified, the repair module tries to resolve the fault. This could happen by a restart or reconfiguration of the affected components.

There are many proposed and implemented approaches for fault diagnosis and repair in autonomous systems. The Livingstone architecture by Williams, Muscettola, Nayak, and Pell (1998) was used on the space probe *Deep Space One* in order to detect failures in the probe's hardware and to recover from them. The fault detection and recovery is based on model-based reasoning. Model-based reasoning uses a logic-based formulation of the system model and the observations. Verma, Gordon, Simmons, and Thrun (2004) used particle filter techniques to estimate the state of the robot and its environment. These estimations together with a dynamic model of the robot were used to detect faults. Rule-based approaches were proposed by Murphy and Hershberger (1996) to detect failures in sensing and to recover from them. Additional sensor information was used to generate and test hypotheses to explain symptoms resulting from sensing failures. Roumeliotis, Sukhatme, and Bekey (1998) used a bank of Kalman filters to track specific failure models and the nominal model.

In this section, a solution for real-time fault diagnosis and repair of control software of autonomous robots is presented. The fault diagnosis follows the model-based diagnosis paradigm (Reiter, 1987). It is based on observations of the current behaviour of the control system's components, a model of the desired behaviour of the control system's components, and the dependencies between them. A monitoring module continuously observes the behaviour of the control software. If a deviation of the desired behaviour is observed, a diagnosis kernel derives a diagnosis, that is, a set of malfunctioning software components explaining the deviation. Based on this diagnosis and on a model of the software components and their connections, a repair module executes appropriate repair actions to recover the system from the fault. The proposed diagnosis system has been implemented and tested as part of the proposed control architecture on RoboCup MSL robots within the robotic soccer scenario (Steinbauer & Wotawa, 2005).

Robot Control Software

Figure 9 shows an overview of the robot control software framework, the features of which have been presented in the preceding sections. In Figure 9, remote CORBA calls are shown as solid lines directed to the server. The data-flow between server and client is shown as chain dotted lines. The figure also shows the dependencies between services. Remote CORBA calls are called *strongly dependent* because a fault in the server directly affects the client. Connections using the event channel are shown as dashed lines, and the data-flow direction is always directed from the producer to the consumer. Connections that rely on this communication mechanism impose a *weak dependency*, that is, the services are loosely coupled and a failure of the server does not cause a failure of the client. The distinction between strong and weak dependencies is later important for the diagnosis and repair process.

The above described structure of the control software, the different types of connections, and

the dependencies between the services are used to build a model of the desired behaviour of the control software. In the next section it is described how this model together with various observations of the behaviour of services and connections are combined to form a diagnosis system for the control software of the robots.

Diagnosis System

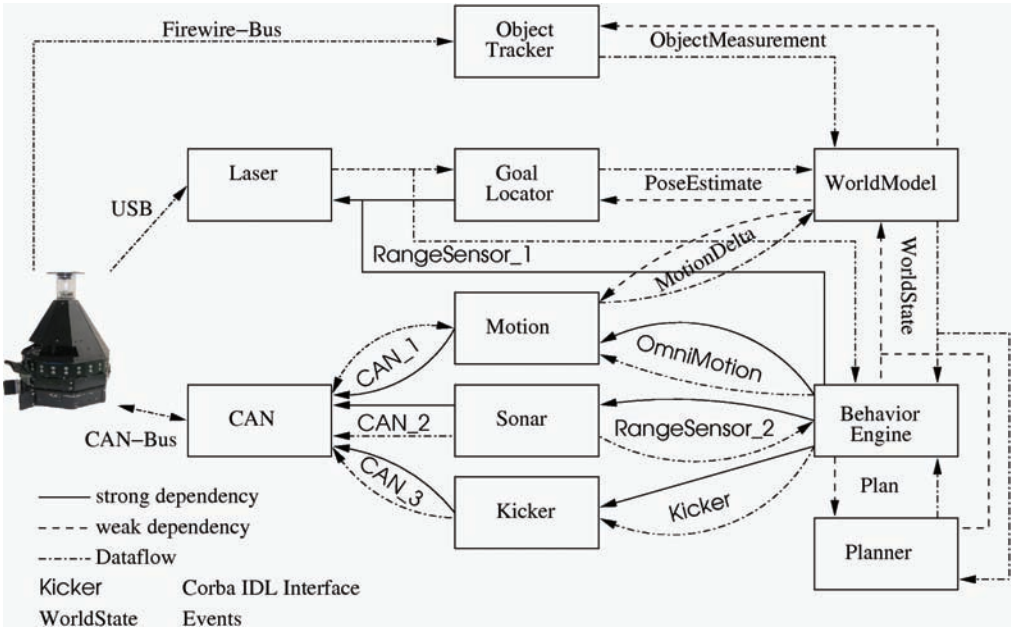
Monitoring

The task of the monitoring module of the diagnosis system is to observe the actual behaviour of the control system. For this purpose, the concept of observers was introduced. An observer monitors the behaviour of a service or the communication between services. The observer determines a misbehaviour of the control system if the observed behaviour deviates from the specified behaviour. In the current implementation, the following observers are used:

- **Periodic event production:** This observer checks whether a specific event *e* is at least produced every *n* milliseconds.
- **Conditional event production:** This observer checks whether an event e_1 is produced within *n* milliseconds after an event e_2 occurred.
- **Periodic method calls:** This observer checks whether a service calls a remote method *m* at least every *n* milliseconds.
- **Spawn processes:** This observer checks whether a service spawns at least *n* threads.

There are several requirements for the monitoring module. First, if observers are used, there should be no, or at least only a minimum necessity for, changes in the control system. Furthermore, the monitoring component should not significantly reduce the overall performance of the control system. Both requirements can be met easily by using mechanisms provided by CORBA (Hen-

Figure 9. Dependencies and data-flow within the robot control software



ning & Vinoski, 1999) and the Linux operating system (OS). The first two observers are implemented using the CORBA event channel. The third observer is implemented using the CORBA portable interceptor pattern. The last observer is implemented using the information provided by the *proc* file-system of the Linux OS. For all these observers, no changes are necessary in the control system. Furthermore, the computational power requirements for all the observers are negligible.

Diagnosis

A fault is detected if an observer belonging to the monitoring module recognizes a deviation between the actual and the specified behaviour of the system. However, so far one does not know which misbehaving service causes this fault. The model-based diagnosis (MBD) paradigm (de Kleer & Williams, 1987; Reiter, 1987) is used to locate the faulty service.

Figure 10 shows an example for the diagnosis process in case of a malfunctioning CAN-Service. First, an abstract model of the correct behaviour of the CAN sonar and motion service is built. Therefore, two predicates are introduced: $AB(x)$ becomes true if a service x is abnormal, meaning x is malfunctioning. $Ok(y)$ becomes true if a connection y, either a remote call or an event, shows a correct behaviour. The model for the correct behaviour of the example could contain the following clauses:

1. $\neg AB(CAN) \rightarrow ok(CAN\_1)$
2. $\neg AB(CAN) \rightarrow ok(CAN\_2)$
3. $\neg AB(Sonar) \wedge ok(CAN\_1) \rightarrow ok(RangeSensor\_2)$
4. $\neg AB(Motion) \wedge ok(CAN\_2) \rightarrow ok(MotionDelta)$

The principles of MBD will be explained with a simple example. Lines 1 and 2 specify that, if the CAN-Service works correctly, then also the connections *CAN_1* and *CAN_2* work correctly. Line 3 specifies that if the sonar service and its input connection *CAN_1* work correctly, the connection *RangeSensor_2* has to show a correct behaviour. Line 4 specifies similar facts for the motion service.

If there is a deadlock in the CAN-Service, the motion and sonar services cannot provide new events or calls, as they get no more data from CAN. This fact is recognized by the corresponding observers and can be expressed by the clause: $\neg ok(RangeSensor\_2) \wedge \neg ok(MotionDelta)$. If a correct behaviour of the system is assumed (expressed by the clause $\neg AB(CAN) \wedge \neg AB(Sonar) \wedge \neg AB(Motion)$, then a logical contradiction is observed. This means a fault was detected.

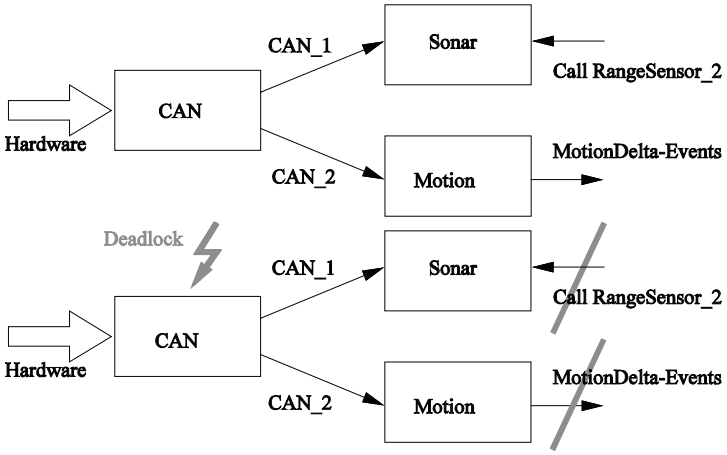
Finding the service that caused the fault is equivalent to finding the set of predicates $AB(x)$ with $x \in \{CAN,Motion,Sonar\}$ that resolves the contradiction. These sets are called *diagnoses*, Δ. Sets with minimal cardinality are preferred, that is, a single faulty service. These diagnoses are in general sufficient as multiple faults are unlikely. In this example, the set $\{AB(CAN)\}$ with only one element is able to resolve the contradiction. Therefore, the faulty CAN-Service is located.

Repair

Once the diagnosis system has found one or more malfunctioning services responsible for a detected fault, it should be able to recover the control system from this fault. Therefore, the repair module determines an appropriate repair action based on the described diagnosis and the dependencies between the services. The repair action consists of a stop and a restart of the malfunctioning services.

The appropriate repair action is derived in the following way: Put all members of the diagnosis D in a set R. The members of this set R are scheduled for restart. In the next step insert all services into R, which strongly depend on a member of R. Repeat this step until no more services are

Figure 10. Diagnosis of a fault in the Can-Service. The upper figure shows the desired behaviour. The lower figure shows the behaviour after a deadlock in the Can-Service.



added to *R*. *R* now contains all services which that to be restarted. But first of all the scheduled services have to be stopped in an ordered way. This means to first stop all services that no other service strongly depends on. Afterward, stop all services for which no more services are running that depend on them. This process is necessary to avoid additional crashes of services caused by a sudden stop of a service another service depends on. Hereafter, restart all affected services in the reverse order. Services that were restarted because of a strong dependency on the malfunctioning services should be able to retain data that it had gained so far or they should be able to recover such data after a restart. Otherwise, the control system may become inconsistent. After this repair action took place, the robots control system is again in the desired state.

CONCLUSION

In this work, a successful control architecture for autonomous mobile robots was presented. The proposed architecture is comprised of four major parts that give the architecture the power to control an autonomous mobile robot in complex tasks in difficult environments while still maintaining a great amount of flexibility. The four parts answer the questions that were posed in the introduction:

- **Control paradigm:** It has been motivated that only a hybrid control paradigm that combines the advantages of reactive and deliberative control enables a robot to perform complex tasks robustly. A three-layered paradigm was used to organize the control of the presented architecture.
- **Framework:** The experiences in building a mobile robot have shown that the adoption of modular frameworks for software and hardware can significantly reduce the development time and costs. At the same time, it increases the flexibility and robustness of the robot. By using this design approach, it was possible to develop four soccer robots from scratch with limited human and financial resources within less than one year.
  The quality and robustness of the robots were demonstrated during a number of RoboCup tournaments where the hardware and software of the robots operated in a stable manner. Moreover, the adaptability and

flexibility of the proposed control solution were impressive. For example, a RoboCup player's strategy could be modified within a few minutes on the field by simply adapting the knowledge base; no re-compilation of the software was necessary. Furthermore, the same framework is also applied successfully for the control of a delivery robot within the office domain.

However, the framework suffers from two major drawbacks. For one, the extensive use of the event channel as a flexible communication mechanism slows down the system and reduces the reactivity of the robot in dynamic environments. In addition, the system's reactivity is limited because of the incorporated classical AI planning techniques, which have a high computational complexity. However, this is necessary because only due to this abstract decision making module is the robot able to deal with very complex tasks. This drawback can be reduced by the increasing power of the used on-board computers and further achievements in the research on AI planning.

- **Robust plan execution:** The deliberative components have been enriched by a robust plan execution and symbol grounding mechanism. These extensions enhance the deliberative component, which plays a crucial part within an architecture aiming at the execution of complex tasks. The enhancements increase the applicability for unpredictable, noisy, and dynamic environments. Plan invariants and a hysteresis-based symbol grounding are used to achieve this.
- **Runtime fault diagnosis and repair:** The presented diagnosis system is capable of real-time fault detection, localization, and repair for the control software of autonomous mobile robots. The proposed system follows the model-based diagnosis paradigm. It uses a general abstract model of the correct behaviour of the control system together with observations of the actual behaviour of the system to detect and localize faults in the software. Furthermore, a repair method was presented that is able to recover the software from a fault. Because of its general methods, the proposed system is also applicable to software other than robot control software.

The presented overall control architecture solves a couple of problems that arise from the deployment of autonomous mobile robots in complex tasks in dynamic and unpredictable domains. It is an excellent example for a general flexible architecture for robust intelligent control.

Chapter 2.21
A Neural Network–Based Mobile Architecture for Mobile Agents

Anand Kuppuswami
University of Western Sydney, Australia

ABSTRACT

Wide area network (WAN) offers advantages like providing myriad services available on globally diversified computers with reasonably simple process. The ability to dynamically create networks offers the processing powers of various processors at our command. With the advent of protocols like SOAP and Web services, the consumption of services are more organized. In spite of various advances in communication techniques, the consumption of services through mobile gadgets is still only at the research level. The major impedances in implementing such systems on a mobile network are the latency factor, abrupt disconnection in service, lower bandwidth and minimal processing power. The mobile agent's paradigm proves to be an effective solution to various issues raised. It has received serious attention in the last decade and several systems based on this paradigm have been proposed and built. All such systems have been designed for a static network, where the service providers and the requestors are connected to the server on a permanent basis. This chapter presents a new framework of managing the mobile environment and the participating nodes with active intelligent migration. The functioning of the mobile agents in such a scenario is also presented.

INTRODUCTION

Mobile devices foster a new set of applications that are receiving enormous support in the global electronic community. This is primarily because of the ability of mobile devices to connect and reconnect with each other dynamically. The ability to create a network of devices "on the fly" can be adjudged as a major advantage of mobile gadgets as compared with the previous computer networks. The ability of being able to communicate and, more importantly, process information irrespective of time and place is a very promising feature offered by mobile technologies, as also ratified by Gray, Kotz, Nog, Rus, and Cybenko (1996). With the advent of the Internet and, especially, in communication, almost all actions related to

an application have been reduced to a few mouse clicks. As is obvious in our day-to-day usage, the Internet is a vast repository of information and services. Even though both Internet and related mobile technologies are very promising, their usage by business is still full of hurdles. For example, accessing a simple HTML page in a mobile gadget requires various configurations in them. This can be attributed to low latency, physical obstruction, and network connectivity of the mobile gadgets. The mobile gadgets have low memory, processing capabilities, and are prone to sudden failure (Jipping, 2002). These factors unveil the problem of client server architecture (Gray et al., 2002b). Often, having a well-thought-out networking architecture is crucial to successful usage of this technology. For example, the huge amount of data that is required to be transported due to various multimedia applications to the client's site for further processing is not possible without a good architecture. This created the need for remote working where code could migrate to a different machine, execute at the new machine, and return with the result. The whole concept of working remotely started with the message passing and remote procedure calls (RPCs) provided by Java (Birrell & Nelson, 1984). But their application was limited, as the client could use only those services provided by the server. If the requested service is not present, then the client has to make intermediate or "Bridge" function class in order to get to the final result. This process results in wastage of resources and bandwidth. As an alternative approach, small subprograms could be written and passed on to the service provider to execute locally. Network Command Language (NCL) (Meandzija, 1986), remote evaluation (REV) (Stamos & Gifford, 1990), and SUPRA-RPC (Stoyenko, 1994) employ this idea in their architecture. All these architectures had one major concern: the code, once migrated to a different machine, cannot remigrate at the end of execution. The architecture also lacked in active coordination between different programs. The absence of inter-communication protocols leads to poor performance of the system.

The novel approach of transportable programs (Gray, 1995; Cybenko, Gray, Wu, & Khrabrov, 1994) offers a promising solution for various issues raised. Transportable agents or mobile agents, as they are called now, are autonomous programs that can migrate from one machine to another machine in the network. By migrating to the machine having the resource, the agents have the advantage of working on site where the resource is present and also use the processor's power. This eliminates all the middleware that is required for transporting the data to the client's site. The mobile agent's paradigm provides an effective solution to the problem of low latency, poor interface, and bad network conditions (Gray et al., 1996). The middleware and the communication control mechanism form the major workload in a client-server architecture; by eliminating them, we can build a better working environment and increase the efficiency of the system. The code and state of code is migrated to another machine for resuming its execution. This also eliminates the interface required for service access. The fact that there is no need for permanent connection makes it very suitable to the mobile environment. The ad hoc client-server model is overridden by the peer-peer model which matures into grid computing, where the machines can act as client or server depending on the environment. The programmer is swayed away from traditional multi-tier architecture to grid computing (Lauvset, 2001).

The majority of the mobile agents present in the literature is designed for a static network architecture. Baring a few mobile agents (Cabri, Leonardi, & Zambonelli, 2002; Kendall, Krishna, Pathak, & Suresh, 1998), intelligence is not embedded into them. We present a new set of mobile agents which work in a volatile mobile environment. Embedded with intelligence, agents can act autonomously, collaborate with other agents, and reduce the

human intervention. The agents are configured to be adaptable, learn from their experience, and mature into experienced agents.

REVIEW OF MOBILE AGENTS AND THEIR LIMITATIONS

A new software architecture for building distributed applications using the mobile agent paradigm, which also supports cross-referencing between agents using Telescript (Dömel, 1996), has been proposed by General Magic. The Telescript agents can begin their execution in any machine, migrate to a different machine, and continue their execution, with the only prerequisite being that all hosts are Telescript enabled. Telescript is an object-oriented language that is a collection of hierarchically organised classes. The Agent class, which is inherited from the Process class, has a method "go", which performs the migration process. When an agent wants to migrate to another machine, it issues the command "go". The agent continues its execution from the command following the "go" command. A server at each site authenticates (Tardo & Valente, 1996) the agents and executes them. Requirements like special hardware and support for single language limits the global implementation.

Tacoma (Johansen, Renesse, & Schneider, 1996)—developed at the University of Tromso and the University of Cornell—are agents written in TCL/HORUS, which is a version of TCL where the HORUS is used for group communication and fault tolerance. They have rear guards which restart lost agents and have features like electronic cash for services. They have protection mechanisms which ensure that there are no runaway agents. Broker services for scheduling and directory services are also implemented. In spite of several advantages, the programmer has to explicitly capture the state information and does not support interruption of the execution of program, which limits its usability.

Agent TCL—D'Agents as it is now called (Gray, Cybenko, Kotz, Peterson, & Rus 2002a)—is a mobile agent system which attempts to strike a balance between the Tacoma and Telescript systems. It uses the flexible scripting language, TCL (Isaacson, 2001) and also provides support for other languages. Various migration and communication primitives help the programmer to code without worrying about the low-level migration protocol and also gives enough granularities for building basic blocks. For security purposes, it uses the SafeTCL (Levy, Ousterhout, & Welch, 1997) protocol. In the Agent TCL (Gray, 1998; Kotz et al., 1999) environment, the agents can migrate from one machine to another, create child agents for performing sub-tasks, access resources across networks, and communicate with other agents residing in local or remote machines. TIAS (Transportable Intelligent Agent System) (Harker, 1995) is an improved version of D'Agents, and offers several patches over existing systems.

A new series of itinerant agents (Chess, Grosof, Harison, Levine, & Parris, 1995) has been proposed which offers a secure environment for remote applications in public networks. Itinerant agents are programs which are dispatched from a source computer to roam among a set of networked computers until they accomplish the required task. The need for knowledge representation and verification is also discussed in their architecture. The Messenger-based operating system (Marzo, Murhimanya, & Harms, 1994) and some work on creating new mobile agents from existing systems (Brazier, Overeinder, Steen, & Wijngaards, 2002) have led to creating mutants like TOMAS (Transaction-Oriented Multi-Agent System) developed by Busetta and Ramamohanarao (1998).

With the working knowledge of various systems, and taking into account their inadequacies, we propose to build a new framework that offers a promising edge over the existing systems. The framework's working includes various modules, like knowledge building, pattern recognition, and intelligent migration. The architectures based on

mobile agents' paradigm vary with one another in several aspects. The process of comparison requires concrete understanding of the terms like desired degree of configurability, scalability, and customizability (Fuggetta, Picco, & Vigna, 1998). The lack of such standardization subdues any work on comparison.

MANAGING MOBILE ENVIRONMENT

There are several issues that have to be addressed before a mobile environment can be implemented. For example, current location of the mobile agent needs to be clearly identifiable. This is required in situations where some parameters need to communicate to the agent. A service that is published in the UDDI directories can be easily availed with the help of Web services (Yang, Hsieh, Lan, & Chung, 2005). In certain cases where the services are not published in the required format, there needs to be some brokering before the services can be consumed (Cybenko & Jiang, 1999). These could be achieved by those brokering, which works as the middleware. One of the most important aspects that needs to be considered is the current working environment. If the nodes in the network are volatile, then the process of migration gets intricate. As the nodes are volatile. the services also offered variegates. Presence of certain nodes may result in the system offering better service, and their absence may force one to look for the second best choice. In the current scenario, there needs to be an active broker, who advises the agent on its migration. As the service offered cannot be compared on a binary basis, there need to be "human aspects" embedded into the broker service.

We propose to utilize the agent tracking feature of architectures like Agent TCL and Telescript, where a central system keeps track of the active agents and their locations. A central server keeps tracks of the service providers. The use of knowledge base is also incorporated into our system. Depending on current requirement, intelligence may or may not be required. In situations where simple binary logics will not suffice, we propose to use advanced models like neural networks; probabilistic methods offer a promising solution.

Introduction to Mobile Environment

Figure 1 presents a sample mobile network where several nodes offering various services are collaborating with each other and the central server. The services are hexa-coded using keywords, which are then registered with the server. In the static scenario all the nodes are permanently connected to the server, whereas in the mobile environment, the nodes will be connected for a shorter time span. The number of nodes connected to the server will also fluctuate. To explain the working of a mobile environment, let us assume that we have eight nodes, of which six are connected to the server. The agents are in active collaboration mode, which could be productive or counter-productive depending on the process.

The static architecture is more like a simple market environment, where we have all the shops and we visit them to consume the services offered. In some cases, the set of current service providers do not offer the solution we need, and we have to settle with the level of services offered. A more generalised architecture would make the service providers mobile. The service providers "walk in and walk out" of the market anytime, at their will. This results in a market that would be highly volatile. There could be a set of nodes that remain connected and offer their services on a more permanent basis, but other nodes could be volatile. The presence or absence of the volatile nodes can have a vast impact on the functioning of the system.

Migration of Nodes

Each node has a header section called the Service Description Header (SDH), as shown in Figure 2, which describes the node in detail. The descriptions include the node name, the speed of connection, the quality of service factor, services offered, proximity index (PI), the operating system, and the language of coding. Whenever the node wants to enter the working environment, it sends a request to the server. The request would contain information like the START_TIME, END_TIME (if applicable), and the broad category of services. The PI would be a number ranging from 0 to 15, signifying how close the service is to the respective keyword. This would be in XML format for compatibility in heterogeneous environment.

Based on this request, the server assigns a unique ID to this node. In some cases this service may be redundant, and in that case server places the node in the queue. Once the node has been assigned an ID, the node prepares the detailed service description. The description will be in XML format and would have the structure as shown in Figure 3.

Similarly, whenever the node wants to exit the operating environment, it sends a termination request to the server. In case of termination, if any agent is being executed in that node, then the termination is postponed till the agent finishes the execution. Based on the START_TIME and the END_TIME, a latency factor and a quality of service factor are assigned to each node.

While assigning a new ID to the node entering the operating environment, the server checks for the existence of previous ID. If the node already had an ID, a new ID is not created and the old ID is retained. While assigning the new ID, the server checks the history for latency factor and the quality of service factor. If the values are lower than the values existing in the server's database, then the lower values are substituted; otherwise, the old values are retained. This process ensures that the quality or the latency factor is never hyped. Once the process of registration is complete, the node becomes an active member.

Challenges of Node Migration

In each instance, prior to the migration of agents between different nodes, a few factors must be considered in detail. Whenever the code migrates, it needs to take with it the working variables, so that it can continue the execution in the new environment. This brings up the question: How

much data needs to accompany the code? Let us consider a simple problem where a mobile agent is required to calculate the amount of tax that needs to be deducted from a salary. In this case, a numerical value is all that needs to accompany the code in the process of migration. This numerical value is enough for the successful execution of the code in the new environment. In this case the service provider has more information than the service requester. In a homogeneous environment, this process is further simplified. Now let us assume a situation in which the image format needs to be changed. For example, we have an image in BMP format and would need to convert it into JPEG format. Here, the mobile code has to transport the whole image to the site of service provider. This suggests that the migration of code would consume more resources than the service provider passing on the service. So we have to calculate the amount of data and the bandwidth of operation, and depending on those values, we decide on the migration.

A NEURAL NETWORK-BASED AGENT FOR INTELLIGENT MIGRATION

In the mobile environment, the nodes are volatile and hence the process of migration cannot be hard-coded. We need a run-time tool that can decide on the address of the future node. Each node varies on the service provided and has a varying level of PI associated with it. This perplexes the migration process. The migration also needs "shrewd attitude" when analysing the service factors. With these additional responsibilities thrust upon the mobile agent, the need for an advanced intelligent assistant arises. We propose an agent called the *broker agent* which performs the decision on migration of agents and acts as the "human intervention."

Request of Service and Broker Agent

When the mobile agent execution stack gets to the "go" command, the mobile agent creates a broker agent (BA). The purpose of the broker agent is to communicate with the server and identify the possible nodes which can offer the required service. The BA will communicate the agent's requirement to the server. This would result in the server identifying more than one node that can offer the required service. The BA must further drill down on the search result and track down the best node.

The list of the keywords and the service description of each node will result in varying system usability. In such a scenario a simple binary logic would not suffice. For example, if the service provider says "IMAGE EQUALIZATION" in the list of services provided and the agent is looking for "HISTOGRAM EQUALIZATION," then the simple binary logic will turn down the listed service. But in the image processing arena, both terms are used synonymously.

Ontology of Keywords and Network Architecture

As a first step, a list of keywords and their corresponding binary codes are prepared. This is presented to the neural network as inputs. The structure of the network is such that it can accommodate future unpredicted inputs. We would need multiple networks for performing multiple tasks. As each of these services does not have a maximum limit on number of keywords, we need a system which can handle this requirement. We suggest a network architecture of 16 input nodes which can accept an input between 0 to 15 for each node. This leads to an infinitely large number of a combinations of input values. The actual structure of the input is explained in the following section. Depending on the complexity of the service required, a *keyword list* (KL) is generated.

Table 1. A sample keyword list

Keyword	Comments
Image	Deals with image operations
Processing	Process images
Histogram	Performs histogram of the image
Equalization	Deals with histogram

A sample KL is shown in Table 1. The comments in the second column only aid the expert in his process of building the KL. This is not used in any part of the automated processing.

For example, let us assume that we need to perform histogram equalization. Then the list of keywords could be histogram, equalization, image, processing, and intensity. Each of them will become the input to the network. This suggests that we need five input nodes. This architecture will successfully work in an environment where the keywords are not emerging and fail otherwise.

To tackle this issue we propose to create agents having architecture which can cater for future keywords. The input to each node would be a value between 0 and 15. We also have decimal inputs which can help in getting accurate solutions. The sample input to the agent for training would be as in Table 2, where we have only shown whole numbers as the input, but decimal values are also accepted.

The input to the agent would depend on the proximity index for each service. For example, if the service provider has the keywords "image" and "processing", and their corresponding PI to be 15 and 8, this suggest that the input to the agent would be "F800 0000 0000 0000." We can map the service provider's PI to the agent input as shown in Table 2

Mapping Keywords

The process of mapping is complex and needs expertise at various stages. When mapping the PI for the known keywords, the process is relatively simple. The mapping complicates when the agent

Table 2. A sample input to the broker agent

Service Provider Keyword PI	Input to Neural Network
Image 15, Processing 8	F800 0000 0000 0000
Histogram 15, Processing 8	08F0 0000 0000 0000
Histogram 15, Equalization 10	00FA 0000 0000 0000
Image 15, Processing 15, Equalization 8	FF08 0000 0000 0000
Image 15, Processing 15, Histogram 15, Equalization 15	FFFF 0000 0000 0000

Table 3. Process of mapping

Keyword	Action
Photo	Mapped to Image
Function	Mapped to Processing
Normalization	New entry created
PCA	New entry created
Picture	Mapped to Image

encounters unknown keywords. An expert's knowledge would then be required to map the new keyword to either an existing one or to add the keyword to the KL. For example, if the service provider has "photo" as the keyword, then we can see that it is very closely related to the keyword "image". In this case, there would be no need to add a new keyword. Now let us suppose that the service provider has a keyword "PCA". Since it is not directly related to any of the existing keywords, there would be a need to alter the KL. A sample scenario is shown in Table 3.

Depending on the agent's service required, the KL may be a huge data repository in itself. This process of mapping cannot be automated at this stage of development.

Training of Network

Initially, when training the network only the five bits are used for training. The set of output values for each set of input has to be decided by an expert. This is a supervised training, which requires the knowledge and experience of a system expert. The output of the system can vary from –1 to +1, signifying how well the service provided suits the requirement. For example if the service provider has the keywords "image" and "histogram", then it has a better chance of catering to the needs when compared to a service which only has "image" as its service keyword. Depending on the PI for each keyword, the input value to the agent varies. A sample set of input and corresponding output can be formulated as shown in Table 4.

This input and output set is employed to train the network using the back propagation algorithm. After the successful completion of training, the neural network will be able to predict the outputs for unknown inputs. The node which evaluates to the highest value is selected as the service provider.

Table 4. A sample training set to the broker agent

Input to Neural Network	Output
F800 0000 0000 0000	+0.5
08F0 0000 0000 0000	+0.8
00FA 0000 0000 0000	+1.0
FF08 0000 0000 0000	+1.0
FFFF 0000 0000 0000	+1.0
F800 0000 0000 0000	-1.0

Process of Agent Learning and Maturing

After the initial phase of training, the agent is released to the network of nodes. The agent starts evaluating each node's service. The BA communicates with each node, gets its SDH, and extracts the keywords and their PIs. Depending on the keyword patterns, each node is evaluated for its service against the agent's requirements. The node having the highest match or the least conflict is selected as the service provider. In this process, if new keywords are encountered, then the agent would be unable to evaluate the performance of that node. In this case, new keywords need to be first mapped before the agent can process them. The keywords need to be mapped before the BA can proceed further. If there is no change in the KL, then without further processing the values are presented to the agent. If there is a change in the KL, the network needs to be retrained using the new sets of input. This is the process where the agent starts learning and maturing. After a series of training, the agent would have matured enough, and would not need further training and can be fully used. This process can be compared to a new staff member in an office who needs a few sessions of training before he can act independently.

IMPLEMENTATION OF INTELLIGENT MOBILE AGENTS

The system is being implemented in the .NET environment using C#, IIS as the Web server, XML, and SOAP protocol for communication. The project has been divided into four phases. In Phase I, the service request module is developed. In Phase II, the mobile environment is developed. In Phase III, the intelligent agents are developed, and in Phase IV, all the modules are integrated and fully implemented. Here we are trying to develop an application where a mobile client captures the image of a person and wants to find more information about him. This would be the case where a security person on his regular rounds finds a suspect but is not sure. In this situation we cannot expect a permanent connectivity with the server. So the ideal situation would be to capture the image and send it to the ground station for further processing. In a more generalised scenario, we can say that any person can capture the image and pass it on to the government agency for further scrutiny. Here there would be a series of activities that need to be performed before the information can be retrieved. The list of activities could range from capturing of image, communicating with the ground equipment, creating the broker agent, selecting the node for service, performing the migration, and processing the image.

All of the activities would have a list of tasks that needs to be completed. For example, image processing would need to perform tasks like image clarity improvement, image format conversion, image clipping (to get rid of background information), image histogram equalization, and image PCA. Each of these tasks would be performed by individual agents working in their environment.

In this chapter we describe the task of performing histogram equalization. Initially the agent is trained as proposed. Then the node communicates with all the nodes in the network suggested by the server. The list of keywords are analysed and the KL is updated. Depending on the KL change, the agent is retrained; this process continues until there is no further change in the KL. This would suggest that the agent has matured enough to perform the operation autonomously. Then the agent starts evaluating the nodes for its service index. The node which evaluates the highest value is selected for the service performance. Phase I has been developed, and Phase II is in the development stage.

CONCLUSION AND FUTURE WORK

We have presented a new framework of mobile agents functioning in a volatile mobile environment. The mobile environment is the generalised situation in the real world where the service providers oscillate between providing and revoking their service. We have presented a managing technique which can perform various tasks relating to managing such an environment. The agents have intelligence embedded into them in the form of neural networks, which acts in a "human way." The agents are initially trained and then let to mature by iterative retraining. This system is presently in the development stage and has several aspects that need further experimenting. Features such as the process of calculating the latency factors for each node are still in the research stages and need experimental data for analysis.

Chapter 2.22
Semantic Web Services for Smart Devices Based on Mobile Agents

Vagan Terziyan
University of Jyvaskyla, Finland

ABSTRACT

Among traditional users of Web resources, industry has a growing set of smart industrial devices with embedded intelligence. Just like humans, they need online services (i.e., for condition monitoring, remote diagnostics, maintenance, etc.). In this paper, we present one possible implementation framework for such Web services. Such services should be Semantic Web enabled and form a Service Network based on internal and external agents' platforms, which can host heterogeneous mobile agents and coordinate them to perform needed tasks. The concept of a "mobile service component" assumes not only exchanging queries and service responses, but also delivering and composition of a service provider. Mobile service component carrier (agent) can move to a field device's local environment (embedded agent platform) and perform its activities locally. Service components improve their performance through online learning and communication with other components. Heterogeneous service components' discovery is based on semantic P2P search.

INTRODUCTION

The intersection of Web Service, Semantic Web, and Enterprise Integration Technologies is recently drawing enormous attention throughout academia and industry (Bussler et al., 2003), and the expectation is that Web Service technology in conjunction with Semantic Web Services will make Enterprise Integration dynamically possible for various enterprises compared to the traditional technologies (Electronic Data Interchange or Value Added Networks).

The Semantic Web is an initiative of the World Wide Web Consortium with the goal of extending the current Web to facilitate Web automation, universally accessible content, and the Web of Trust. Tim Berners-Lee (Berners-Lee et al., 2001) has a vision of a Semantic Web, which has ma-

chine-understandable semantics of information, and trillions of specialized reasoning services that provide support in automated task achievement based on the accessible information. Management of resources in Semantic Web is impossible without use of ontologies, which can be considered as high-level metadata about semantics of Web data and knowledge (Chandrasekaran et al., 1999). DAML-S or DAML for Services (Ankolekar et al., 2002; Paolucci et al., 2002) provides an upper ontology for describing properties and capabilities of Web services in an unambiguous, computer-interpretable markup language, which enables automation of service use by agents and reasoning about service properties and capabilities. There also is a growing interest in the use of ontologies in agent systems as a means to facilitate interoperability among diverse software components (Ontologies, 2003). The problems related to that are being highlighted by a number of recent large-scale initiatives (e.g., Agentcities, Grid computing, the Semantic Web and Web Services). A common trend across these initiatives is the growing need to support the synergy between ontology and agent technology.

The key to Web Services is on-the-fly software composition through the use of loosely coupled, reusable software components (Fensel et al., 2002). Still, more work needs to be done before the Web service infrastructure can make this vision come true. Among the most important European efforts in this area is the SWWS (Semantic Web and Web Services, swws.semanticweb.org) project, which is intended to provide a comprehensive Web Service description, discovery, and mediation framework.

Usually a Web service is accessed by human users or by applications on behalf of human users. However, there already exists a growing new group of Web service users, which are smart industrial devices, robots, or any other objects equipped by embedded intelligence. There is a need to launch special Web services for such smart industrial devices. Such services will provide necessary online information provisioning for the devices, allow the heterogeneous devices to communicate and exchange data and knowledge with each other, and even support cooperation between different devices. There are many open questions to be answered within this research area.

In this paper, we discuss an approach for implementing emerging Semantic Web and Web services technologies to a real industrial domain, which is field device management. The goal of this paper is to discuss possible implementation framework to Web services that automatically follow up and predict the performance and maintenance needs of field devices.

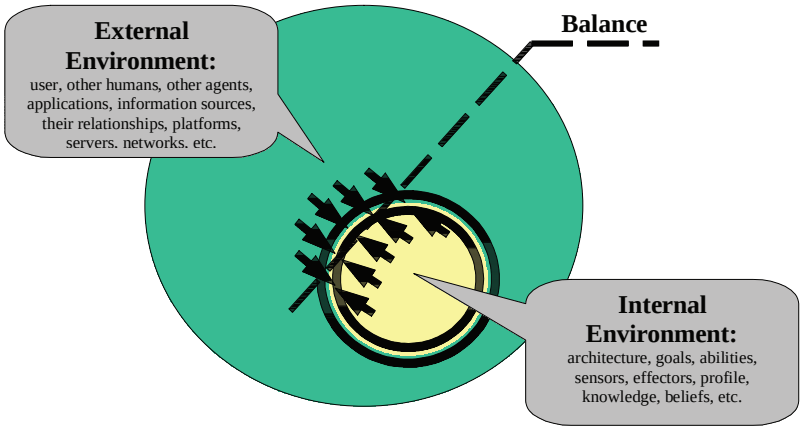
The rest of the paper is organized as follows: Section 2 briefly introduces our concepts of an intelligent agent and mobility; Section 3 presents two alternative architectures for distributed problem solving based on mobile agents; Section 4 describes the domain of field device maintenance and ways of implementing agents in it; Section 5 discusses implementation issues related to the Web service network (OntoServ.Net) of smart devices based on integration of Semantic Web services and multiagent technologies; Section 6 concludes.

AGENTS, SEMANTIC BALANCE, AND MOBILITY

In spite of the existence of many definitions for the concept of an intelligent agent, we will use our own. The definition is based on the concept of Semantic Balance (Terziyan & Puuronen, 1999). In Figure 1, the concept of internal and external environments is illustrated.

We consider Intelligent Agent as an entity that is able to keep a continuous balance between its internal and external environments in such a way that in the case of unbalance, the agent can choose a behavioral option from the following list:

Figure 1. Internal and external environments of an agent



- *make a change within the external environment* to be in balance with the internal one;
- *make a change within the internal environment* to be in balance with the external one;
- find out and *move to another place* within the external environment where balance occurs without any changes;
- *communicate* with one or more agents (human or artificial) to be able *to create a community* so that the internal environment of the community will be in balance with the external one.

This means that an agent is:

1. goal-oriented, because it should have at least one goal—to keep a continuous balance between its internal and external environments;
2. creative because of the ability to change external environment;
3. adaptive because of the ability to change internal environment;
4. mobile because of the ability to move to another place;
5. social because of the ability to *communicate to create a community.*

Thus, we see that mobility is an important adaptation ability of an intelligent agent.

"MOBILE AND DISTRIBUTED BRAINS" ARCHITECTURES

Assume that there is a certain intelligent task (i.e., remote diagnostics of a device based on sensor data) that appears somewhere on the Web. Assume also that necessary intelligent components ("distributed brains") to perform this task are distributed over the Web (e.g., in the form of Web-Services). Finally, assume that there is also an intelligent engine able to perform integration

of autonomous components for solving complex tasks.

Consider the following two architectures for this distributed problem solving:

- *Mobile Engine architecture*. To integrate distributed service components into one transaction in order to solve the task, the intelligent engine (i.e., mobile transaction management agent) makes necessary visits to all distributed platforms that host these services and provides all necessary choreography. Mobility here is an option that can be replaced by remote access to the components.
- *Mobile Components architecture*. Alternatively, the necessary components discovered for performing the task move to the platform where the engine is resized and choreography is performed locally. According to business models around the concept of a Web-service, it is natural to assume that services (intelligent components, in our case) should be "self-interested," and whenever they move, they should serve according to the interests of their creators. This means that the appropriate concept for such components is the concept of mobile agents. An agent is a self-interested entity that can act according to certain goals whenever it needs to accomplish a task.

Both architectures can be considered appropriate for implementation of an environment for distributed monitoring and remote diagnostics Web services for field devices, which is discussed in the following sections of this paper.

FIELD DEVICE MANAGEMENT AND AGENT TECHNOLOGIES

The expectations from smart field devices include advanced diagnostics and predictive maintenance capabilities. The concerns in this area are to develop a diagnostics system that automatically follows up the performance and maintenance needs of field devices and also offers easy access to this information. The emerging agent and communication technologies give new possibilities in this field. Field device management, in general, consists of many areas; the most important are:

- Selection
- Configuration
- Condition monitoring
- Maintenance

Valuable information is created during each phase of device management, and it would be beneficial to save it into a single database. This information can be utilized in many ways during the lifetime of the devices, especially since life-cycle cost (or lifetime cost) of all assets is getting more and more attention. Accordingly, the concept of life-cycle management of assets has become very popular (Pyötsiä & Cederlöf, 1999).

Field Agent is a software component that automatically follows the "health" of field devices. This agent either can be embedded to a device (Lawrence, 2003) or resized at the local network. It is autonomous, it communicates with its environment and other Field Agents, and it is capable of learning new things and delivering new information to other Field Agents. It delivers reports and alarms to the user by means of existing and well-known technologies such as intranet and e-mail messages. Field device performance has a strong influence on process performance and reliable operation in more distributed process automation architecture based on FieldBus communication (Metso, 2003; Sensodec, 2003). In this situation, easy online access to the knowledge describing field device performance and maintenance needs is crucial. There is also a growing need to provide automatic access to this knowledge, not only to humans, but also to other devices, applications, expert systems, agents, and the like, which can

use this knowledge for different purposes of further device diagnostics and maintenance. Also, the reuse of collected and shared knowledge is important for other field agents to manage maintenance in similar cases.

While monitoring a field device via a single information channel (Figure 2), one can get useful information about some dimension of the device state; then derive some useful patterns from this information, which can be considered as "symptoms" of the device's "health"; and finally recognize these symptoms using "Ontology of Patterns."

If we monitor a device via several information channels (Figure 3), then appropriate Field Agent Infrastructure allows not only deriving and recognizing "symptoms" of the device's "health," but also deriving and recognizing a disease itself using "Ontology of Diseases." In any case, history data, derived patterns, and diagnoses can be stored and used locally. However, there should be a possibility for easy access to this information and also sharing it with other agents for reuse purposes.

There are at least two cases where such distributed infrastructure is reasonable. The first one is when we are monitoring a group of distributed devices that are physically and logically disjointed; however, they all are of the same type. In this case any history of derived patterns and

Figure 2. Agent-based symptom recognition in device monitoring

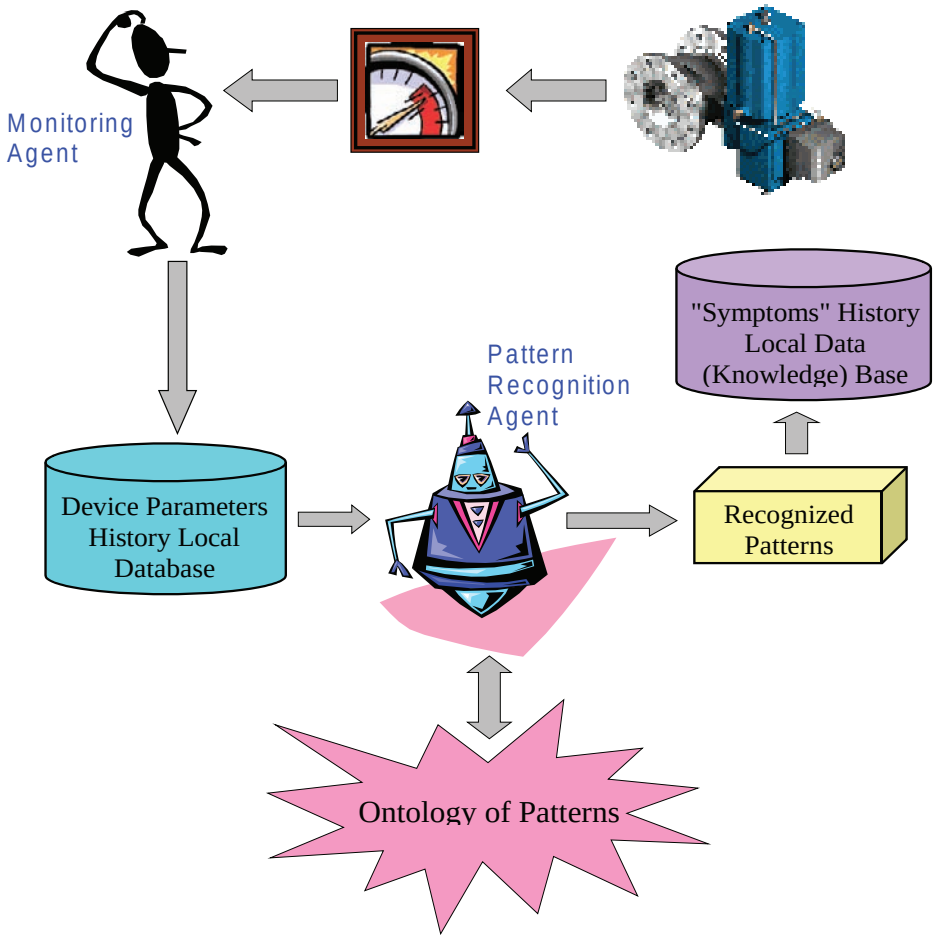


Figure 3. Agent-based diagnostics of field devices

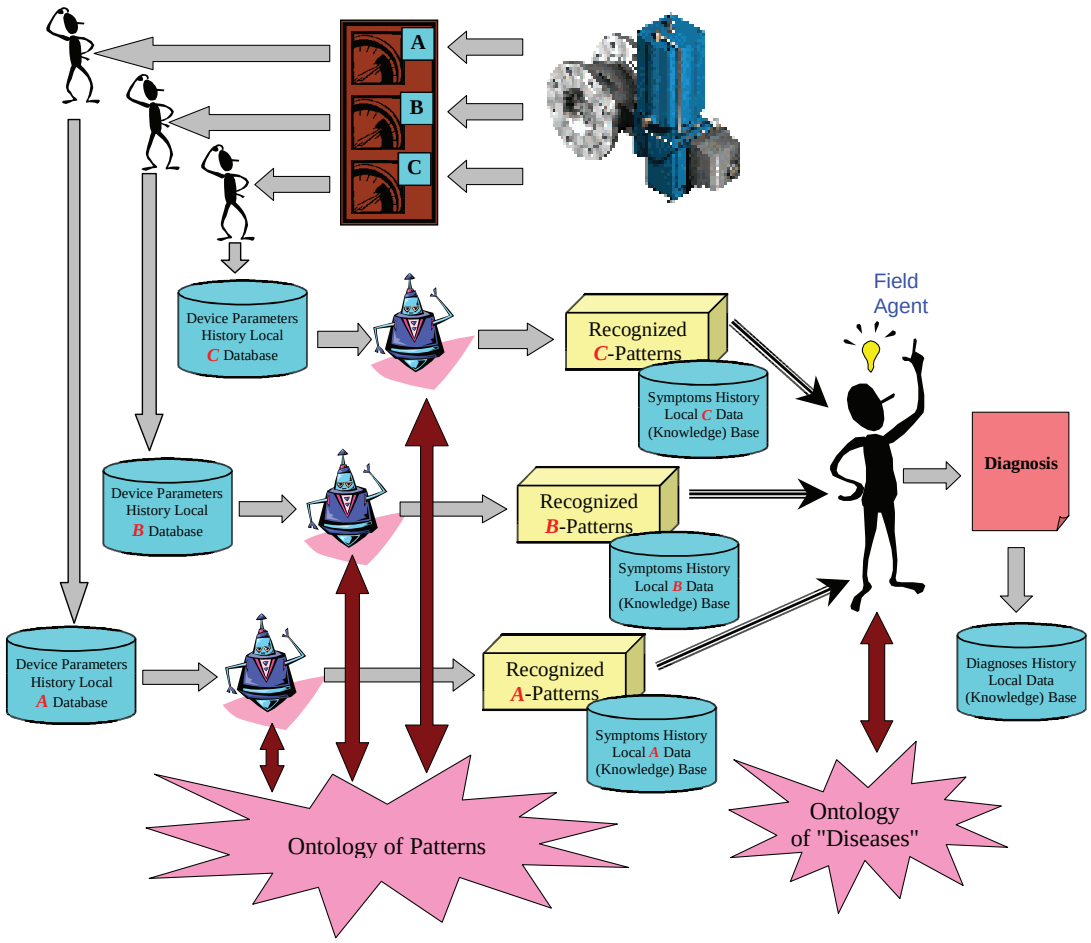

diagnoses from one device can be useful to better interpret the current state of any other device from the group.

The second case relates to the monitoring of a group of distributed devices of different types that are considered as a system of physically or logically interacting components. In such a case, it would be extremely important for every field agent to use outcomes from other field agents as a context for interpretation of the produced diagnosis. Thus, in these two cases, appropriate field agents should communicate with each other (i.e., in peer-to-peer manner) to share locally stored online and historical information and thus improve the performance of the diagnostic algorithms. This allows even the cooperative use of heterogeneous field devices produced by different companies that share common communication standards and ontologies.

We are considering the case when (predictive) maintenance activities can be performed not only by humans, but also by embedded automatics controlled by agents. We also assume that the Semantic Web and Intelligent Web Services concepts can be applied to the problems of interoperability among field devices and will result in the essential improvement of field device maintenance performance.

ONTOSERV.NET IMPLEMENTATION ISSUES

The OntoServ.Net concept was developed by the Industrial Ontologies Group (http://www.cs.jyu.fi/OntoGroup) as a large-scale automated industrial environment for asset management. First, we consider maintenance of assets, but in general, this concept also can be applied to process control, improvement of operating efficiency, field-performance diagnostics, and the like. Better maintenance provided by OntoServ.Net considers maintenance information integration, better availability of operational data, and shift from reactive and preventive maintenance toward predictive and proactive maintenance, which means, first of all, reduced Total Life Cycle Cost of machines. OntoServ.Net is also a network of industrial partners that can share maintenance methods and information developed by working on a specific machine (i.e., device, equipment, installation). Improved locally, maintenance experience can be shared.

In addition, it is assumed that there are special commercial maintenance (diagnostics) services supported either by manufacturers of machines or by third parties. Browsing a device's internal state is extended to automatic diagnostics and recovery within a network of maintenance services or even within a network of platforms hosting several maintenance services. The role of a maintenance service is first to organize the gathering and integration of field data to learn from it, and then to support its clients (field devices) by providing remote diagnostics and maintenance services. Implementation of such large-scale environment in OntoServ.Net presents many problems to be solved. The challenge here is standardization of maintenance data across various software systems within OntoServ.Net and existing industrial systems.

Ontology-Based Standardization of Maintenance Data

We are focusing on maintenance data, which comes from field devices. For remote diagnostics (i.e., in the case of predictive maintenance), this data need to be sent to some other place beyond the local computing system (whether it is a computer or an embedded system). We assume that a maintenance network without centralized control requires some global standard for data representation in order to provide compatibility of network nodes.

We consider standardization based on ontological description of data. An ontology-based approach here stands as an alternative for development of a maintenance-specific set of standards/vocabularies/procedures for information exchange. We use the ontology concept and data representation framework, which was developed within Semantic Web activities. Ontology-based information management is more flexible and scalable, and also has the potential to become the next-generation standard for information exchange on the Internet. An ontology engineering phase includes development of upper-ontology (schema for ontology) and development of ontology itself, which includes specific data about maintenance domain (i.e., device descriptions, diagnostic methods description, etc.). Concrete data are annotated in terms of upper and common ontology. Here, ontology provides a basis for a well-understood common language to be used between devices and systems.

To consider field devices as data sources, the information that needs to be annotated includes sensor data, control parameters, and other data that presents the relevant state of the device for the maintenance process. A special piece of device-specific software (OntoAdapter) is used for translation of raw diagnostic data into standardized maintenance data. This adapter can be integrated into a legacy system used for device management or can be developed independently from existing software, if such a solution is appropriate and possible.

The type of software that uses data being described in an ontological way can vary, depending on the needs. It can be a data browser, control panel for the operator, computing system, database storage, and so forth. Because of the way data are represented, it never will be processed incorrectly, since the software can check itself on whether data semantics (as annotated) are the same or compatible with the data processing needs of the unit.

Additional benefits come from data annotation for software development, even if there is no need to deliver information outside of the original computing system. There is no more need to develop special formats of maintenance data exchange between applications, since it is already presented in a common standard by means of ontology. Software can be developed in a modular, scalable manner with support for this standard (ontology). Such commitment to the shared (upper) ontology will provide compatibility of software.

Ontology-Based Diagnostics Based on Maintenance Data

It is assumed that there are special commercial diagnostic units (maintenance services) supported either by manufacturers of machines or by third parties. Browsing a device's internal state is extended to an automatic diagnostics and recovery within a network of maintenance services. As already mentioned, the role of maintenance service is first to organize gathering and integration of field data and learning based on it, and then to support its clients (field devices) providing remote diagnostics services.

Considering the various aspects of maintenance network development, the following statements are true:

1. There are diagnostic software components (also called classifiers or diagnostic units) that perform predictive/proactive diagnostics. These diagnostic units obtain maintenance data delivered to them either locally or from a remote source, and provide diagnosis as an output.
2. Diagnosis provided by a classifier can be of several types: the class of state an observed device has; the in-depth diagnostics; and the [maintenance] actions/activities that are required.
3. Diagnostic units are specialized in certain aspects of maintenance diagnostics, so a device usually needs support from a set of different diagnostic units that operate and can be replaced independently.
4. Diagnostic units (components), in general, are not device-specific and perform similar diagnostic tasks in a variety of device monitoring systems.
5. Diagnostic units [OntoServ.Net] are platform-compatible and developed separately from maintained devices; thus, they can be used on any platform within OntoServ. Net.
6. Once a diagnostic unit possesses the ability to learn, the maintenance experience it gets will be available for diagnostics of other devices. This is done by means of running a copy of a classifier on other maintenance platforms or presenting its experience in a way that will allow reusing it by other diagnostic units. There is interest especially

in the capabilities of integration of such information obtained worldwide and applied effectively to individual devices.

7. A maintenance platform is a computing environment in which maintenance services (i.e., diagnostic units, etc.) are installed. It supports device-specific interfaces for connecting devices. On one side, it provides a maintenance-managing core with installed services and, on other side, it supports a connection to a maintenance network consisting of maintenance platforms of other devices — specialized centers for remote maintenance. Such services can be implemented, based on agent technology (Gibbins et al., 2003). Taking into account the openness of the system, the issues of security and trust management are considered as exceptionally important (Kagal et al., 2001).
8. A maintenance platform manages maintenance information exchange between devices and diagnostic units residing locally and elsewhere in the maintenance network. It also supports the search of required network resources and upgrades of installed software, and supports a mobility feature for maintenance services.

Since the available set of classifiers can vary, the type of classifier (its purpose) is specified in order to allow selection in cases, when necessary. Every classifier has its description attached — information concerning its capabilities. The description also contains information on how to use the classifier, what inputs it requires, and what output it provides.

Preliminary classification mechanism of a maintenance platform takes into account which services (classifiers) are available now, and selects those that declare themselves able to deal with the class of problems derived during the pre-classification phase. Here, pre-classification is similar to human-operator work, which can detect some abnormal device behavior and use analysis tools in order to find the source of the problem.

It is assumed that some historical maintenance data are available and are used for automatic learning of the kind of maintenance actions to be performed. This knowledge in the model supports the automated reasoning mechanism, which implements preliminary diagnostics of the device state and can identify certain deviations from normal operational state and run an appropriate diagnostic service.

The Industrial Ontologies Group is involved in the maintenance data processing, based on the descriptions of available maintenance resources (i.e., classifier services, as it was shown) and explicit representation of knowledge for initial data pre-processing.

Service descriptions allow changing of service easily. Diagnostic knowledge allows automated maintenance system activity and makes it possible to reuse the acquired knowledge (presented in the specific classification model as data, rules, etc.). A newly installed device that has no historical data yet can use the classification ontology of some other device of the same type.

We use application of Semantic Web technology for maintenance data description, service component description, and representation of classification knowledge. Those descriptive data pieces have to be in some common format for the whole maintenance system. RDF and its derivatives are a perfect basis for that.

Ontology-Based Diagnostic Services Integration

To be able to integrate heterogeneous resources and services over the Web, we have to describe them in a common way, based on common Ontology. Considering the resources in an industrial product's maintenance domain, we distinguish the following resources: smart devices, which are represented by services of their alarm or

control systems (or some software interface); a set of diagnostic services or classifiers; platforms, which are represented by clusters or a collection of elements; human, which can be represented by some special service; and large enterprises' systems. This ontology-based annotation must comprise not only a resource's description (i.e., parameters, inputs, outputs), but also many other necessary things that concern its goals, intentions, interaction aspects, and so forth. Ontology-based means that we have to create ontologies to be used by all such resources.

Each service represents a three-level resource: input parameters, black box (service engine), and output parameters. Since all services are heterogeneous, we have a need to describe each resource (service) with a common ontology and create a shell (OntoShell), which will provide common descriptions and make the service realization transparent. OntoShell is the main core of such integration environment. It has to be expanded in a scalable and modular manner, so that it may represent a mediation platform for the set of adapted, semantically annotated resources (cluster of OntoShells). OntoShell is a shell (frame) for these resources, which is a mechanism for making ontological description and providing interoperability. One of the important parts of OntoShell is an OntoAdapter for resources. If we are talking about transformation of existing resources to semantically enabled ones, then we have to develop the mechanisms for accessing the resources. These resources are developed, based on different specific standards on both content (WSDL, C/C++ (dll), Java, SQL Server, DCOM, CORBA, etc.) and transport levels (TCP, HTTP, RMI, etc.). In this case, we have to design and develop corresponding software modules (OntoAdapters) for semantic, content, and transport levels. It will be these construction blocks that will fill OntoShell, depending on the resource's description.

A set of services represents the three-level automated diagnostic system. The first level is represented by the alarm system of the device (WatchDog), which signals a change in the normal device state. The main maintenance diagnostic system (service) forms the second level of the system via preliminary (initial) diagnostics. It contains preliminary diagnosis classification based on the ontology of the device condition. The result of such initial classification is deciding on what kind of classifier (diagnostic service) is needed to make further data processing. This system initiates the third level of diagnostic for making a decision about precise diagnosis. Request for further classification is sent to respective classifiers of the centralized diagnostic system directly taking into account the probability of classifier belonging to that class of problem.

Semantic Peer-to-Peer Discovery of Maintenance Services

Within the OntoSert.Net concept, a peer-to-peer architecture of global network of maintenance Web-services is assumed. The architecture provides support for registration of maintenance service profiles based on ontology shared within the network. The profiles are registered in a local repository. The architecture includes a platform steward module, which implements a semantic search engine. The engine searches among local maintenance services, using the semantic match procedure, for one with a profile that corresponds to the query. A Steward also implements peer-to-peer functionalities like query forwarding and sending, neighbor registration, and so forth.

When the Platform Steward makes a decision about the necessity of using external Maintenance Services, it sends a formalized query to neighbor platforms. Such a necessity can occur if the requested Maintenance Service is absent on the local platform or cannot provide sufficient performance, or if the Steward needs opinions of other Classifying Services (i.e., during learning). If the neighbors can't satisfy the query, they forward it to their own neighbors, and so on. Thus, the

query can roam through many platforms in the Global Network, which increases the probability of finding the required service.

When a platform receives a query that it can satisfy, it sends the response to the query initiator about its location. The query initiator can collect a number of such responses — a list of potential partners.

To increase the efficiency of a search of Maintenance Semantic Web-services and its automated nature (initiators of the search are Smart Devices), the system should inherit the concepts of Semantic Web. That means:

1. Development of common Ontology for the Global Network, which contains a classification of Maintenance Services in a hierarchical tree and explicit definition of relations between such classes. Another option might be to provide possibilities to manage several pre-existing ontologies (Mena et al., 2000).
2. Every platform creates a local repository of profiles of available Maintenance Services based on Ontology.
3. Each Platform Steward must have a Semantic Search Engine that will find a semantic match between the query and each profile in the local repository.
4. Each Platform Steward must have a Semantic Query Engine that composes formalized queries.

Thus, we are using a combination of centralized architecture for service discovery within the platforms of services and peer-to-peer architecture for service discovery across the platforms (Arumugam et al., 2002). A Platform Steward provides centralized capabilities when it manages service discovery within its internal platform, and at the same time, it can behave in a peer-to-peer manner when it interacts with external service platforms.

CONCLUSION

The goal of this paper is to provide a possible implementation framework for Web services that automatically follow up and predict the maintenance needs of field devices. The concept of a mobile service component supposes that any component can be executed at any platform from the Service Network, including the service requestor side. This allows delivery of not only the service results, but also of the service itself. A mobile service component carrier (agent) can move to a field device's local environment (embedded agent platform) and perform its activities locally. Service components improve their performance through online learning and communication with other components. Heterogeneous service components' discovery is based on semantic P2P search. This paper addresses the very basic challenges related to Web services for smart devices and partly the related implementation issues. More research is needed to validate some of concepts discussed in this paper.

ACKNOWLEDGMENTS

The author is grateful to Tekes (National Technology Agency of Finland) and cooperating companies (Agora Center, University of Jyvaskyla, TeliaSonera, TietoEnator, Metso Automation, Jyvaskyla Science Park) for the grant supporting the activities of the SmartResource project. I am also grateful to Dr. Jouni Pyotsia from Metso Automation for useful consultations and materials. Also, thanks to colleagues from Industrial Ontologies Group (O. Kononenko, A. Zharko, and O. Khriyenko) for useful discussions related to the implementation issues.

Chapter 2.23
Towards Autonomic Infrastructures via Mobile Agents and Active Networks

Stamatis Karnouskos
SAP Research, Germany

ABSTRACT

As we move towards service-oriented complex infrastructures, what is needed, security, robustness, and intelligence distributed within the network. Modern systems are too complicated to be centrally administered; therefore, the need for approaches that provide autonomic characteristics and are able to be self-sustained is evident. We present here one approach towards this goal, i.e., how we can build dynamic infrastructures based on mobile agents (MA) and active networks (AN). Both concepts share common ground at the architectural level, which makes it interesting to use a mix of them to provide a more sophisticated framework for building dynamic systems. We argue that by using this combination, more autonomous systems can be built that can effectively possess at least at some level of self-* features, such as self-management, self-healing, etc., which, in conjunction with cooperation capabilities, will lead to the deployment of dynamic infrastructures that autonomously identify and adapt to external/internal events. As an example, the implementation of an autonomous network-based security service is analyzed, which proves that denial of service attacks can be managed by the network itself intelligently and in an autonomic fashion.

INTRODUCTION

Systems and services are becoming more ubiquitous, which calls for sophisticated solutions to be in place. As we move towards the "Internet of things" (Dolin, 2006), it can be expected that millions of devices of different size and capability will be connected and interact with each other

over IP, e.g., sensor networks (Marsh, 2004). Therefore, any approach will have to take into consideration that:

- Complexity will increase
- Heterogeneity in devices, software platforms, online services, etc., will increase
- A large proportion of end-nodes will be connected wirelessly to the backbone infrastructure (the line of wired vs. wireless systems will blur more)
- Bandwidth and computing power will increase
- Ad-hoc computing, collaboration, task delegation, and environmental adaptation will be basic necessities
- On-demand software and service deployment will be vital
- Security and its satellite services will gain importance

In such an assumed future infrastructure, autonomic systems are expected to be of considerable help, since they will be able to be at a great degree self-sustained and also react to a dynamic changing environment.

Autonomic computing (Sterritt et Al., 2005) was introduced by IBM as a means to target increasing computer system complexity, and aimed initially at automating management of enterprise computational systems. In *The Vision of Autonomic Computing* (Kephart & Chess, 2003) it is stated that the dream of interconnectivity of computing systems and devices could become the "nightmare of pervasive computing," in which architects are unable to anticipate, design, and maintain the complexity of interactions. The essence of autonomic computing is system self-management, freeing administrators from low-level task management whilst delivering an optimized system. In a self-managing system, or Autonomic System, the human operator does not control the system directly, but only defines general policies and rules that serve as an input for the self-management process. For this process, IBM has defined the following four functional areas:

- **Self-configuration:** Automatic configuration of components
- **Self-healing:** Automatic discovery, and correction of faults
- **Self-optimization:** Automatic monitoring and control of resources to ensure the optimal functioning with respect to the defined requirements
- **Self-protection:** Proactive identification and protection from arbitrary attacks

There are two strategies in achieving autonomic behavior, i.e., through adaptive learning and via integral engineering into systems (Sterritt, 2004). Our approach focuses on how to engineer such an autonomous system, while adaptive learning, or self-learning, is seen as an ad-hoc component that can be imported from the domain of intelligent agents.

AMALGAMATION OF ACTIVE NETWORKS AND MOBILE AGENTS

Active and programmable networks (Karnouskos & Denazis, 2004) introduce a new network paradigm where network-aware applications and services can be not only distributed, but also can configure the heterogeneous network to optimally respond to task-specific requirements. We are able to utilize within the network: (a) computation, as we are able to compute on data received from active nodes, and (b) programmability, as we can inject user code into the network nodes in order to realize customized computation. Being able to achieve the above, we succeed in decoupling network services from the underlying hardware, deploy fine-grained customized services, relax the dependencies on network vendors and

standardization bodies, and generally open the way for higher-level. network-based application programming interfaces.

Agents are software components that act alone or in communities on behalf of an entity and are delegated to perform tasks under some constraints or action plans (Jennings & Wooldridge, 1996). One key characteristic of agents is mobility (mobile agents), which allows them to transport themselves from node to node and continue their execution there. Additionally, autonomy, independent decision-making, goal-directed behavior, and social ability are also key characteristics agents may possess (Genesereth & Ketchpel, 1994). Mobile agent technology has established itself as an improvement of today's distributed systems due to its benefits, such as dynamic, on-demand provision and distribution of services, reduction of network traffic and dependencies, fault tolerance, etc. The number of mobile agent platforms coming from the commercial sector, as well as academia, is increasing day by day.

Active networks and Mobile Agent technology are very close to each other, sharing common ground on theoretical/conceptual and implementational levels. From the viewpoint of mobile agent research, existing active network approaches take mobile active code very close to the mobile agent paradigm:

- **Capsule:** A typical code mobility paradigm, i.e., a single mobile agent
- **Active/programmable node:** Instantiation of code on-demand

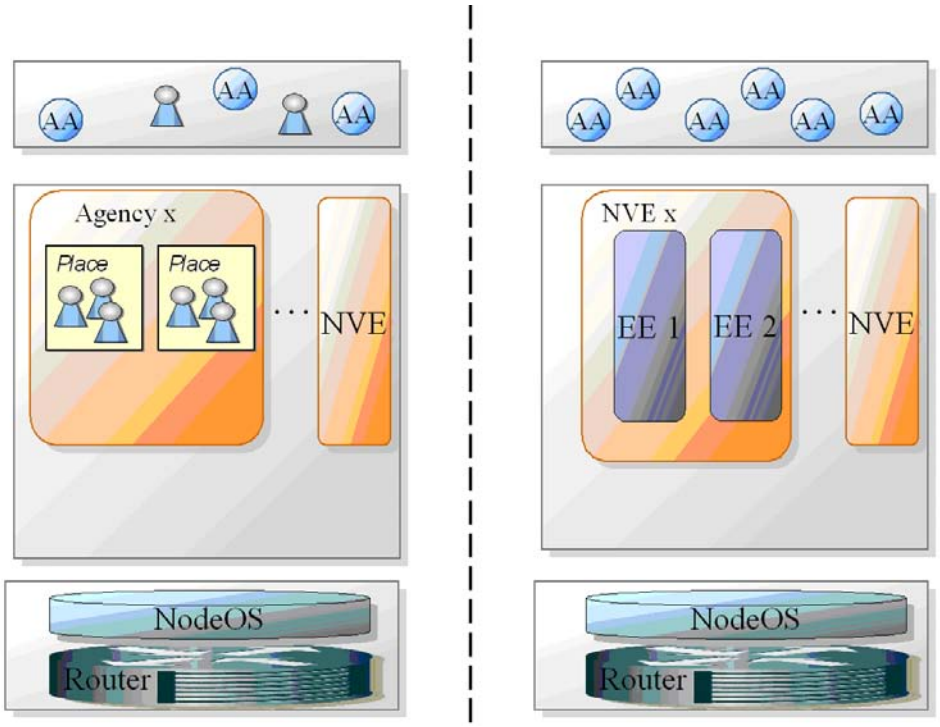
From the active network research viewpoint, the mobile agent technology is one of the possible technologies that can be used to build active networks. Mobile agents are regarded as specific types of active code and a MA-based node as a specific type of active network node. Due to the fact that the MA research arena has existed more than a decade now, it is far more advanced in active code-related matters, therefore, it could provide a boost to specific AN matters at conceptual and implementation levels.

The right side of Figure 1 depicts the architecture of a legacy active node, while the mobile agent based implementation is depicted on the right side. We can clearly distinguish the following levels:

- Active applications/services which exist as a result of the execution of active code within an EE. An active code can: (a) provide a standalone service, or (b) cooperate with other active codes residing on the same EE (EE-based service), on different EEs in the same node (multi-EE service), or even on different EEs in different nodes (network multi-EE service).
- Execution environments where the active code executes. As an active node is expected to host multiple execution environments, these environments must have the ability to communicate with each other and to group in order to ease interactions. There are several functional types of EE aggregation, such as node virtual environment (NVE), node virtual environment network (NVEN), execution environment network (EEN), etc.
- NodeOS, which is an operating system for active nodes. The nodeOS provides generic services to the hosted Ees, e.g., inter-EE communication (at the EE, NVE, or Active Application level), router resource management, EE isolation, etc. The nodeOS offers these services based on several facilities, such as resource control, security, management, demultiplexing facilities, etc.

As shown in Figure 1, one of the execution environments is the agent execution environment. This is the agency as described within the MASIF (OMG-MASIF, 1998) standard. The agent system consists of Places. A Place is a context within

Figure 1.The agent-based AN node versus the legacy one



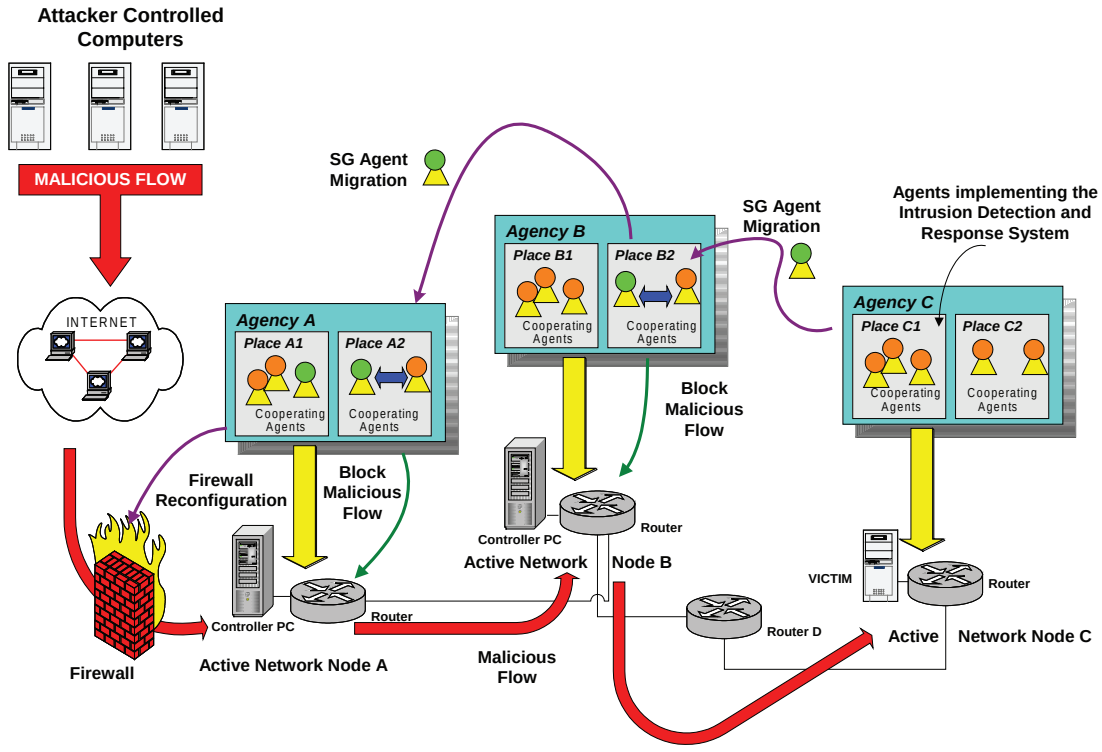
an agent system in which an agent is executed. This context can provide services/functions such as access to local resources, etc. Cooperating agents reside in the agent-based Ees, and via the facilities offered to them (re)-program the node. These can be either mobile agents (e.g., visiting agents) or even stationary intelligent ones that reside permanently in the EE, implementing various services. The integrated approach of agents and active networks allows us to apply several security techniques at the network programming level (Karnouskos, 2001) that promote service and network security. Further information on this architecture and its security issues can be found in Karnouskos (2002). The mobile agent framework is able to realize the abstract functions of the EE, NVE, etc. The AAs are considered, for implementation reasons, to be mobile agents, but could also be applications that partially depend on them.

APPLICATION SCENARIO

An autonomic computing system (ACS) is able to (re)-configure itself in response to varying environmental conditions. Such a dynamic system can deal with unknown intrusions or attacks and is event-able to recover from malfunctions or heal itself. The scenario presented here deals with a network-based security system that is able to depict at some degree the characteristics of an ACS.

Securing a network nowadays is synonymous with hardening of its services. However, this approach makes the network inflexible and blurs the line between security and usability. Furthermore, each node has its own requirements on security which may also be varying in time. Within the vision of "Internet of things," such per-node or even per-task modification of security would be impossible to manage due to the large number and complexity of devices. Furthermore, those devices will build ad-hoc, short-lived networks, where the burden of taking such actions may not be justified. Additionally, no common base exists among various security solutions available in the market. In other words, available products do not communicate with each other (interoperate), and work alone for their own and their distribution company's good, not necessarily for the user's network. A collaborative approach must be considered; however, due to the nature of the future networks, this must be done on-demand and customized to the specific context. Community-aware tactics on the other side may offer a better alternative. Adopting modeling approaches from the evolution of biological systems (Forrest et al., 1997), they are seen as networks formed from cooperating living parts that interoperate at various levels and share information. ACS systems

Figure 2. DoS threat management



seem a promising approach towards that direction, mainly due to their self-* characteristics.

We assume a typical denial of service (DoS) attack scenario. As depicted in Figure 2, the network topology consists of various active nodes (e.g., nodes A, B,and C) and legacy nodes (e.g., node D). In normal operation, the agents that implement our system reside within the agencies and filter the flow that is directed to the node. At some point, the attacker initiates the DoS attack via the compromised hosts against the AN node C. One agent in node C detects the attack. This can be a result of an attack signature recognition (if the attack is known and exists in the system database) or a result of a dynamic correlation of events received by the system. Once the attack is detected, several security guards (SG) are released within the network (dynamic lookup of the neighboring nodes) and the attack information is disseminated towards the other nodes that reside within the path of the attack. In this way, the agents continue in an autonomic way to roam the network, identify the nodes that are prone to this attack, and share information which eventually lead to a policy change and blocking of the specific malicious traffic within that node. At the end, the malicious flow is blocked towards the borders of the domain, and the network nodes are protected from this attack. Further detailed information about this approach can be found in Karnouskos (2004).

The engines behind the data analysis and event correlation, as well as decision and action management, can be standalone; however, it is much more interesting if they act in a collaborative manner. . Therefore, at each domain, central analysis points (CAP) exist which have an overview of what is happening in the domain, thereby making it easier to recognize attacks that include multiple nodes in different parts of the network. CAPs have the global view, and therefore are more efficient in attack recognition and decision making, while the action is done locally on each node; this tactic allows thin components to be deployed even to devices that do not feature high computational capabilities.

The result of this approach is that we have a network that features, at some degree, characteristics if autonomic systems. More specifically:

- **Self-configuration:** Automatic configuration of the different components that recognize the attacks is done. The agents are goal-driven and are able to reconfigure themselves based on the environmental context they act on.
- **Self-healing:** Automatic discovery and correction of faults for network parts is done. Once this is detected, the specific sub-network part can be isolated in order to avoid network misbehavior, and classical solutions to the problem can be applied.
- **Self-optimization:** Automatic monitoring and control of resources of the network can be done. In that case, early indicators can be correlated and emerging problems are easier to pinpoint.
- **Self-protection:** The network is protected from well-known attacks, including those that can be dynamically identified based on the correlation of events or even with "socializing" (i.e., information exchange) with other networks.

As presented, our approach deals with some aspects of ACS; in the future, more specific research should be invested towards a fine-grain exploitation of each of the features in detail. Self-managing mechanisms can have several instantiations: self-government, self-correction, self-organization, self-scheduling, self-planning, self-administration, self-optimization, self-monitoring, self-adjusting, self-tuning, self-configuration, self-diagnosis of faults, self-protection, self-healing, self-recovery, self-learning, self-sensing/perceiving, self-modeling, self-evolution, self-assessment of risks, etc. (Tianfeld & Unland, 2004).

CONCLUSION

We have presented an approach that is based on the amalgamation of active networks and mobile agents. We merge specific capabilities from each domain, e.g., the network programmability from active networks and the autonomic, goal-driven social characteristics of mobile agents, in order to create a powerful combination and implement a system that depicts, at some degree, behavior that characterizes autonomic systems. The approach taken is open and can be seen as a platform to further integrate research results coming from the two domains. Furthermore, we have not yet touched issues like self-learning mechanisms, which however, initially could be imported from the work already done by the research community on intelligent software agents. Security, trust, and privacy issues as identified by Cardoso and Freire (2005) need to be further examined, especially because our collaborative approach taken here heavily depends on them. Finally, other approaches that move towards the usage of agents for implementing specific scenarios also exist, e.g. (Soldatos et al., 2006).

The essence of autonomic computing systems is the creation of dynamic infrastructures that can deal in a proactive way with changing environmental contexts; this is a fact that is gaining importance as we move towards a complex heterogeneous infrastructure, e.g., as depicted in the "Internet of things," where all interconnected devices will also form ad-hoc networks for even task-specific goals. Without such approaches, large-scale complex computing systems will be unmanageable.

KEY TERMS

Active Application: This is the code that is actually executed in the Execution Environment of the node. Via its execution in the EE, the code programs the node according to the user's preferences.

Active Networks: Active networks are a communication paradigm that allows packets flowing through a communication network to dynamically modify the operation of the network.

Autonomic Computing: An initiative started by IBM in 2001. Its ultimate aim is to create self-managing computer systems to overcome their rapidly growing complexity and to enable their further growth.

DoS: Denial of service attacks result in computers consuming their resources for malicious events without being able to further process legitimate user requests

Execution Environment: This is the place where the active code executes. The EE offers access to the core node resources via a policy-controlled scheme. This can be, for instance, a mobile agent system that takes care of the execution of an agent.

Mobile Agents: A mobile agent is a composition of computer software and data which is able to migrate (move) from one computer to another autonomously and continue its execution on the destination computer.

Sensor Networks: Sensor networks are computer networks of many, spatially distributed devices using sensors to monitor conditions at different locations, such as temperature, sound, vibration, pressure, motion, or pollutants. Usually these devices are small and inexpensive, so that they can be produced and deployed in large numbers, and so their resources in terms of energy, memory, computational speed, and bandwidth are severely constrained.

Chapter 2.24
Mobility Management in Mobile Computing and Networking Environments

Samuel Pierre
Ecole Polytechnique de Montreal, Canada

ABSTRACT

This chapter analyzes and proposes some mobility management models and schemes by taking into account their capability to reduce search and location update costs in wireless mobile networks. The first model proposed is called the built-in memory model; it is based on the architecture of the IS-41 network and aims at reducing the home-location-register (HLR) access overhead. The performance of this model was investigated by comparing it with the IS-41 scheme for different call-to-mobility ratios (CMRs). Experimental results indicate that the proposed model is potentially beneficial for large classes of users and can yield substantial reductions in total user-location management costs, particularly for users who have a low CMR. These results also show that the cost reduction obtained on the location update is very significant while the extra costs paid to locate a mobile unit simply amount to the costs of crossing a single pointer between two location areas. The built-in memory model is also compared with the forwarding pointers' scheme. The results show that this model consistently outperforms the forwarding pointers' strategy. A second location management model to manage mobility in wireless communications systems is also proposed. The results show that significant cost savings can be obtained compared with the IS-41 standard location-management scheme depending on the value of the mobile units' CMR.

INTRODUCTION

Mobile communication networks are made possible by the convergence of several different technologies, specifically computer networking protocols, wireless-mobile communication systems, distributed computing, and the Internet. With the rapidly increasing ubiquity of laptop computers, which are primarily used by mobile users to access Internet services such as e-mail and the World

Wide Web (WWW), support of Internet services in a mobile environment has become a growing necessity. Mobile Internet providers (IPs) attempt to solve the key problem of developing a mechanism that allows Internet protocol (IP) nodes to change physical locations without changing IP addresses, thereby offering Internet users the so-called "nomadicity." Furthermore, advances in wireless networking technologies and portable information devices have led to a new paradigm of computing called *mobile computing*. According to this concept, users who carry portable devices have access to information services through a shared infrastructure regardless of their physical location or movements. Such a new environment introduces new technical challenges in the area of information access. Traditional techniques to access information are based on the assumptions that the host locations' distributed systems do not change during computation. In a mobile environment, these assumptions are rarely valid or appropriate.

Mobile computing is distinguished from classical, fixed-connection computing due to the following elements: (a) the mobility of nomadic users and the devices they use, and (b) the mobile resource constraints such as limited wireless bandwidth and limited battery life. The mobility of nomadic users implies that the users might connect from different access points through wireless links and might want to stay connected while on the move, despite possible intermittent disconnections. Wireless links are relatively unreliable and currently are two to three times slower than wired networks. Moreover, mobile hosts powered by batteries suffer from limited battery life constraints. These limitations and constraints provide many challenges to address before we consider mobile computing to be fully operational. This remains true despite the recent progress in wireless data communication networks and handheld device technologies.

In next-generation systems supporting mobile environments, mainly due to the huge number of mobile users in conjunction with the small cell size, the influence of mobility on the network performance is strengthened. More particularly, the accuracy of mobility models becomes essential to evaluate system design alternatives and network implementation costs. The device location is unknown a priori and call routing in general implies mobility management procedures. The problems which arise from subscriber mobility are solved in such a way that both a certain degree of mobility and a sufficient quality of the aspired services are achieved.

This chapter analyzes the problem of managing users' mobility in the context of mobile computing and networking environments. Mobility management implies two major components: *handover management* and *location management*.

Handover management is the way a network functions to keep mobile users connected as they move and change access points within the network. Generally, there are two types of handover: intracell handover and intercell handover. Intracell handover occurs when a user experiences degradation of signal strength within a cell. This leads to a choice of new channels with better signal strength at the same *base transceiver station* (BTS), also called *base station* (BS). Intercell handover occurs when a user moves from a cell to another. In this case, the user's connection information is transferred from the former BTS to the latter one. The following procedure occurs for both intracell and intercell handovers. First, the user initiates a handover procedure. Then, the network or the mobile unit (depending on the unit that controls the handover operation) provides necessary information and performs routing operations for the handover. Finally, all subsequent calls to the user are transferred from the former connection to the latter one.

Location management is the process used by a network to find the current attachment point of a mobile user for call delivery (Akyildiz & Wang, 2002). The first step of the procedure is the *location registration*. In this phase, the mobile

user periodically notifies the network of its new access point. The notifications allow the network to authenticate users and update their location profiles. The second step is the *call delivery*. When a call destined to a user reaches the network, a search for the user's profile is usually conducted in a local database. Then, the call is forwarded to the user according to his profile.

This chapter aims to analyze different mobility management schemes and protocols in order to state their applicability to handle some key issues related to emerging mobile environments. The main concerns include the search for efficient and cost-effective location management schemes allowing to provide services and applications to users with an acceptable quality of service. The next section summarizes background and related work. Then we propose some new location management schemes, evaluate the performance of these schemes, and present some numerical examples. Finally, the chapter concludes and outlines future research directions.

BACKGROUND AND RELATED WORK

Mobility is the primary advantage offered by *personal communication systems* (PCS). Location management is one of the most important issues of mobility management. Location management techniques essentially consist of partitioning the coverage area into many *location areas* (LAs) which are sets of cells. *Mobile Units* (MUs) within a cell communicate with a cell BS through wireless links. BSs, in turn, are connected to the wireline network through a *mobile switching center* (MSC) which serves a single LA. Each MSC is identified by a unique address. This address is stored in the memory of the MUs that are roaming in the MSC's LA and is broadcasted by the cell BSs within that particular LA. The MU compares the broadcasted address with the address stored in its memory. When these two addresses differ, the MU recognizes that it has moved to a new LA and sends a registration message to the MSC of the new LA. Then, the MSC forwards this message to the network database. In PCS, the wireline network uses the *Signaling System Number 7* (SS7) to carry user information and signaling messages between the MSCs and the location databases.

Main Standards and Basic Procedures

Two major standards are used for location management, namely IS-41 (Gallagher & Randall, 1997; TIA/EIA, 1996) and Global System for Mobile Communications [GSM] (Mouly & Paulet, 1992). This chapter only considers the IS-41 standard, which uses a two-level database architecture consisting of an HLR and some *visitor location registers* (VLRs). Each network comprises a single HLR and many VLRs. The HLR is a centralized database containing the profiles of its assigned subscribers. Most of the current PCS manufacturers implement a combined MSC and VLR with one VLR per MSC. A VLR stores the profiles of the MUs that are currently residing in its associated LA. Figure 1 illustrates the PCS architecture and signaling network.

Two main procedures are used in the IS-41 location management scheme: *location update* and *location search*. A location update occurs when an MU moves to a new LA; a location search occurs when a fixed or mobile host wants to communicate with an MU whose current LA is unknown. In IS-41, the HLR is queried for every location search or update, resulting in tremendous strain on the use of the network resources as the number of PCS subscribers increases.

We describe the location update and location search procedures as specified in revision C of the IS-41 standard (TIA/EIA, 1996), along with some additional models that were proposed to augment it (Cayirci & Akyildiz, 2002; Lin, Lee, & Chlamtac, 2002). Figure 2 illustrates the

Figure 1. PCS architecture and signaling network

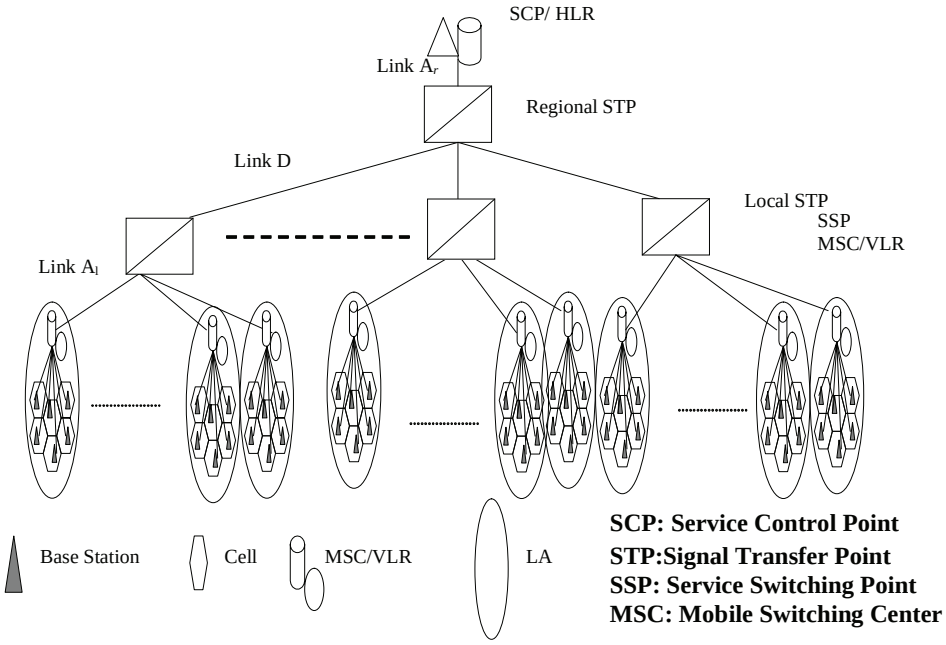

Figure 2. Location update procedure according to the IS-41 scheme

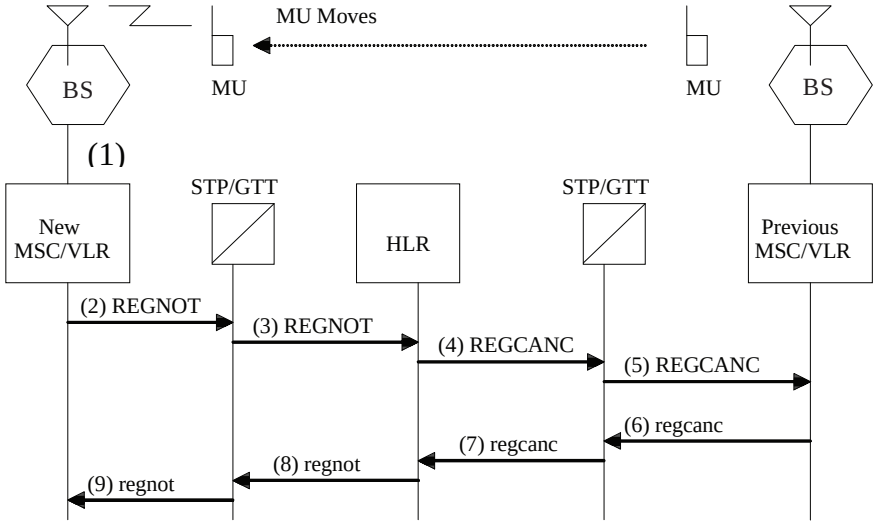
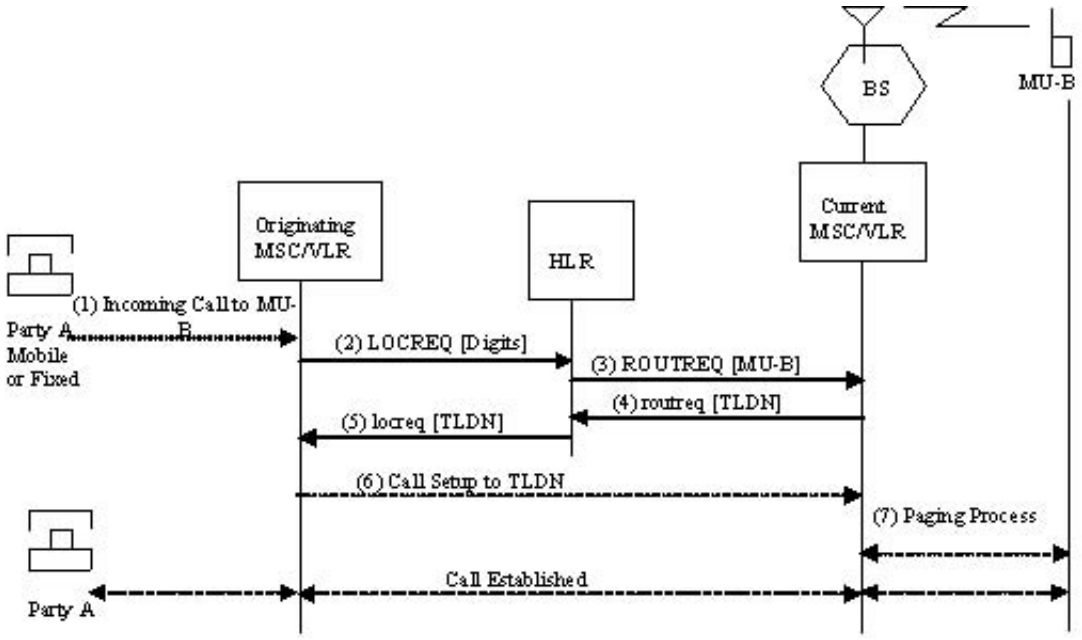


location update procedure of the IS-41 standard which can be described as follows. When an MU enters a new LA, it registers at its MSC or VLR. Then, the new MSC/VLR sends a *registration notification* message (REGNOT) to the network database HLR through an Single Transfer Point (STP) node. The STP node executes the global title translation (GTT) procedure using the MU's identification number in order to determine the HLR of the MU. Upon receiving the registration message, the HLR sends a *registration cancellation* message (REGCANC) to the MU's previous MSC/VLR. The previous MSC deletes the MU's profile in its associated VLR and sends a *cancellation acknowledgment* message (regcanc) to the HLR. The HLR acknowledges the location update by sending a regnot message that includes the MU's profile to the new MSC/VLR. When the new MSC/VLR receives the regnot message, it starts providing service to the MU.

The IS-41 location search procedure is presented in Figure 3. In this figure, a call is initiated to the mobile unit B (MU-B) through an originating MSC/VLR which sends a *location request* (*LOCREQ*) message to the HLR of the called MU through an STP node using the GTT technique. Upon receiving the request, the HLR sends a *routing request* (ROUTREQ) message to the MU-B's current MSC/VLR, which then allocates a temporary location directory number (TLDN) for the call and returns it to the HLR in a routreq message. The HLR relays the TLDN to the originating MSC/VLR in a locreq message which routes the call to the TLDN. Finally, the current VLR/MSC launches a paging process to find the MU-B's current cell. At this point, the communication has been established.

In these two procedures, the network database HLR is queried every time the MU moves to a new LA or receives a call. Several strategies have

Figure 3. Location search procedure according to the IS-41 scheme



been proposed to reduce the location update load and location search costs (Escalle, Giner, & Oltra, 2002; Mao, 2002; Suh, Choi, & Kim, 2000).

Advanced Mobility Management Schemes

A new signaling protocol was proposed by Wang & Akyildiz (2001) for intersystem roaming in next-generation wireless networks. According to this protocol, LAs that are on the boundary of two adjacent systems (*X* and *Y*) are called *peripheral location areas* (PLAs). Therefore, they are PLAs in systems *X* and *Y*. The intersystem location registration is controlled by a *boundary interworking unit* (BIU), which ensures the compatibility between the two systems and maintains a database of the roaming information of the mobile terminals (MTs) moving between the two networks. The underlying principle of this protocol is that the MT can request a location registration of intersystem roaming when it is in a PLA. As a result, it may finish signaling transformation and authentication before it arrives at the new system. Using this protocol, the HLR is not involved unless the MT goes from a PLA to a non-PLA. Moreover, Boundary Location Register (BLR) provides MTs with up-to-date location information; the incoming calls of the intersystem-roaming MTs are delivered to the serving MSC/VLR directly, rather than delivering it to the previous system. The numerical results show that the BLR protocol can reduce signaling costs, the latency of location registration, and call delivery, as well as call-loss rates for the MTs moving across different networks.

The models generally used to determine the optimal distance threshold are often based on certain simplified assumptions that do not give an accurate representation of a realistic cellular network (structured topology and configuration, geometric or exponential cell residence time distribution, symmetric random walk as a movement model, etc.). Wong and Leung (2001) overcome these drawbacks by focusing on the determination of the optimal update boundary for the distance-based location update algorithm, in a realistic environment, in order to minimize the expected total cost between call arrivals. The proposed model is applicable to arbitrary cell topologies; the call residence time can follow a general distribution and the movement history is taken into account. An implementation is described using an arbitrary cell topology. The location update is decided upon a simple table lookup.

Numerical results show that the proposed model gives a more accurate update boundary (distance threshold) in real wireless cellular environments compared with those derived from a hexagonal cell configuration with random-walk movement pattern. This is due to the fact that the network can maintain a better balance between the processing due to location update and the ratio bandwidth used for paging between call arrivals. The main drawback is the use of a Poisson distribution for the call arrival rate, although this may not be the case in real mobile environments.

The user mobility pattern (UMP) proposed by Cayirci and Akyildiz (2002) for location updates and paging where MTs keep track of their UMPs in a data structure called *user mobility pattern history* (UMPH). The UMP is a list of cells expected to be visited by the MT, and the UMPH records the mobility history of an MT. The model proposed by these authors differs from the other user profiles or history-data-based location update techniques in two main aspects. The first aspect is that according to this model, MTs are responsible to predict and register the UMPs, reducing the signaling traffic (for maintaining UMPH) and increasing the resolution of the data in UMPH. The second aspect is that an effective selective paging can be executed, based on call delivery times, by using the UMP nodes (pairs of cell identification and expected call entry time).

The performance of the UMP scheme is compared with the time-based and movement-based location update techniques, the blanket,

the selective, and the velocity paging techniques. The UMP technique creates less location update traffic than the other techniques when reasonable time intervals and movement thresholds are used. It consistently outperforms other paging performance techniques.

Cayirci and Akyildiz (2003) proposed the *traffic-based static LAD* (TB-LAD) scheme where the mobile traffic between the cells is predicted according to the characteristics of the crossing loads. Then, by using these traffic expectations, the traffic-based cell-grouping technique groups cells into LAs such that the neighbor cell with higher intercell traffic is assigned to the same LAs. Since the number of cells in an LA is a fixed parameter in TB-LAD, paging traffic is undisrupted. However, a better design of an LA reduces the number of location updates. Therefore, the TB-LAD decreases the number of location updates without increasing the number of paged cells during a call delivery.

To investigate this concept, traffic data was collected in a metropolitan area. Then, the relation of inter-LA traffic with the cell size and the number of cells in an LA was analyzed, and the performance was compared with the one of a *proximity-based LAD* (PB-LAD). Experimental results show that the TB-LAD reduces inter-LA traffic from 27% to 36% on the average over PB-LAD. TB-LAD outperforms PB-LAD when the average cell size exceeds 2,000 m and the average number of cells within an LA is superior to nine. In the metropolitan city where the experiments were conducted, the optimal solution was obtained with an LA size larger than 13 cells and a cell size larger than 2,500 m.

A trade-off cost analysis was made for the movement-based location update and paging in wireless mobile networks without using simplifying assumptions. A general framework was proposed by Fang (2003) for the study of such problems, and analytical results were derived to obtain the crucial quantity and the average number of location updates during an interservice time (used in all cost analyses under general assumptions). The analytical approach and results developed in his paper can be very useful to design an optimal mobility management scheme for future wireless mobile networks. In fact, the study shows that the total cost of the location update and paging is a convex function of the movement threshold.

Location Management with Mobile IP

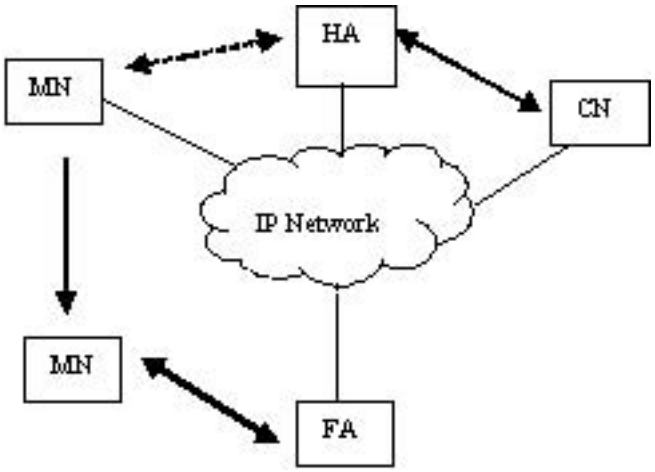
Mobility support in the IP protocol was developed by the Internet Engineering Task Force (IETF), leading to the Mobile IP protocol and all-IP networks (Chiussi, Khotimsky, & Krishnan, 2002). Currently, two versions of Mobile IP are available, Versions 4 (IPv4) and 6 (IPv6). An MN is a mobile node able to move from one subnet to another without requiring a change of IP address. The MN accesses the Internet via a home agent (HA) or a foreign agent (FA). The correspondent node (CN) is a node that connects with the MN. The HA is a local router on the MN's home network, and the FA is a router on the visited network. Figure 4 illustrates a Mobile IP network architecture.

The following operations are introduced by the Mobile IP protocol:

1. *Discovery*: How an MN finds an agent (HA or FA).
2. *Registration*: How an MN registers with its HA.
3. *Routing and Tunneling*: How an MN receives datagrams when visiting a foreign network.

Location management operations include agent discovery, movement detection, forming care-of-address (CoA), and location (binding) update. Handover operations include routing and tunneling.

Figure 4. Mobile IP network architecture



Discovery

To detect movement from one subnet to another, the MN uses two methods: advertisement lifetime and network prefix.

Advertisement Lifetime: The first detection method is based upon the lifetime field of the Internet Control Message Protocol (ICMP) router advertisement message. An MN records the lifetime indicated in any agent advertisement until that lifetime expires. If the MN has not maintained contact with its FA when the lifetime elapses, it must solicit a new agent.

Network Prefix: The second method uses the network prefix-detection movement. In some cases, an MN can determine whether or not a newly received agent advertisement was received on the same subnet by using its CoA. If the prefixes differ, the MN can assume that it has moved. This method is not available if the MN is currently using an FA's CoA. Once it has discovered a new FA and obtained a new CoA, the MN performs the location update procedure as follows:

1. The MN registers a new CoA with its HA by sending a binding update.
2. The MN notifies its CN of its current binding information.
3. If the binding update has an expiration date, the CN and the HA send a binding request to the MN to obtain the MN's current binding information.

Registration

When visiting any network away from home, each MN must have an HA. The MN registers with its HA in order to track the MN's current IP address. Two IP addresses are associated to each MN: one for location and one for identification purposes. The new IP address associated to an MN while it visits a foreign link is called its CoA. The association between the current CoA and the MN's home address is maintained by a mobility binding, so that packets destined to the MN may be routed using the current CoA, regardless of the MN's current point of attachment to the Internet.

Each binding has a predetermined lifetime period, which is negotiated during the MN's registration, after which time the registration is deleted. The MN must reregister within this period in order to continue servicing this CoA. Depending on its method of attachment, the MN sends location registration messages (when moving between two subnets or once the lifetime elapses) directly to its HA, or through an FA which forwards the registration to the HA. In either case, the MN exchanges registration request and registration reply messages based on IPv4 as follows.

1. The MN registers with its HA using a registration request message (the request may be relayed to the HA by the current FA).
2. The HA creates or modifies a mobility binding for that MN with a new lifetime.
3. The appropriate agent (HA or FA) returns a registration reply message containing necessary information on the request status, including the lifetime granted by the HA.

Routing and Tunneling

The process of routing datagrams for an MN through its HA often results in the utilization of paths that are significantly longer than optimal. Route-optimization techniques for Mobile IP employ the use of tunnels to minimize inefficient path use. For example, when the HA tunnels a datagram to the CoA, the MN's home address is effectively shielded from intervening routers between its home network and its current location. Once the datagram reaches the agent, the original datagram is recovered and delivered to the MN. Currently, there are two protocols for routing optimization and tunnel establishment: route optimization in Mobile IP and the tunnel establishment protocol.

Route Optimization in Mobile IP: The route optimization aims to define extensions to basic Mobile IP protocols that allow better routing so that datagrams can travel from a CN to an MN without first going to the HA. These extensions provide a means for nodes to cache the binding of an MN, and then tunnel datagrams directly to the CoA indicated in that binding, bypassing the MN's HA.

Tunnel Establishment Protocol: In this protocol, Mobile IP is modified in order to perform among arbitrary nodes. Upon establishing a tunnel, the encapsulating agent (HA) transmits protocol data units (PDUs) to the tunnel endpoint (FA) according to a set of parameters. The process of creating or updating tunnel parameters is called tunnel establishment. Generally, the establishment of parameters includes a network address for the MN. In order to use tunnel establishment to transmit PDUs, the HA must determine the appropriate tunnel endpoint for the MN. This is done by consulting a table that is indexed by the MN's IP address. After receiving the packets, the FA "decapsulates" the PDUs and sends them to the MN.

Mobile IP provides simple scalable mobility solutions. However, it causes excessive signaling traffic and long delays. Xie and Akyildiz (2002) introduced a distributed and dynamic, regional location management mechanism for Mobile IP to distribute traffic and dynamically adjust the regional network boundaries more efficiently. (A distributed gateway foreign agent (GFA) system architecture is proposed where each FA can function as either an FA or a GFA). This distributed system may allocate signaling load more uniformly. An active scheme is adopted by the distributed system to dynamically optimize the regional network size of each MN according to its current traffic load and mobility.

The distributed and dynamic scheme proposed by Xie and Akyildiz (2002) can perform optimally for all users from time to time, and the system robustness is enhanced. Since the movement of MNs does not follow a Markov process, a novel, discrete, analytical model for cost analysis, and also a new iterative algorithm to find out the optimal number of FAs in a regional network,

which consumes terminal network resources, was proposed. The proposed model is not plagued by constraints on the shape and the geographic location of Internet subnets.

Analytical results demonstrate that the signaling bandwidth is significantly reduced through the proposed distributed system architecture compared with the IETF Mobile IP regional registration scheme. It also demonstrates that the dynamic scheme has significant advantages under time-variant user parameters in cases where it is difficult to predetermine the optimal regional network size. The location management scheme requires that all FAs be capable of functioning as both FAs and GFAs. This increases the processing capability requirements of each mobile agent. There is additional processing load on the MTs, such as the estimation of the average packet arrival rate and subnet residence time.

Lee and Akyildiz (2003) proposed a cost-efficient scheme for route optimization to reduce the signaling costs caused by route optimization. Link-cost functions represent the network resources used by the routing path; signaling costs reflect the signaling and processing load incurred by route optimization. A Markovian decision model was used in order to find an optimal sequence for route optimization. In order to simplify the decision process, the model was restricted to intradomain handoff, which resulted in a decision rule. The optimal sequence is obtained by following the decision rule at each decision stage (minimizing the total cost). The performance of the optimal sequence is compared with the other sequences' action with route optimization (ARO) and action without route optimization (NRO). Simulation results show that the optimal sequence provides the lowest costs among the given sequences.

The recent advent of voice-over IP (VoIP) services and their fast growth is likely to play a key role in successful deployment of IP-based convergence of mobile and wireless networks. Kwon, Gerla, and Das (2002) have focused on mobility management issues regarding VoIP services in wireless access technologies. Different mobility management schemes are explored with a focus on Mobile IP and Session Initiation Protocol (SIP; Lin & Chen, 2003; Wu, Lin, & Lan, 2002); these two approaches are compared. The shadow registration concept is also presented; it aims at reducing distribution time in interdomain handoff for VoIP sessions in mobile environments. Considering the functionality of authentication, authorization, and accounting (AAA), the signaling message flow is illustrated for the two approaches in the presence and absence of shadow registration. Finally, an analytic comparison between the two approaches (Mobile IP and SIP) in terms of delay at initial registration and distribution in intradomain- and interdomain-handoff delay is presented.

Based on the previous analyses, numerical results show that the disruption for the Mobile IP handoff approach is smaller than the SIP approach in most situations. However, SIP shows shorter disruptions when the MN and the CN are nearby. Even though the smooth handoff is not taken into consideration in the disruption analyses, it is argued that it will play an important role in reducing disruption in interdomain handoff in the Mobile IP approach.

Misra, Das, Dutta, McAuley, and Das (2002) presented two enhancements to the Intradomain Mobility Management Protocol (IDMP) for IP-based hierarchical mobility management so that it can be used in a 4th Generation (4G) cellular environment. Thus, it would be highly relevant to develop IP-layer-fast handoff and paging solutions that would work across heterogeneous access technologies.

To minimize packet loss during intradomain handoffs, a time-bound localized multicasting approach is presented. By proactively informing its associated mobility agent (MA) of an imminent change, an MN enables the MA to multicast packets for a limited time span to a set of neighboring subnets. Subnet agents (SAs) buffer such multicast

packets for a short while. Then, if the MN enters its subnet, the SA is able to immediately forward these packets to the mobile, thus eliminating packet-loss delays.

Next-generation mobile and wireless networks are already under preliminary deployment and they are likely to use the current existing infrastructure for economic reasons. Global roaming in current and next-generation networks is a major issue for the integration and the interoperability of different systems. Zahariadis, Vaxevanakis, Tsantilas, Zervos, and Nikolaou (2002) proposed a hierarchical cell architecture consisting of an infrastructure that is either installed or under development. Soft horizontal-mobility management mechanisms and vertical handover (for Wireless Local Area Networks [WLAN], 2nd Generation [2G], and satellite networks) are discussed. An enhanced roaming scenario for next-generation networks is initiated by the MT and supported by an all-mobile IP network.

Mao (2002) presented an *intralocation-area location update* (intra-LA-LU) strategy in order to reduce paging traffic in mobile networks while keeping the standard location area update unchanged within the LA. The intra-LA-LU is performed whenever the MT changes its location between the anchor cell (the MT residing cell) and the rest of the cell in the LA. For call delivery, either the anchor cell or the other cells of the LA are paged to locate the MT. The proposed analytical model considers a continuous-time Markov chain to describe the MT movement.

Compared to the conventional location-tracking scheme, one can think that the proposed strategy will add an extra cost by performing the inter-LALUs. However, numerical results indicate that the savings of paging costs is much more significant than the newly added location update costs. The proposed strategy is suitable for users roaming in the LAs associated with their homes or workplaces. If the location of a mobile subscriber is uniformly distributed within an LA, the proposed strategy should not be used in order to avoid the intra-LA-LU, which is not suitable in this case.

Personal number (PN) or follow-me service allows users to access telecommunication services from any terminal in any location within the service area. In the existing systems, users have to manually register a phone number every time they enter a new area, which is an unsuitable solution.

Lin et al. (2002) proposed an enterprise approach for *automatic follow-me service* (AFS). The significance of the proposed approach is that AFS can be integrated with existing follow-me databases to automate PN services offered by different Public Switched Telephone Network (PSTN) service providers. AFS automatically connects calls to a user at any location with appropriate communications terminals. The authors showed how to implement AFS with the VoIP and Bluetooth technologies. More specifically, the AFS utilizes VoIP to communicate with the follow-me database in the public network, and Bluetooth is used to implement radio-tracking mechanisms. Then, the impact of polling frequency on power consumption and call misrouting was presented. The analysis provided shows that, based on the AFS cost functions, the optimal polling frequency can be found efficiently. One of the future extensions consists of developing automatic polling-frequency-adjustment heuristics based on the proposed analytic model.

NEW MOBILITY MANAGEMENT MODELS AND SCHEMES

This section introduces three new mobility management models: the *built-in memory model* (Safa, Pierre, & Conan, 2002), the *global location management scheme* (Safa et al.) and the Mobile IP network architecture (Diha & Pierre, 2003). Two of these models are based on the IS-41

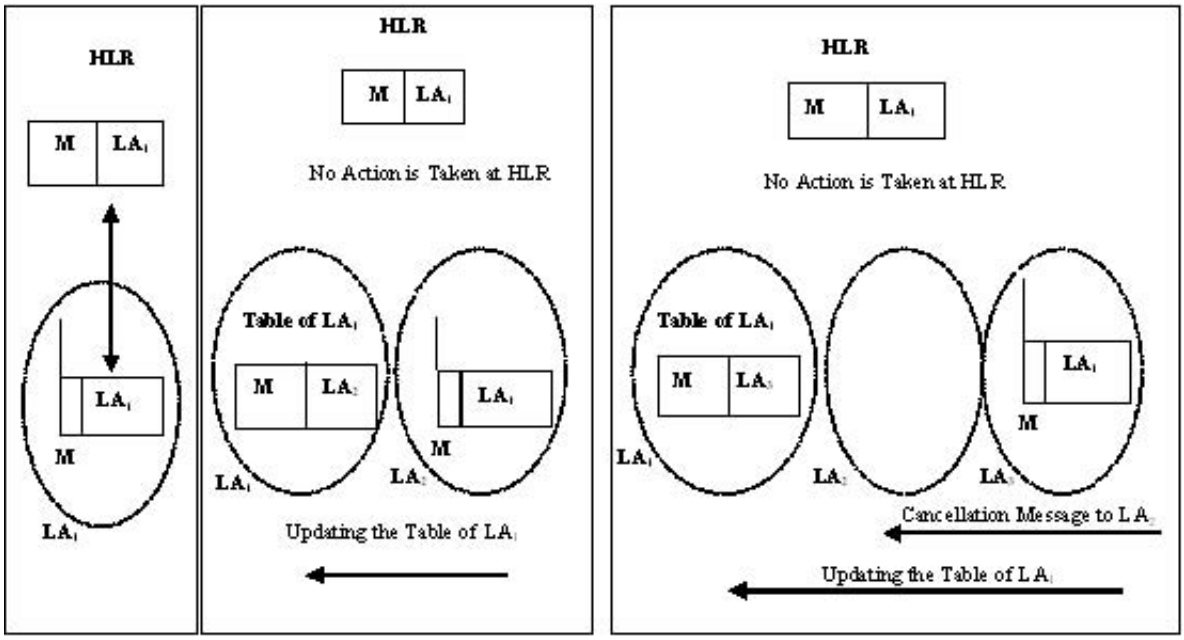
standard and aim to improve upon this standard to some extent.

Built-In Memory Model

The built-in memory model is based on the IS-41 standard with additional small, built-in MU memory and a pointer table for each LA. In this model, we define an MU's anchor LA as the LA for which the MU's data location was updated at the network database HLR. The MU built-in memory stores the address of its anchor LA, that is, the MU built-in memory data and the MU location data at the HLR are the same. The pointer table comprises two columns: the MU identification number (MIN) and the MU's current LA. The LA pointer table stores the current LA addresses of the MUs which consider this particular LA as their anchor LA. When the MU moves to a new LA, the new LA queries the MU's anchor LA to update the pointer table, that is, to create a pointer between the MU's anchor LA and the new LA. Consequently, no location update operation is performed at the HLR level. When the MU is called, its HLR is queried to determine its anchor LA. If it no longer resides in that LA, the call is forwarded to the MU's current LA by passing over a single pointer.

Figure 5 illustrates the built-in memory model. We assume that an MU joins the network in the location area LA_1 and registers at the MSC/VLR of this LA. Then, the MSC/VLR of the LA_1 location area queries the HLR to update the MU's location data (Figure 5a). Once the HLR is updated, the MU also updates its built-in memory. In other words, the location area LA_1 becomes the MU's anchor LA. Figure 5b shows how the MU moves to a new location area LA_2. Then,

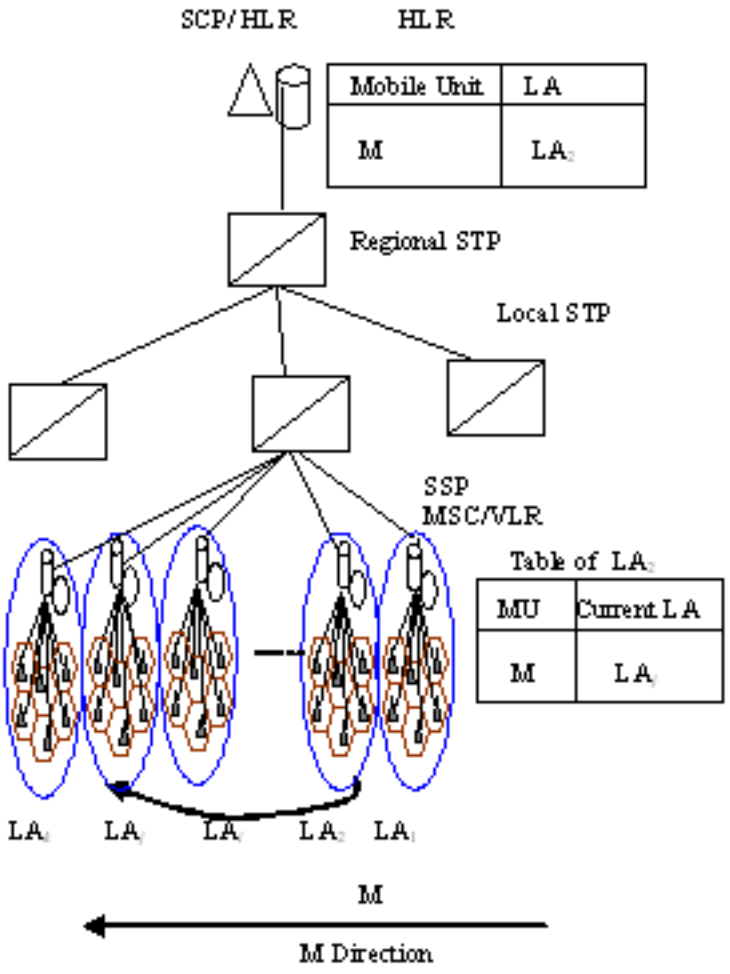
Figure 5. Illustration of the built-in memory model



(a) *(b)* *(c)*

instead of accessing the HLR, the MSC/VLR of the new location area LA_2 sends a query to the MU's anchor LA (LA_1) in order to establish a pointer between the MU's anchor LA (LA_1) and the current LA (LA_2). A pointer is established by updating any existing MU's location information in the pointer table of the MU's anchor LA, or adding this information to the table if there is none. If the MU leaves or returns to its anchor LA, the MSC/VLR of the MU's new LA sends a message to the MU's previous LA. However, when the MU's movement does not involve its anchor LA, the MSC/VLR of the MU's new LA sends two messages: a cancellation message to the MU's previous LA and a pointer updating message to the MU's anchor LA. This scenario is shown in Figure 5c. After the MU moves to the location area LA_3, the MSC/VLR of this LA sends a cancellation message to the MSC/VLR of the location area LA_2 and an updating message to

Figure 6. Example of the updating procedure



the MU's anchor LA (LA_1) in order to establish a pointer from LA_1 to LA_3.

The location update procedure in the memory built in model is shown in Figure 6. It is assumed that an MU joins the network in the location area LA_i, registers at the MSC/VLR of LA_i, and updates its location data in the HLR and its built-in memory, thus location area LA_i is the anchor LA of the MU.

A New Global Location Management Scheme

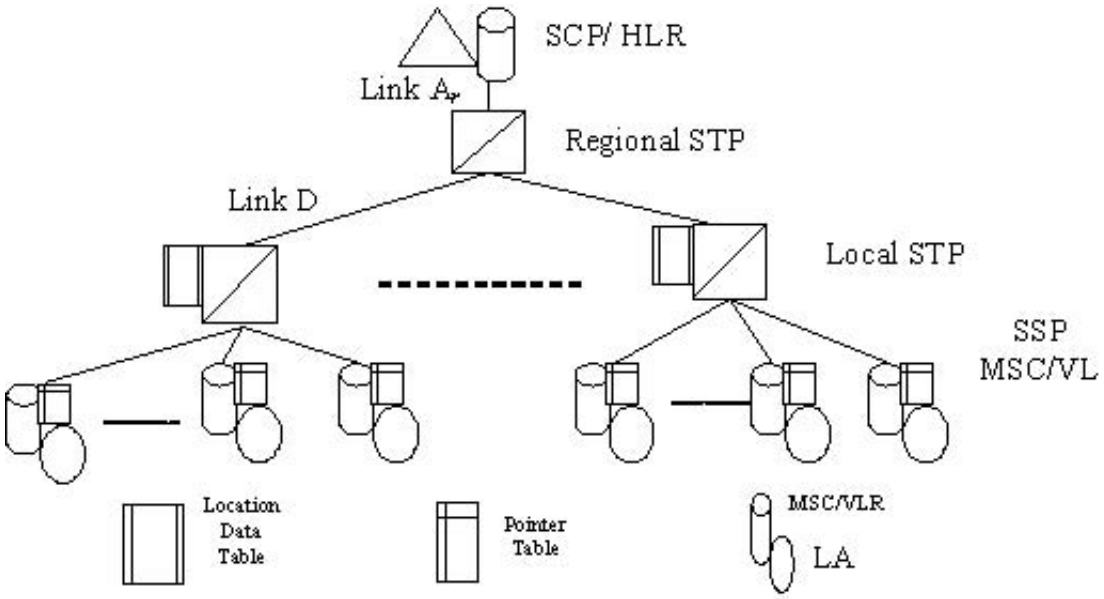
A second approach, called the global location management scheme, adds two tables to the conventional signaling network architecture (Figure 1), which are respectively identified as *location data* and *pointer tables.* A location data table is stored on an Local Signal Transfer Point (LSTP) node to serve all LAs connected to this LSTP. It contains the location information of some selected MUs, generally the ones which are frequently called from these LAs. This can significantly reduce the call-delivery procedure costs when the called MU has a profile in the location data table. Moreover, if this is not the case, there are no extra costs. In general, the use of a location data table serving many areas presents the following advantages:

- reduces network traffic by minimizing the number of updating queries sent to the data tables or to the HLR,
- saves table-installation costs,
- reduces data-storing redundancies and memory space wastes, and
- increases the frequency of locating an MU without accessing the network database. (For example, consider the case where an MU is often called from location area LA_1 but rarely from a neighboring location area LA_2. Since the same location data table may serve the two LAs, the called MU will be found locally even though it is called from LA_2.)

A pointer table is added to each LA. In order to explain the usefulness of the pointer table, we introduce the concept of the "anchor location area" of an MU as the LA in which the MU's location information is updated at the HLR. A pointer table of an anchor LA contains a pointer to the current LA of all the MUs having this LA as anchor LA. At this point, we must distinguish between two kinds of MU movements: an intra-STP move such that the new and the old LAs are connected to the same LSTP, and an inter-STP move such that the new and the old LAs belong to two different LSTPs.

We assume that each MU has a built-in memory that stores the address of its anchor LA and the addresses of the STP nodes which store the MU location information in their location data tables. This built-in memory is updated in either of two cases: The MU location information in the network database HLR is updated or the MU location information is added to a location data table. When the MU's movement is intra-LSTP, the pointer table of its anchor LA is queried to update the pointer to create a pointer between the anchor LA and the new LA. Hence, no location update operation is performed at the HLR. When the MU's movement is inter-LSTP, its new LA becomes its anchor LA and all information about the MU is then deleted from the previous anchor LA. The detailed location update and location search procedures of the proposed scheme will be presented further. They operate according to the signaling network architecture shown in Figure 7. It is implicitly assumed that when an MU's location information is added to a location data table, the MU is informed of this fact when it is called from any LA served by that location data table. Consequently, this operation does not require any additional costs.

Figure 7. Architecture of the signaling network used in the global location management scheme



When an MU moves to a new LA, a location update procedure is performed as illustrated in Figures 8 and 9, respectively, for intra-LSTP and inter-LSTP movements. For intra-LSTP movements, its anchor LA is updated instead of the HLR according to the following steps.

1. The MU moves to a new LA and sends a location update message to the MSC/VLR of this new LA.
2. The MSC of the new LA registers the MU with its associated VLR and sends a cancellation message to the previous LA.
3. The new LA queries also the MU's anchor LA in order to create a pointer from the anchor LA to the new LA. In other words, no location update operation is performed at the HLR. The anchor LA is the LA which stored the MU's address in the built-in memory of the MU and in the HLR.
4. and 5. The new LA receives an acknowledgement from both the previous and the anchor LAs.

When the MU's movement is inter-LSTP, the location update procedure shown in Figure 9 is performed. The steps of this procedure are described as follows.

1. The MU moves to a new LA and sends a location update message to the MSC/VLR of this new LA.
2. The MSC of the new LA registers the MU in its associated VLR and sends a registration notification message to the HLR via the STP.

Figure 8. Updating procedure for an intra-LSTP move

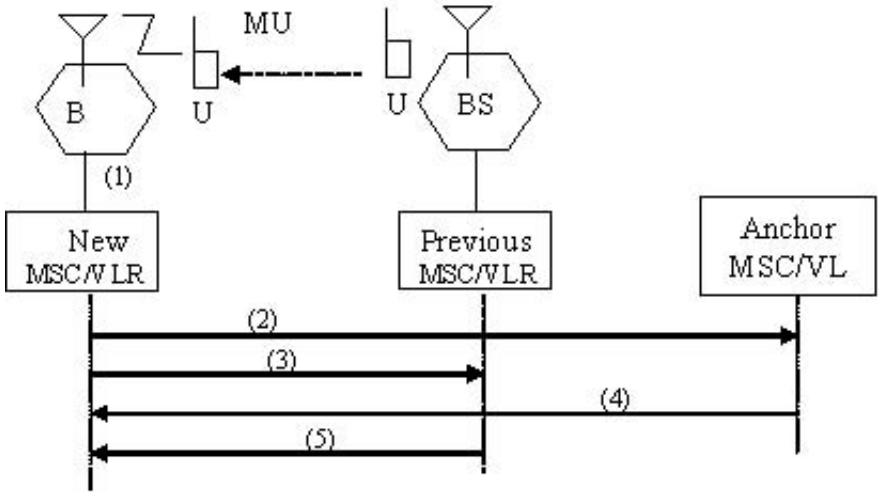


Figure 9. Updating procedure for an inter-LSTP move

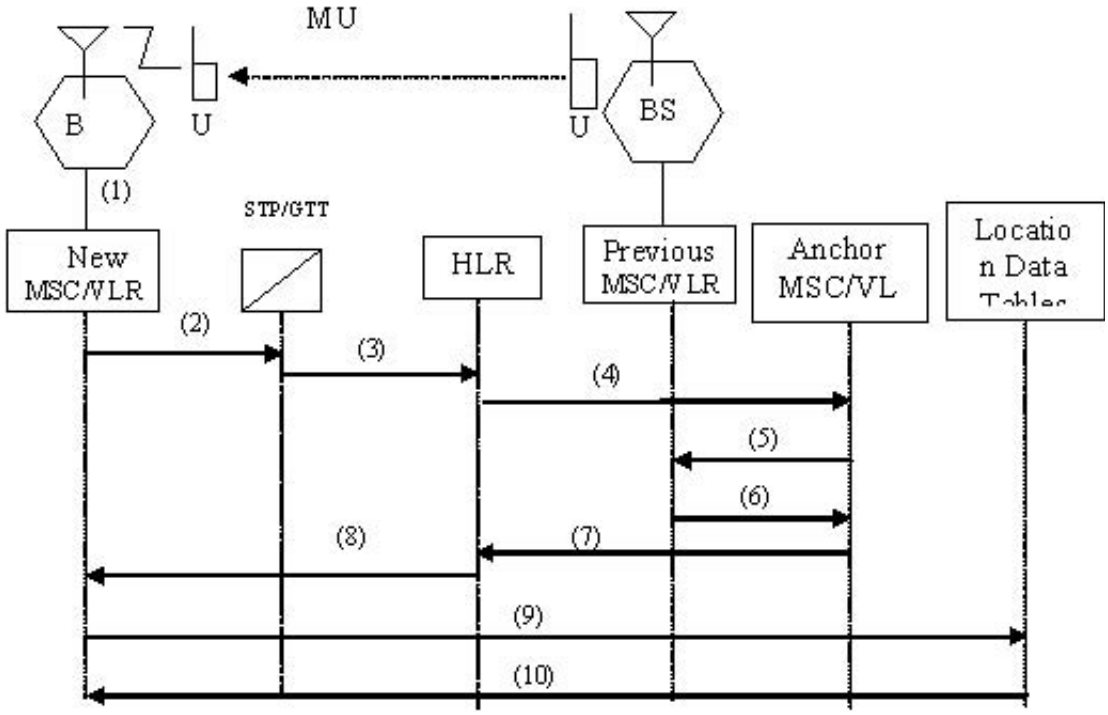

3. The STP uses the MU's identification number and executes the GTT procedure to determine the MU's HLR. The registration message is then forwarded to the HLR.
4. The HLR sends a registration cancellation message to the MU's anchor LA.
5. The MU's anchor LA sends a cancellation message to the previous (old) MSC/VLR.
6. The old MSC deletes the MU's profile in its associated VLR and sends a cancellation acknowledgment message to the MU's anchor LA.
7. The anchor LA sends an acknowledgment to the HLR and deletes the MU's profile in its pointer table.
8. The HLR sends a registration confirmation message to the new MSC/VLR and provides the profile of the MU in this message. The new MSC/VLR becomes the MU's anchor LA.
9. The new MSC/VLR sends an update message to location data tables whenever necessary. (The MU provides the MSC/VLR with the addresses of those location data tables as stored in its built-in memory.)
10. After updating the MU data, the data location table sends an acknowledgement message to the new LA.

The location search procedure involves determining the current serving LA of a called MU. Figures 10, 11, 12, and 13 show four distinct, possible scenarios which must be followed by this procedure according to the proposed location management scheme.

Scenario 1: The first scenario, shown in Figure 10, addresses the case where the called MU has a record in the location data table and it is roaming in its anchor LA (i.e., the LA address stored in the location data table). The steps of Figure 10 are described as follows.

1. A call is initiated to an MU, forwarded to the MSC of the calling unit.

Figure 10. Searching procedure (Scenario 1)

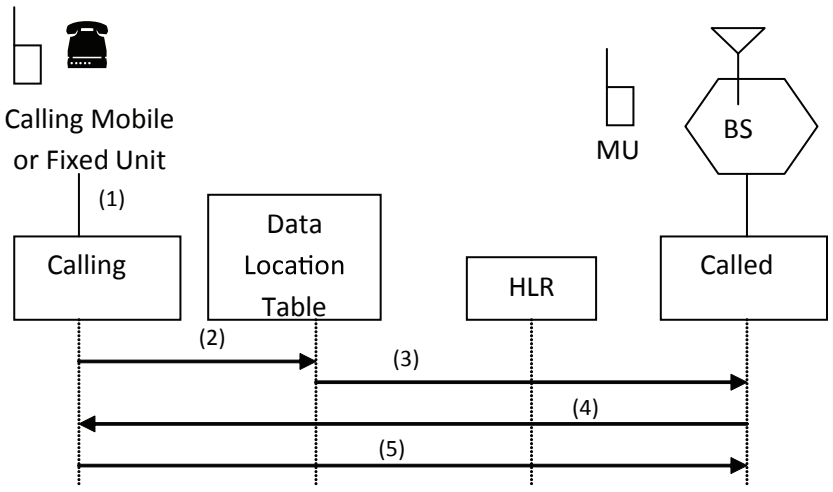

Figure 11. Location search procedure (Scenario 2)

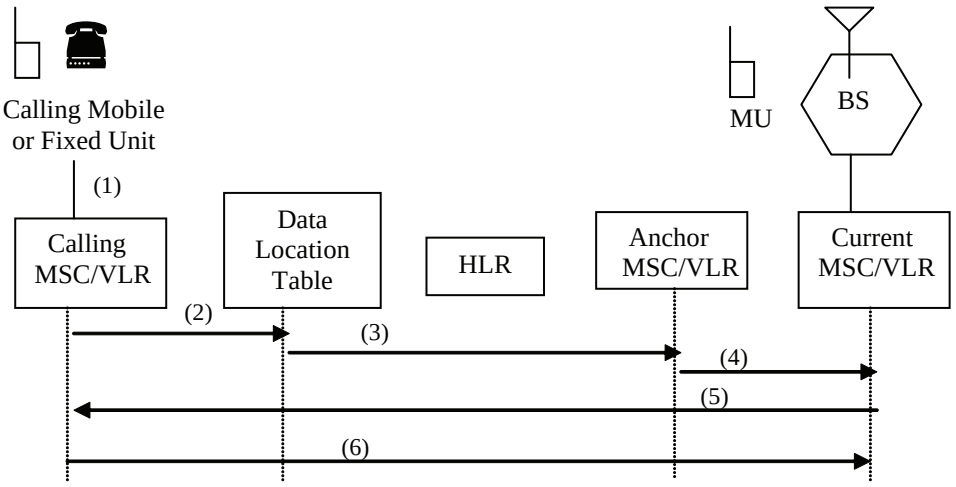

Figure 12. Location search procedure (Scenario 3)

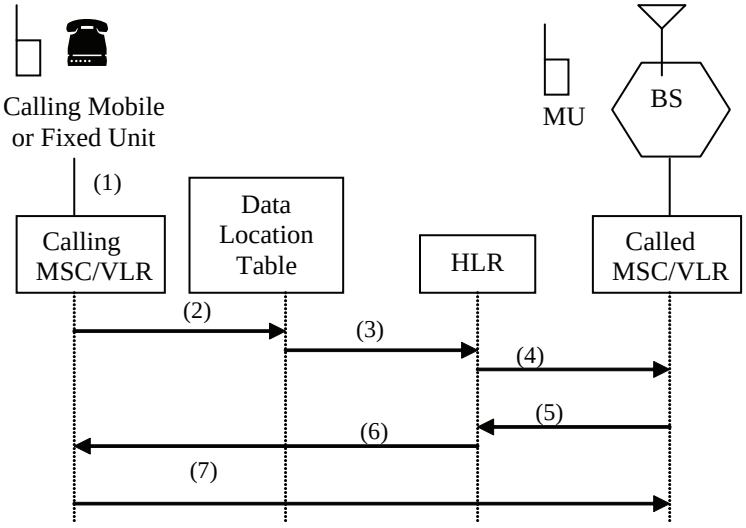
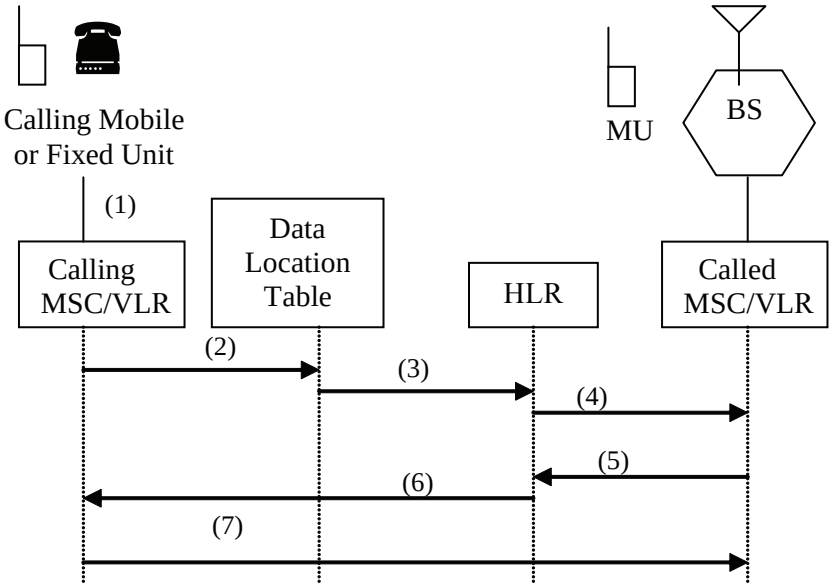


2. The MSC sends a location request to its associated location data table which determines the anchor LA of the called MU.
3. The request is then forwarded to the anchor LA of the called MU.

Figure 13. Location search procedure (Scenario 4)



4. The called MU's MSC assigns a TLDN to the call and sends it to the calling MSC.
5. The calling MSC sets up a connection to the called MSC using this TLDN.

Scenario 2: The second scenario, shown in Figure 11, is similar to the first one. However, we assume that the called MU has a record in the location data table of the calling MU, but is not roaming in its anchor LA. In this case, a pointer should be crossed, at the destination side, to reach the current LA of the called MU. Then, the MU's current LA assigns the call a TLDN and sends it to the calling LA, which establishes a connection to the called MSC using this TLDN.

Scenario 3: The third scenario, shown in Figure 12, is the IS-41 call delivery scenario. In this case, the called MU does not have any records in the location data table, and the HLR is queried in order to determine the current LA of the called MU TLDN.

Scenario 4: The fourth scenario, shown in Figure 13, illustrates the situation where the called MU does not have any record in the location data table and is not roaming in its anchor LA. In this case, a pointer should be traversed to reach the current LA of the called MU. Then, the MU's current MSC/VLR assigns a TLDN to the call and returns it to the HLR, which forwards it to the calling MSC/VLR before the connection is established.

A New Mobile IP Network Architecture

Figure 14 illustrates a new Mobile IP network architecture proposed by Diha and Pierre (2003). The architecture introduces the following main features.

- Multiple connections of MNs and CNs to an FA or HA with different arrival rates in the network.
- The different procedures associated with an MN (registration, discovery, tunneling, and routing) represent different tasks with a specific priority.
- Multiprocessor agent (HA or FA). In this chapter, HA is emphasized. Also the HA is redundant to allow failure recovery. A main processor dispatches the different tasks arriving to an agent. A set of faster processors is defined to handle high-priority tasks.
- A processor can breakdown with a probability *p* and restarts with a probability 1 - *p*.

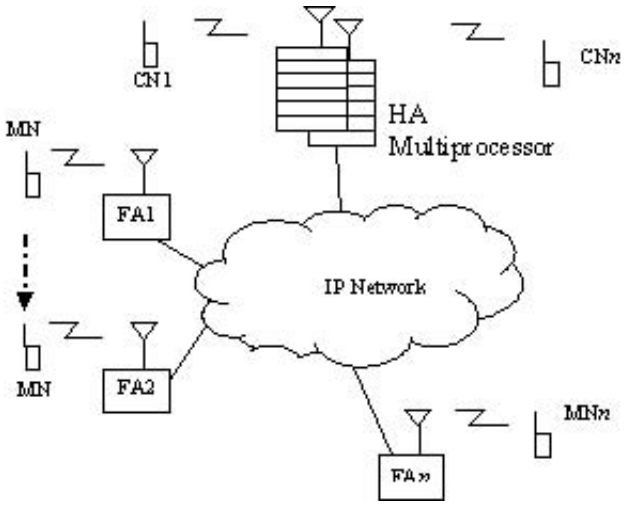
Based on this architecture, a set of new algorithms was defined to manage mobility with IP in mobile networks: registration algorithm, discovery algorithm, routing and tunneling algorithm, and task-scheduling and assignment algorithm.

Registration Algorithm

The registration procedure is a task running on the HA with the highest priority. It can preempt any other mobility management task for a given user. For example, during a tunneling procedure, if a registration request is received for the same user, the tunneling process will be delayed until the registration is completed. The different stages of the algorithm are described as follows.

1. The MN sends a registration request to the HA (it may imply the FA).
2. The HA verifies if a task other than the registration is in process for the same user. If so, this task is preempted by the registration task.

Figure 14. Mobile IP network architecture



3. The HA sends a response to the MN (it may imply the FA).
4. If the request is accepted, the procedure is completed; otherwise, the MN reattempts registration by sending a new request.

Discovery Algorithm

The discovery algorithm also introduces the notion of priority and it is based on lifetime expiration. The different steps are described as follows.

1. If the lifetime has expired and the MN notices the presence of an FA, it sends a registration request to the FA.
2. The FA verifies if higher priority tasks (e.g., registration procedure) are simultaneously executed for the same MN. If that is the case, the discovery process is delayed until the high-priority task execution is completed.
3. The FA returns a response to the MN.
4. If the registration succeeds, the MN sends new location information to its HA for location update.

Routing and Tunneling Algorithm

The new routing and tunneling algorithm also introduces the notion of priority. Thus, during a tunneling procedure, if a registration procedure is

received for the same user, the location procedure will be suspended until registration is completed. The algorithm steps are the following.

1. The HA receives data for an MN.
2. The HA verifies if registration is requested for the same user. In that case, the HA suspends the tunneling process until registration is completed.
3. The HA verifies if the MN is in the local network. If so, the packets are delivered through a regular IP packets-delivery procedure; otherwise, the HA forwards the packets to the MN via its current FA using its CoA.

Task Scheduling and Assignment Algorithm

The scheduling part of the algorithm is based on the Earliest Deadline First (EDF) algorithm (Johnson & Perkins, 2001). The tasks are sorted according to deadlines and assigned to processors. If a task is critical, it is assigned to a faster processor. A task is assigned to a processor only if its current utilization rate is less than one. This ensures that a processor is not used at its full capacity while others are not used. The algorithm verifies that the targeted processor is not broken down before assigning it a task. Figure 15 shows the task scheduling and assignment algorithm.

PERFORMANCE ANALYSIS

This section analyzes empirical results associated with some mobility management models proposed in the previous section. Then, their performance is evaluated by comparing them with other schemes.

Built-In Memory Model

To evaluate the performance of the location update scheme in the built-in memory model, we use a timing diagram similar to the one used by Jain and Lin (1995). The steady-state case between two consecutive phone calls was considered. In this analysis, MUs are classified by their CMR. The CMR is defined as the average number of calls to an MU per time unit, divided by the average number of times the MU changes LAs per time unit (or mean arrival rate/ mean mobility rate). If we assume that the incoming calls to an MU has a mean arrival rate λ, and the time that the user resides in an LA has mean 1/u, then, the CMR may be expressed by the following:

$$\text{CMR} = \frac{\lambda}{\mu}.$$

The objective is to determine the classes of MUs for which the memory-built-in model yields net reductions in signaling traffic and database loads. We define a(K) as the probability that the MU moves across K LAs between two phone calls. In order to evaluate a(K), the timing diagram shown in Figure 16 is used, where t_c denotes the interval between two consecutive phone calls to a mobile unit M. We suppose that the MU resides in a location area LA_0 when the first call arrives. After the first call, the MU visits another K LAs and remains in the location area LA_j for a period T_j ($0 \le j \le K$). Let t_i ($0 \le i \le K$) be the moment when the MU enters a new LA. T_i is then the interval between t_i and t_{i+1}. Let t_m denote the interval between the arrival of the first call and the time when the MU moves out of location area LA_0. Let T_i ($0 \le i \le K$) be independent, identically distributed, random variables with a general distribution $F_M(T_i)$, the density function $f_M(T_i)$, and the mean $E[T_i]$. The Laplace transform of T_i is then:

$$f_M^*(s) = \int_{t=0}^{\infty} e^{-st} f_M(t)dt. \quad (1)$$

Let $d_m(t)$ be the density function of t_m. Based on the random observer property (Mitrani, 1987), we can show that:

$$d_m(t) = \frac{1}{E[T_i]} \int_{x=t}^{\infty} f_M(x)dx = \frac{1}{E[T_i]}[1 - F_M(t)]. \quad (2)$$

Furthermore, we assume that the MU's residence time in an LA is exponentially distributed with parameter *m*. Hence, the density function of the MU residence time random variable T_i is $f_M(t) = \mu e^{-\mu t}$, and the expected residence time of an MU at an LA is

$$E[T_i] = \frac{1}{\mu}.$$

If the call arrivals to an MU are Poisson processes with mean arrival rate l, then, the interarrival time between two calls t_c is exponentially distribute with density function

$$f_c(t) = \lambda e^{-\lambda t} \text{ and } E[t_c] = \frac{1}{\lambda}.$$

Thus, the Laplace transform of te distributio of t_m is:

$$d_m^*(s) = \int_{t=0}^{\infty} e^{-st} d_m(t)dt = \int_{t=0}^{\infty} e^{-st} \mu[1 - F_M(t)]dt$$

$$= \frac{\mu}{s}[1 - f_M^*(s)]. \quad (3)$$

The probability a(K) that the MU moves across K LAs between two phone calls can be derived using Equations 1, 2, and 3:

$$\alpha(K) = \frac{\mu}{\lambda}[1 - f_M^*(\lambda)]^2[f_M^*(\lambda)]^{k-1}. \quad (4)$$

Let N denote the average number of location update operations performed among K moves. From Equation 4, N can be derived as follows:

$$N = \sum_{i=0}^{\infty} i\alpha(i) = \frac{\mu}{\lambda} = \frac{1}{CMR}. \quad (5)$$

Let M and L denote, respectively, the costs of IS-41 location update and location search procedures. Let m be the cost of the location update operation in the proposed built-in memory model. Let T denote the cost of traversing a link (pointer) between two LAs. We denote total costs between two consecutive calls for various operations used in this analysis as follows:

- U_{IS41}: Total cost of location update operations using the IS-41 scheme
- S_{IS41}: Total cost of location search operations using the IS-41 scheme
- $Total_{IS41}$: Total cost of location update and location search operations using the IS-41 model
- U_{BM}: Total cost of location update operations using the built-in memory strategy
- S_{BM}: Total cost of location search operations using the built-in memory model
- $Total_{BM}$: Total cost of location update and location search operations using the built-in memory model

The average number of location search operations executed between two consecutive phone calls is one. In the worst-case scenario, the cost of the location search procedure in the built-in memory model equals the cost of location search in the IS-41 scheme, plus the cost of traversing

a pointer. Then, the total costs can be easily calculated with the following:

$$U_{IS41} = \frac{M}{CMR}, \quad (6)$$

$$Total_{IS41} = U_{IS41} + S_{IS41} = \frac{M}{CMR} + L, \quad (7)$$

$$U_{BM} = \frac{m}{CMR}, \text{ and} \quad (8)$$

$$Total_{BM} = U_{BM} + S_{BM} = \frac{m}{CMR} + L + T. \quad (9)$$

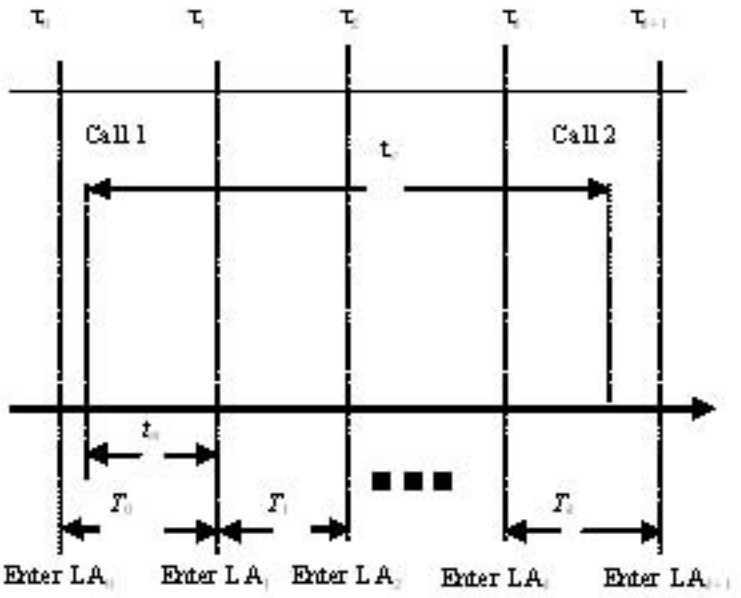
As a first approximation, we consider the values of the operation costs as follows. We observe that the location update procedure and the location search procedure in the IS-41 scheme involve the same number of messages between HLR and VLR databases. Therefore, we assume that $M = L$. Using the same reasoning, we observe that the number of messages in the built-in memory location-update procedure is about 4 times the number of messages required to cross links between two LAs served by the same LSTP, that is, we set $T = m/4$. Finally, we normalize $M = 1$. Then, from Equations 6, 7, 8, and 9, we obtain:

$$\frac{U_{BM}}{U_{IS41}} = \frac{m}{M} = m, \quad (10)$$

$$\frac{Total_{BM}}{Total_{IS41}} = \frac{4(m + CMR) + m * CMR}{4(M + CMR)}, \text{and} \quad (11)$$

$$\frac{S_{BM}}{S_{IS41}} = \frac{L + \frac{m}{4}}{L} = 1 + \frac{m}{4}. \quad (12)$$

Figure 16. Timing diagram



For simulation purposes, we assume approximate values for *m*. Figure 17 shows the total location update cost in the built-in memory model compared to the total location update costs in the IS-41 model when $m = 0.2$ and $m = 0.5$. We observe that for $m = 0.2$, the built-in memory model results in a cost reduction of 80% while the extra cost paid to locate an MU is, in the worst case, 5%. For $m = 0.5$, the total reduction of the location update cost is 50% and the extra cost required to locate the MU is 12.5%. The reduction level depends on the *CMR* of each MU. When *CMR* is low, significant cost savings are obtained with the location update in the built-in memory model. However, when *CMR* tends to infinity, the location update cost in both models tends to zero. This can be explained as follows. As *CMR* tends to infinity, the MU never moves out of an LA, so location updates are not performed.

Figure 18 shows that the reduction obtained in the total cost varies between 22% and 78% when $m = 0.2$, and between 8% and 52% when $m = 0.5$. To gain a better understanding of these results, we analyze the lower and upper bounds for the relative cost $Total_{BM}/Total_{IS41}$ given in Equation 11. We note that the lower and upper bounds of this performance measure occur as $CMR \to 0$ and $CMR \to \infty$, respectively. Then, we can write:

$$m \le \frac{Total_{BM}}{Total_{IS41}} \le 1 + \frac{m}{4}. \qquad (13)$$

Equation 13 can be explained as follows. When the *CMR* is low, the mobility rate is high compared to the call arrival rate, and the total costs of both schemes are dominated by the cost of the location update procedure. Since the built-in–memory, location-update procedure results in significant cost reduction, it outperforms the IS-41 scheme. Conversely, when the *CMR* is high, the call arrival rate is high compared to the mobility rate, and the cost of the location search procedure

Figure 17. Total location update cost: IS-41 versus built-in memory when (a) m = 0.2 and (b) m = 0.5

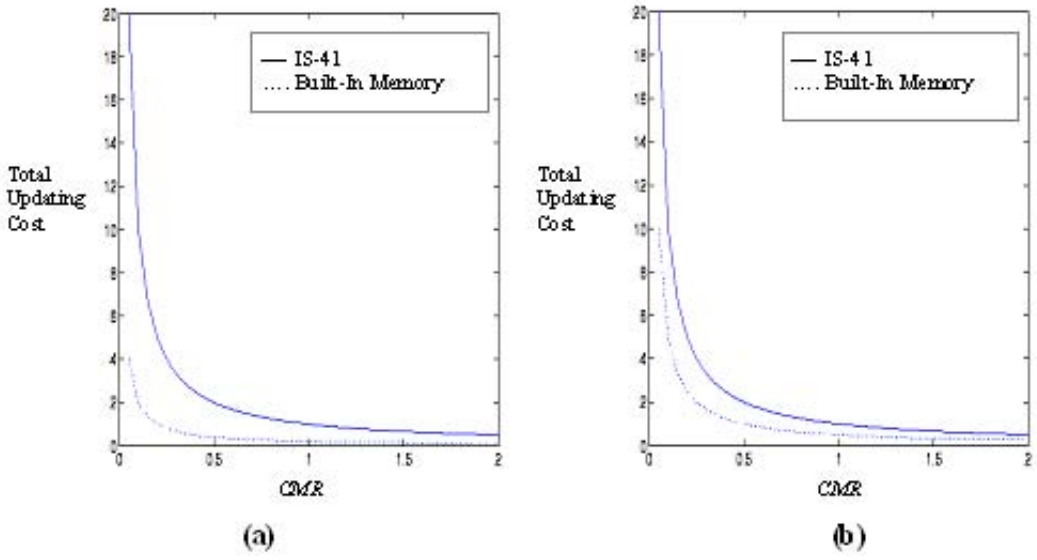


Figure 18. Reductions obtained with the built-in memory model

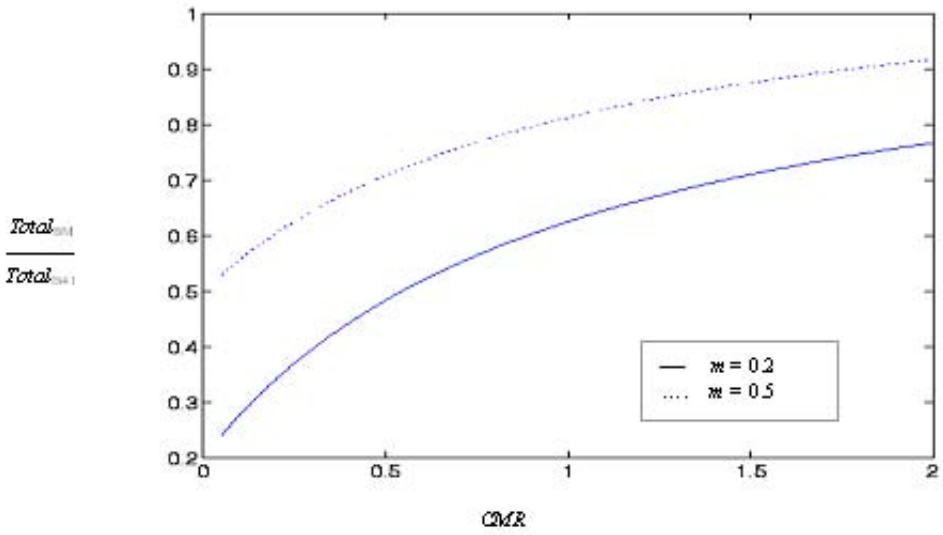

dominates. As the average number of incoming calls to an MU increases, the $Total_{BM}$ value approaches the $Total_{IS41}$ value. When the $CMR \rightarrow \infty$, the MU never moves out of its LA. In this case, it is likely to update the HLR which will point to the MU's current LA. Consequently, the cost of the location search procedure will be equal in both schemes and the upper bound of $Total_{BM}/Total_{IS41}$ will be 1. Otherwise, the $Total_{BM}/Total_{IS41}$ upper bound will be $1 + m/4$ where $m/4$ represents the cost associated with moving between two LAs in the memory-built-in scheme.

The Global Location Management Scheme

This section investigates classes of users for which the global location management scheme yields a net reduction in signaling traffic and database loads. All users can be classified according to their CMR. For each target MU, the following quantities are defined.

l: Average number of calls to a target MU per time unit
m: Average number of times the user changes LA per time unit
1/m: Average LA residence time for a target MU
p: Probability that the called MU has a profile in the location data table
q: Probability that the new LA (VLR/MSC) is served by the same LSTP as the previous VLR (intra-LSTP movement)
r: Probability that the called MU is found in its anchor LA

The costs of the various operations used in the proposed architecture are denoted as follows.

U_{intra}: Location update operation costs when the MU's move is intra-LSTP

U_{inter}: Location update operation costs when the MU's move is inter-LSTP

U_{global}: Estimated cost of a location update operation

S_1: Cost of a location search operation using Scenario 1 (i.e., when the called MU has a record in the location data table and is found in its anchor LA)

S_2: Cost of a location search operation using Scenario 2 (when the called MU has a record in the location data table and is not found in its anchor LA)

S_3: Cost of location search operation using Scenario 3 (when the MU has no record in the location data table and is found in its anchor LA)

S_4: Cost of location search operation using Scenario 4 (when the MU has no profile in the location data table and is not found in its anchor LA)

S_{global}: Estimated cost of a location search operation

C_{global}: Total cost for location search and location update operations

The estimated cost for the location update procedure is given by:

$$U_{global} = qU_{intra} + (1 - q)U_{inter}. \quad (14)$$

The estimated cost for the location search procedure is given by:

$$S_{global} = p(rS_1 + (1 - r)S_2) + (1 - p)(rS_3 + (1 - r)S_4). \quad (15)$$

The total cost per time unit for location search and location update is given by:

$$C_{global} = mU_{global} + lS_{global}. \quad (16)$$

In order to compute the cost of the location update procedure based on the global scheme using the reference network architecture (Figure 7) and the two procedures presented in Figures 8 and 9, we define the following costs for crossing various network elements.

A_l: Cost of transmitting a message on A-link between Service Switching Post (SSP) and LSTP

D: Cost of transmitting a message on D-link between LSTP and Regional Signal Transfer Point (RSTP)

A_r: Cost of transmitting a message on A-link between RSTP and Service Control Point (SCP)

L: Cost of processing and routing a message by LSTP

R: Cost of processing and routing a message by RSTP

C_H: Cost of a database update or query at the HLR

C_v: Cost of a database update or query at the VLR

Based on the location update procedure shown in Figure 8, the location update cost for an intra-LSTP move is given by:

$$U_{intra} = 8A_l + 4L + 2C_v. \quad (17)$$

For an inter-LSTP move, the cost of a location update operation equals the cost of the location update according to the IS-41 standard, plus the cost of updating the location data tables that store the location data of the moving MU, and the cost of updating the MU's previous anchor LA. According to Figure 9, this cost is given by:

$$U_{inter} = 4(A_l + L + A_r + D + R) + 4A_l + 2L + 2C_V + C_H + \sum_{k \in E} U_k, \quad (18)$$

where E is the set of location data tables to be updated after an inter-LSTP move and U_k is the cost of updating a location data table:

$$U_k = 2(A_l + L + R + 2D).$$

The estimated cost of the location update procedure can be derived using Equations 14, 17, and 18 as:

$$U_{\text{global}} = q(8A_l + 4L + 2C_v) + (1 - q)(4(A_l + L + A_r + D + R) + 4A_l + 2L + 2C_V + C_H + \sum_{k \in E} U_k)$$

$$= 8qA_l + 4qL + 2qC_v + 8A_l + 6L + 4A + 4D + 4R + 2C_V + C_H + \sum_{k \in E} U_k - 8qA_l - 6qL - 4qA_r - qD - 4qR - 2qC_V - qC_H - q \sum_{k \in E} U_k,$$

which can be simplified as:

$$U_{\text{global}} = 8A_l + 4L + 2C_V + (1 - q(2L + 4A_r + 4D + 4R + C_H + \sum_{k \in E} U_k). \quad (19)$$

Let t be the probability that the LAs of the called MU and calling unit are connected to the same LSTP. Since updating the location data table and the pointer table involves a simple access to a local memory, we assume that there are no additional costs to update or query this kind of table.

Scenarios 1 and 2 are applied when the called MU has a record in the location data table of the calling MU. The cost of Scenario 1, which is used when the called MU is found in its anchor LA, is given by:

$$S_1 = t(4A_l + 2L + C_V) + (1 - t)(4A_l + 4L + 2R + 4D + C_V)$$
$$= 4tA_l + 2tL + tC_V + 4A_l + 4L + 2R + 4D + C_V - 4tA_l - 4tL - 2tR - 4tD - tC_V$$
$$= 4A_l + 4L + 2R + 4D + C_V - 2tL - 2tR - 4tD. \quad (20)$$

When the called MU is not found in its anchor LA, Scenario 2 is applied. The cost of this scenario equals the cost of Scenario 1, plus the cost of passing over a pointer from the anchor LA of the MU to its current LA. This cost is given by:

$$S_2 = S_1 + 2A_l + L$$
$$= 6A_l + 5L + 2R + 4D + C_V - 2tL - 2tR - 4tD. \quad (21)$$

When the called MU does not have its location information stored in the location data table, Scenarios 3 and 4 are applied. The cost of Scenario 3, which is used when the called MU is found in its anchor LA, equals the cost of the location search in IS-41, given as:

$$S_3 = 4(A_l + L + A_r + D + R) + C_V + C_H. \quad (22)$$

When the called MU is not found in its anchor LA, Scenario 4 is applied. The cost of this scenario equals the cost of Scenario 3, plus the cost of passing over a pointer from the anchor LA of the MU to its current LA. As in Equation 21, this cost is:

$$S_4 = S_3 + 2A_l + L. \quad (23)$$

The total cost per time unit for locating an MU can be expressed as follows:

$$S_{\text{global}} = p(rS_1 + (1 - r)S_2) + (1 - p)(rS_3 + (1 - r)S_4). \quad (24)$$

Using Equations 21, 26, 27, 28, and 29, this cost can be rewritten as follows:

$$S_{\text{global}} = 6A_l + 5L + 4A_r + 4D + 4R + C_V + C_H - p[2t(L + R + 2D) + 4A_r + 2R + C_H] - r(2A_l + L). \quad (25)$$

The total cost per time unit for location update and location search using the global architecture is obtained using Equations 16, 19, and 25.

$$C_{\text{global}} = m[8A_l + 4L + 2C_V + (1 - q(2L + 4A_r + 4D + 4R + C_H +)] + \sum_{k \in E} U_k,$$
$$l\{6A_l + 5L + 4A_r + 4D + 4R + C_V + C_H - p[2t(L + R + 2D) + 4A_r + 2R + C_H] - r(2A_l + L)\} \quad (26)$$

For comparison purposes, we need to evaluate the costs of the original IS-41 scheme. We denote costs for various operations used in the IS-41 scheme as follows:

U_{IS41} : Cost for a location update operation
S_{IS41} : Cost for a location search operation
C_{IS41} : Total cost per time unit for location search and location update operations

The total cost per time unit for location update and location search under the IS-41 scheme is:

$$C_{\text{is41}} = mU_{\text{is41}} + lS_{\text{is41}}, \quad (27)$$

where

$U_{\text{is41}} = 4(A_l + L + A_r + D + R) + 2C_V + C_H$, and
$S_{\text{is41}} = 4(A_l + L + A_r + D + R) + C_V + C_H$.

Defining the relative cost of the global location management scheme as the ratio of the total cost per time unit for the global scheme to that of the IS-41 scheme, $C_{\text{global}}/C_{\text{is41}}$, we get as a function of the user's CMR:

$$\frac{C_{\text{global}}}{C_{\text{is41}}} = \frac{U_{\text{global}} + (\lambda/\mu)S_{\text{global}}}{U_{\text{is41}} + (\lambda/\mu)S_{\text{is41}}}. \quad (28)$$

Relation 28 uses the four probability terms: *p, q, r,* and *t*. Both *p* and *r*, which were defined above, can be used to classify users.

In order to quantify *q* and *t*, we assume that an LSTP consists of $x * x$ LAs arranged in a square, and each LA is itself a square. MUs are assumed to be uniformly distributed throughout the LSTP area and each MU exhibits the same arrival call rate at every VLR/MSC. Furthermore, each time an MU leaves an LA, one of the four sides is crossed with equal probability. Then, the probability that the MU's move is inter-LSTP is equal to the probability that the MU is in a border LA, multiplied by the probability that the MU's next move is to an LA belonging to a different LSTP. Define:

P_1 = Prob[MU lies in a border LA of the LSTP] = $4(x - 1)/(x * x)$
P_2 = Prob[MU's next move is to an LA belonging to a different LSTP] = 1/4
Þ Prob[MU's move is inter-LSTP] = $P_1 * P_2$ = $(x - 1)/(x * x)$.

Hence,

q = Prob[MU's move is intra-LSTP] = $1 - (x - 1)/(x * x)$.

Also, let us assume that all of the network SSPs are uniformly distributed among *n* LSTPs, and each SSP corresponds to a single LA. For example, take the case of the public, switched telephone network that includes 160 local access transport areas (LATAs) across the seven Regional Bell Operating Company (RBOC) regions (Bellcore, 1992), assuming one LSTP per LATA and the average number of LSTPs is 160/7, or 23 per region. Given that there are 1,250 SSPs per region, the number of SSPs per LSTP is 1250/23. Hence,

$$x = \sqrt{\frac{1250}{23}} \approx 7.4 \Rightarrow q \approx 0.88.$$

Under the conditions stated above, the probability *t* that both calling and called users are found in the same LSTP equals $1/n$ Þ $t = 1/23 = 0.043$. Further quantitative results associated

to the performance of the four scenarios can be found in Safa et al. (2002).

CONCLUSIONS AND FUTURE WORK

In this chapter, we analyzed and proposed some mobility management models and schemes by taking into account their capability to reduce search and location update costs in wireless networks. The first model proposed is called the built-in memory model; it is based on the architecture of the IS-41 network and aims to reduce the HLR access overhead. The performance of this model was investigated by comparing it with the IS-41 scheme for different CMRs. Experimental results indicate that the proposed model is potentially beneficial for large classes of users and can yield substantial reductions in total user-location management costs, particularly for users who have a low CMR.

The built-in memory model appears promising when the higher elements of the network constitute the network performance bottleneck. The results show that the cost reduction obtained on the location update is very significant, while the extra costs paid to locate an MU simply amount to the costs of crossing a single pointer between two LAs. The built-in memory model was also compared with the forwarding pointers' scheme. The results show that this model consistently outperforms the forwarding pointers' strategy.

A second location management model to manage mobility in wireless communications systems was also proposed. According to this scheme, two tables are added to the IS-41 network architecture. A pointer table is added to each LA, and it tracks the MUs that moved out of this LA by setting a single pointer from this LA to the current LA. The location data table is located on an LSTP node and contains the data location of the MUs that are frequently called from the LAs connected to this LSTP. The results have shown that significant cost savings can be obtained compared with the IS-41 standard location management scheme, depending on the value of the MUs' CMR.

Finally, we presented the Mobile IP network architecture and mobility management algorithms in a real-time context. Compared to some conventional architecture and algorithms, the implementation of the architecture and algorithms produced better results for the location update and tunneling average times, as well as the CMR.

Many investigations are ongoing in real-time mobility management for Mobile IP networks. Such investigations address the implementation of real-time algorithms in real networks and suggest new algorithms and architectures. Also, since the current protocols are designed for micromobility, the global roaming area remains a highly challenging research domain.

Chapter 2.25
Location Area Design Algorithms for Minimizing Signalling Costs in Mobile Networks

Vilmos Simon

Sándor Imre
Budapest University of Technology and Economics, Hungary

ABSTRACT

In the next generation, IP-based mobile networks, one of the most important QoS parameters, are the delay and the delay variation. The cell handover causes incremental signalling traffic, which can be critical from the point of view of delay variation. It worsens the quality parameters of the real-time services, which are the backbone of next generation mobile commercial services. We have designed and implemented two algorithms: a location area forming algorithm (LAFA) and a cell regrouping algorithm (CEREAL), which can help us to guarantee QoS parameters in the next generation mobile networks. We used our realistic mobile environment simulator to generate input statistics on cell changes and incoming calls for our algorithms and by comparing the values of the cost functions proposed by us, we recognized that significant reduction was achieved in the amount of the signalling traffic; the location update cost was decreased by 40-60% in average.

INTRODUCTION

Signalling delay and the delay variation are very important service quality parameters of the next generation, IP based mobile networks. The cell handovers in mobile networks causes an incremental signalling message overhead (Akyildiz, Mcnair, Ho, Uzunalioglu, & Wang, 1998), which affects the delay variation and it is critical in the case of timing-sensitive real-time media applica-

tions. The signalling overhead is caused because the location information of a mobile is maintained by registration (Wong & Leung, 2000), where the mobile terminals update their location area information to their home agents. The determination of the location of the user is also important because the demand of mobile location dependent information services (LDIS) has fuelled in recent years. Jayaputera and Taniar (2005a) proposed a new approach to generate a query result for location-dependent information services. Another scope is when the users location moves from one base station to another and the queries cross multi-cells. Jayaputera and Taniar (2005b) gave an approach of mobile query processing in these situations.

The determination of the optimal number of cells in each location area (LA) is a very important task, but the optimal partition of cells into LAs is an NP-hard problem. There was an important contribution in the determination of the optimal number of cells in an LA (Saraydar, Kelly, & Rose, 2000), but they were not focusing on the selection of the optimal set of cells for each LA. Therefore, we propose a solution to obtain the optimal partition of cells for every LA.

The location area structure means that we can join several cells into one administrative unit—so-called location—and in this way, the cell border crossings inside this domain will be hidden for the upper hierarchical levels. Signalling overhead will be produced only when we cross a domain border, but that is rarer than a cell handover, thus, the traffic of signalling messages will be reduced (Cayirci & Akyildiz, 2003).

The question arises: What size the LA should be? Both increasing and decreasing the size have their own benefit. On the one hand, if we join more and more cells into one LA, then the number of LA handovers will be smaller, so the number of location update messages sent to the upper levels will decrease. However in the case of numerous cells belonging to a single LA, an incoming call will cause lots of paging messages (Zhang, Castellanos, & Campbell, 2002) since we must send one to every cell to find where is the mobile user inside that LA. That will increase the load of base stations.

On the other hand, if we decrease the number of cells, then we do not need to send so many paging messages (hereby we will load less links and the processing time will decrease, too), but then the number of LA changes will increase.

Accordingly, we must search for the optimal compromise between these two conflicting aspects (Li, Kameda, & Li, 2000).

The LA management is classified according to its use of time, distance, movement profile information in its paging, and location update procedures. The location update can be performed due to the time elapsed since the last registration process (Jun & Ho) or the number of cell boundary crossings measured since the previous update (Tsai & Hsiao, 2001). Wong and Leung (2001) recommend a distance-based scheme where the location update will be performed when a mobile user moves a threshold number of cells away from the cell where the last registration process was carried out. The hybrid of distance-based and zone-based is studied by Casares-Giner and Mataix-Oltra (2002). Bar-Noy, Kessler, and Sidi (1995) have compared time-, distance-, and movement-based schemes in terms of location management cost and they have shown that the distance-based one performs best. However, its implementation is hard since the distance of the mobile terminal has to be computed dynamically as it moves from cell to cell.

In this article, we propose a zone-based LA solution since they are used in all the deployed cellular mobile systems.

Our aim was to decrease the amount of administrative messages, so we designed an LA forming algorithm (LAFA) based on the statistical probabilities of the moving directions (Simon, Huszák, Szabó, & Imre, 2003) chosen by the mobile users. We have implemented this graph algorithm using the cell border crossing prob-

abilities as input. We propose a mobility simulator developed by us for the generation of a realistic border crossing and incoming call pattern as an input for our algorithm. Furthermore, we propose a cell regrouping algorithm (CEREAL), too, for a refinement optimization using an error function defined for the LA partitions, which was produced by the LA forming algorithm. The implemented program calculates the cost functions (see Section 5) of the random and of our LA forming algorithm, in the function of the paging and location update importance weights.

This article is organized as follows: the mathematical description of our paging and location update cost function is introduced in the second section. The LAFA is presented in the third section. In the fourth section, we give the CEREAL for the optimal refinement, while in the fifth section our results are shown and discussed. In the sixth section, we draw conclusions.

Cost Structure

Most of the references (Madhow, Honig, & Steiglitz 1995; Xie, Tabbane, & Goodman, 1993) related to the location area design are focused on how to determine the optimal number of cells for an LA. In this article, we presented an algorithm, which can give us the optimal partition of cells into LAs.

Although there had been earlier attempts to optimize location update cost or paging cost or a combination of them in Abutaleb and Li (1997), Akyildiz, Ho, and Lin (1996), and Merchant and Sengupta (1995), however, the aspect of minimizing the location update cost with a heuristic algorithm (LA forming algorithm) first, and after using that basic partition as an input to a regrouping algorithm, which will minimize the aggregated cost function, was not considered there. So, we have split this complex problem into two sub problems to optimize the location update cost and the aggregated cost, one after another. We defined the location and paging cost functions differently than in the previously mentioned related works because of the handling of the two sub problems.

The Paging Cost Function

On the arrival of an incoming call, the mobile switching center sends a paging message to every base station under its control in order to find out the called mobile terminal (MT) (Bhattacharje, Saha, & Mukherjee, 2004). So, each cell in the given LA will carry all the paging traffic associated with the called MTs within that LA. In order to characterize a network configuration, we define a paging cost function for the l^{th} LA by which we can describe the bandwidth seized by the paging operations in a given interval:

$$C_{p_l} = \sum_{i=1}^{K} N \cdot \lambda_i \cdot B_p \qquad (1)$$

where

- N is the number of cells in the given l^{th} LA.
- λi is the incoming call rate to the given i^{th} MT.
- B_p is the paging cost.
- K is the number of MTs in the l^{th} LA.

With Eq. (1), we can determine cost of the traffic induced by paging messages for a given LA, generated by the incoming calls in the given interval. The total paging cost for the LAs in our system:

$$C_p = \sum_{l=1}^{M} C_{p_{ll}} = \sum_{l=1}^{M} \sum_{i=1}^{K} N \cdot \lambda_i \cdot B_p = \sum_{l=1}^{M} N \cdot B_p \cdot \sum_{i=1}^{K} \lambda_i \qquad (2)$$

where M is the number of LAs in our system.

Location Update Cost Function

We define a location update cost function for our network, which will help us to determine the LA

handovers caused by the mobile users crossing the LA boundary (Chiussi, Khotimsky, & Krishnan, 2002), which generates additional location update traffic; namely they need to inform their home agents about their new location (Akyildiz et al., 1999).

The location update cost for the k^{th} LA:

$$C_{lu_k} = B_{lu} \cdot \sum_{j=1}^{B} q_j, \quad (3)$$

where

- B_{lu} is the cost required for transmitting a location update message.
- q_j is the intensity of cell boundary crossings on the j^{th} boundary.
- B is the number of the exterior cell borderlines.

The total location update cost for the LAs in our system:

$$C_{lu} = \sum_{l=1}^{M} C_{lu_k} = \sum_{l=1}^{M} B_{lu} \cdot \sum_{j=1}^{B} q_j, \quad (4)$$

where M is the number of LAs in our system.

Our final goal is to maximize the intra-domain traffic because in this way we can decrease the number of the LA handovers, and therefore, the total amount of administrative messages. We can reduce the number of handovers by joining the cells along the dominant moving directions. This LA forming principle will be introduced in the third section.

To evaluate the algorithms we need. the minimized expectation value of the aggregated cost function, with variable weight factors, which takes into consideration both aspects of forming LAs:

$$\min E\{w_1 \bullet Cp + w_2 \bullet C_{lu}\}. \quad (5)$$

On the basis of the importance of paging or rather location update cost, we can use different weights, and in that way we can dynamically vary the sizing based on the actual point of view and the required QoS parameters.

Because of the expectation value is a homogeneous linear operator, the Eq. (5) expression becomes:

$$\min(w1 \bullet E\{Cp\} + w_2 \bullet E\{C_{lu}\}). \quad (6)$$

The Location Area Forming Algorithm (LAFA)

We model our network with the $G(V,E)$ graph where the cells are the graph nodes $v \in V$ and the cell border crossing directions are represented by the edges $e \in E$ of the graph (see Figure 1).

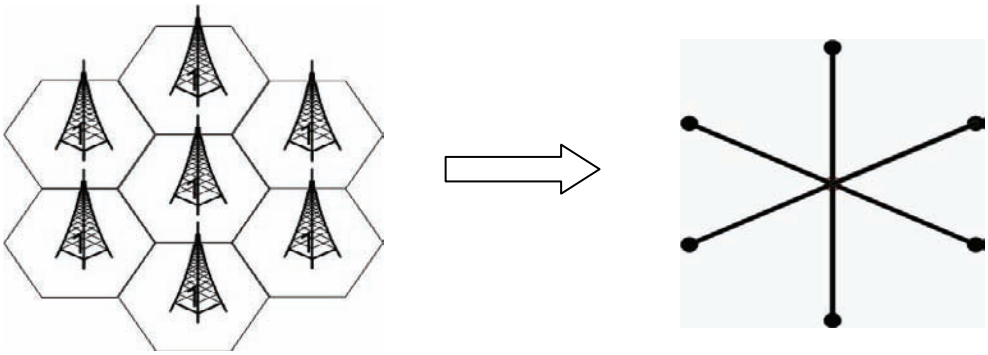
Definitions

- If $\{v_1,v_2\} \in E$ then the cells represented by v_1 and v_2 are adjacent.
- If $\{v_1,v_2\}$ and $\{m_1,m_2\}$ are the end points of $e,f \in E$, and $\{v_1,v_2\} \cap \{m_1,m_2\} \neq 0$, then the cell border crossing directions e,f are adjacent.
- If the set of nodes of graph F is consistent with the set of nodes of graph G and the edges of graph F are an acyclic subset of edges of graph G, the graph F is the spanning tree of the graph G.
- If the weight function $c:E \rightarrow \Re$ is defined on the edges and the sum of its edge weights is maximal among the spanning trees of graph G, the graph F is the maximum weight spanning tree of the graph G.

The Algorithm

A moving direction matrix can be defined to every cell, which contains the statistical probabilities of the moving directions chosen by the mobile us-

Figure 1. The representation of the mobile system by a graph



ers when they step across the cell borders. This mobility pattern database can be obtained by measurements, which is attainable for the mobile operators. In our case, we have developed a mobility simulator (see the fifth section), which serves as a realistic cell boundary crossing and incoming call pattern as an input to our algorithms.

We define weights to the edges of the graph G, not negative real numbers in the range [0,1], based on the probability matrix, namely the weight of the edges is consistent with the cell border crossing probabilities.

We must divide graph $G(V,E)$ into subgraphs $G_i(V,E)$, so that the subgraphs contain the maximum weight spanning tree. The set of edges of those maximum weight spanning trees will give us the cell groups, which compose the LAs.

Starting from the s=1 initial point, we choose from edges joint to the node s, the one, which has the biggest weight (c_{mac}), if there is more than one biggest weight, then we choose one of them randomly and include it into the set of edges $L_1(L_1=\{e_1\})$ (Figure 2). The two nodes connected by this edge are included into set $U_1=\{s_1,v_1\}$. In the next step, we search for the second largest weight (if there is more than one, we choose it in the same way as in the first step), and we examine those two nodes belong to the U_1set. If both are in the set V/U_1, then the edge, which connects them, is included into the L_2 set of edges ($L_{21}=\{e_1\}$) and the two belonging nodes into the setU_2. If one of them is in the set U_1, then we must make an evaluation step.

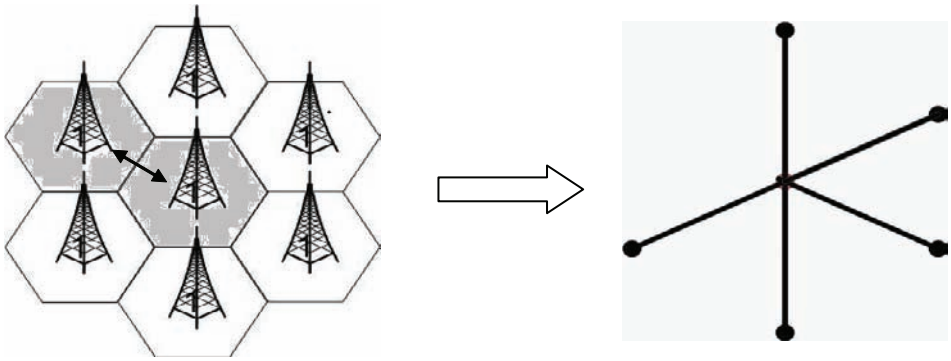
We must check if inequality

$$\frac{c_m}{\frac{1}{n}\cdot\sum_{i=1}^{n} c_i} > K \quad , \tag{7}$$

is satisfied, where c_m is the weight of the examined edge, and c_i are the weights of edges in the U_1 set. K is the lower bound, given by us. If the inequality is satisfied, the edge can be included into this set ($L_1=\{e_1, e_2\}$). If the inequality is not satisfied, this edge can not be included into this set, namely the cell which is represented with this node, can not be joint into this LA. Another upper bound can be used, we can give the maximum number of cells in one LA.

In this way, we can join the cells, which are in the same dominant moving directions, so the number of domain handovers can be decreased (highways, footpaths, etc.).

Figure 2. Joining the two nodes (cells) into one set (LA)



We run this algorithm until we get the U_i partition of nodes V, so this partition will give us the groupings of cells into clusters, namely the D_i location areas.

THE CELL REGROUPING ALGORITHM (CEREAL)

The partition of cells is an NP-hard problem; therefore, we propose a heuristic algorithm. We have developed a regrouping algorithm, which would help us to refine the cell grouping in cases when it is necessary.

Definitions

- For cell i, $Y_i=(Y_1, Y_2)$ is a two dimensional probability variable, where $Y_{i1}=q_{iF}$, q_{iF} is the border crossing intensity of the cell i and $Y_{i2}=\sum_{j=1}^{N}\lambda_j$, where λ_j is the expectation value of the incoming call distribution, and N is the number of the mobile terminals in the cell i.
- The LAFA gives us a partition of cells $\{D_1, D_2,... D_M\}$ in location areas, where M is the number of areas in our mobile system. Then $Y=\bigcup_{i=1}^{M} Di$ and $D_i \cap D_j = 0$, if $i \neq j$.

The Algorithm

If $|D_i|$ is the number of cells in the given D_i location area, then we can define the center of the area by

$$\overline{D_i} = \frac{1}{|D_i|}\sum_{Y_l \in D_i} Y_l \qquad (8)$$

We can define the distance of the Y_j cell from the D_i location area as

$$d\left(Y_j, D_i\right) = d\left(Y_j, \overline{D_i}\right) = \left(\sum_{l=1}^{2}\left(Y_{jl} - \overline{D_{il}}\right)^2\right)^{1/2}. \qquad (9)$$

A very important parameter in our regrouping algorithm will be the error function of our location area system

$$W\left(D_1,...D_M\right) = \sum_{i=1}^{M}\sum_{Y_j \in D_i} d^2\left(Y_j, D_i\right). \qquad (10)$$

Our goal is to minimize the error function by transposing the cells into adjacent location areas, and by this, we can reduce the distances among them, what will result in a significant reduction of location update and paging costs.

Steps:

1. The calculation of the initial area centers and the initial error function ($\overline{D_i}$,$W(D)$).
2. For the first cell (Y_1) and the adjacent location areas (D_i), given by our location area forming algorithm, we calculate:

$$\Delta(D_i,Y_1)=\frac{|D_i|\cdot d^2(Y_1,D_i)}{|D_i|+1}-\frac{|D(Y_1)|\cdot d^2(Y_1,D(Y_1))}{|D(Y_1)|-1} \quad (11)$$

where $D(Y_i)$ is the location area, which contains the Y_i cell.
We can prove that if we re-group the Y_i cell from the $D(Y_1)$ location area to the D_i area, the error function of our location area system will change by exactly $\Delta(D_i,Y_1)$.
So if

$$\min_{\substack{1<i<M',\\ D_i\neq D(Y_1)}} \Delta(D_i,Y_1)=\Delta(D_k,Y_1)<0, \quad (12)$$

where M^1 is the number of the location areas, which are adjacent with cell Y_1, then we transpose the cell Y_1 from location area $D(Y_1)$ to D_k.
Calculate the new location area centers and add the $\Delta(D_k,Y_1)$ to the former error function value.
3. Iterate the 2nd step for every Y_i.
4. If there are no more cells to transpose, we can stop, otherwise repeat step 2.

This regrouping algorithm will give us the final LA partition, which will minimize the inter LA movement, and by this the signalling load, too.

QUANTITATIVE ANALYSIS

Optimal partition of cells into LA-s is an NP-hard problem, so we could give only a quantitative analysis of the problem and evaluate our algorithm with a mobility simulator in two different mobility environments.

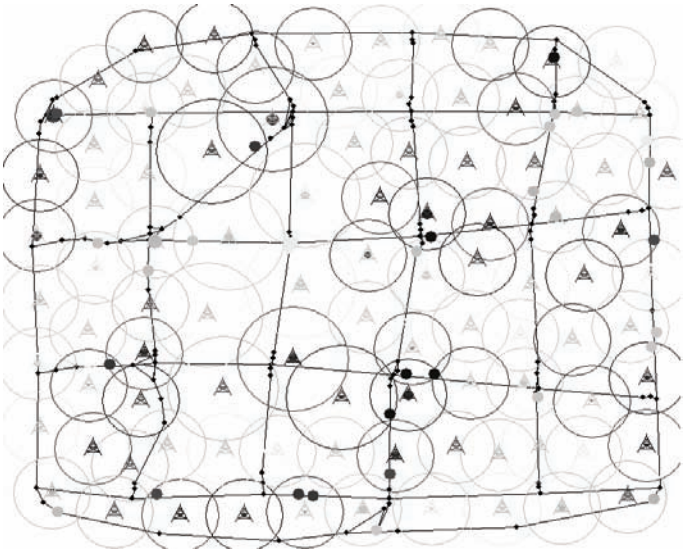
In this section, we will present our cost evaluation results using the mobility simulator as an input generator for our algorithms. The simulator produces cell changing and incoming call statistics, which are used to run our algorithms and to calculate the cost functions.

The Mobility Simulator

We developed a simulator (see screenshot in Figure 3), which will give us a realistic cell boundary crossing and incoming call database in a given mobile system, as an input to our algorithms. In the simulator, we can give an arbitrary road grid covered by cells of different size (for example WLAN, UMTS, GSM cell). We can choose between mobile terminals of different velocities, and we can give the incoming call arrival parameter to every mobile.

This way we can design different types of mobility environments (rural environment with highways or a densely populated urban environment with roads and carriageways), and grids of cells adapted to these environments. The mobile terminals will move on that road grid choosing randomly a point on the road, just like in a real life. Because in everyday action, the mobile users typically move to manage their duty tasks or entertainment (for example workplace, school, cinema, bank), and they want to arrive there in the shortest time, so we implemented the Dijkstra's algorithm to find the shortest path of mobile terminals to their wanted destination. For every mobile terminal, an incoming call arrival parameter is defined. When a call arrives to the mobile, the program assigns it

Figure 3. A designed urban environment in our mobility simulator, with a road grid covered by cells



to the cell where the mobile is in that moment. It is the same case when a mobile terminal changes a cell, the simulator register the cell's identifier in the base station transition matrix. On the end of the simulation, we get a cell boundary crossing and an incoming call distribution for every cell in our system.

With this database, which is a good representation of the mobility patterns in real life, we can run our LA forming algorithm, and evaluate it by the defined location update cost function (4).

Simulation Results

We compared the performance of a random LA partition and the LA forming algorithm by using two typical mobility environments.

We designed a rural and an urban mobility environment in our mobility simulator, the first one is rarely populated, but on the belonging highways, a big number of mobile terminals are moving with high speeds, while the second environment is densely populated, with mobile terminals moving with smaller velocities. In the rural environment, the average cell size is larger then in the urban, accordingly there is a smaller number of cells. We run the simulation on a moderate sized example network; the rural mobile system consisted of 99 base stations, while in the urban system it was about 123 base stations. Then we stored the output of the simulation, namely a cell boundary crossing matrix (base station transition matrix) and the incoming call distribution for every cell. This database was the input of our LA forming program, which designed a LA partition for both mobility environments.

1. **Employing only the LAFA:** Based on these LA partitions, we computed the location update cost (in total number of handovers between the LAs in the simulation period), and we computed the same cost for a ran-

domly designed LA partition where we can give the number of cells in one LA, and then the program designs an LA partition. It is important to point out that the randomly designed LA do not mean that the cells are joined by a random way; the cells joined to the same LA are on the dominant moving directions, so the random LA-s can be considered as a planed partition, but not the optimal one. So the results are compared to these planed structures, not to haphazard partitions.

For the rural environment, the results of the simulation are given in Figure 4 where the upper bound of LA axis represent the number of cells given in the random design or rather the additional upper bound of cells which was given in the LAFA, when Eq. (7) is satisfied. In Figure 4, the location update cost decreases as the upper bound becomes higher, but then the paging cost will increase, too. So in the random partition we can decrease the location update cost if we increase the size of the LAs, but then the paging cost will be a serious problem. A significant advantage of the LAFA is that it reduces the location update cost very significantly, by not increasing the number of cells in one LA, so the paging cost can be kept on a lower level. In the domain of 5-10 cells in an LA, our new scheme reduces the inter LA traffic by 40-60 percents on the average.

In Figure 5, the results for the urban environment can be seen. It is very similar to the rural; however, the location update cost is remarkably reduced without increasing the paging signalling load. The decrease is very significant in the interval of five to eleven cells. In the interval between 12 and 15, does mean that by increasing the number of cells the location update cost does not decrease, but the Eq.(7) is not satisfied so the algorithmic LAs are already finished, so the cost does not change.

Another simulation was done to investigate the effect of the value of parameter K (7), which can be dynamically modified, depending on the model we want to deploy. It changes in the (0,1) interval, as it converges to 1, the size of the LA-s are decreasing, so we expected that the location update cost will increase significantly as the parameter K increases. Figure 6 shows the results obtained in the rural environment as the value of parameter K is increasing, the location update cost of the random partition is increasing too, the cost of the LAFA is not increasing till K=0.5 value, but

Figure 4. The location update cost in rural environment, in random and algorithmically partition

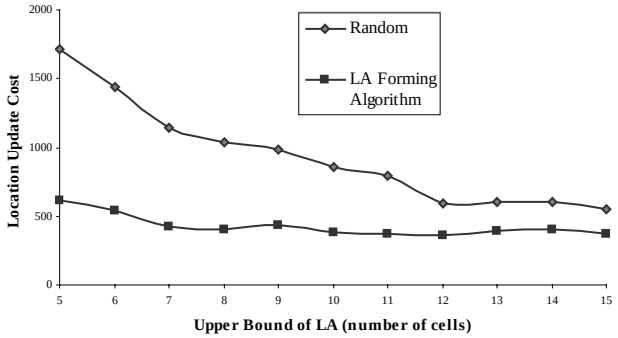


Figure 5. The location update cost in urban environment, in random and algorithmically partition

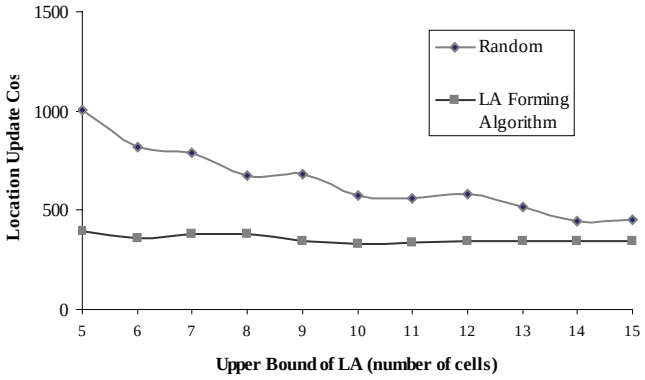

Figure 6. The location update cost vs. the value of parameter K (rural)

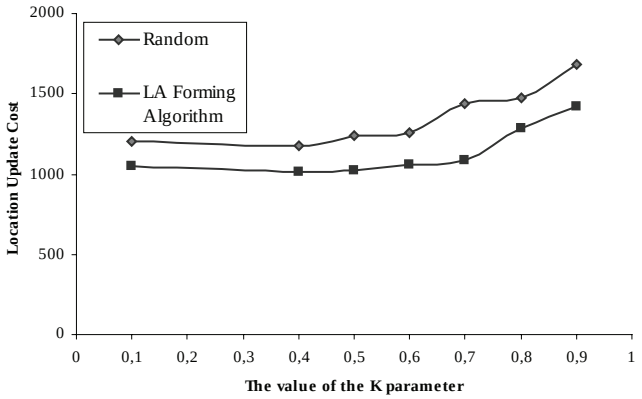

after it follows the cost of the random partition. So the algorithm outperforms the random partition in every value of parameter K, especially for the lower values that are characteristic for our algorithm. The minimum of the location update cost is reached for the value 0.4 of parameter K.

In the urban environment the results are more effective, the cost of the LAFA is lower by 30-40% (see Figure 7), depending on the value of parameter K. The minimum is reached in at value of 0.5 of parameter K.

Figure 7. The location update cost vs. the value of parameter K (urban)

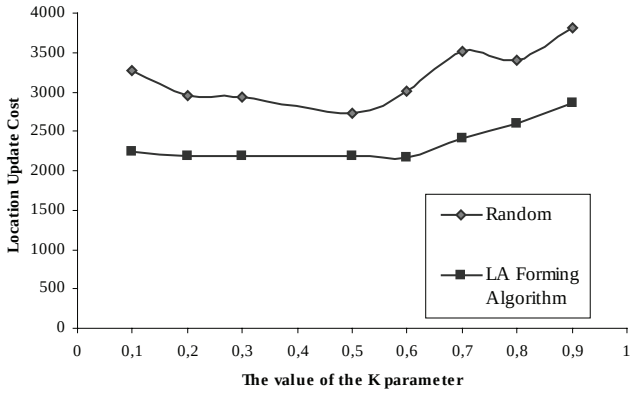

Figure 8. The total cost vs. the value of parameter K (rural)

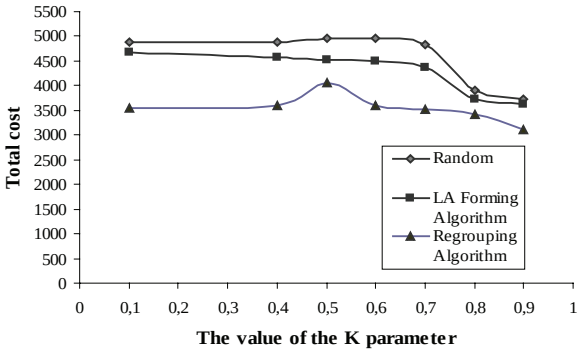
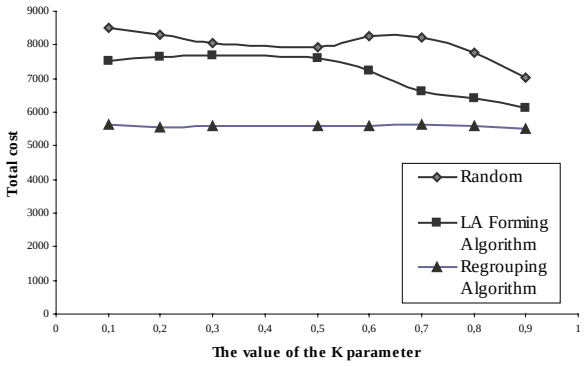


2. **Employing both algorithms:** We examined what will happen if we employ our regrouping algorithm on the initial partitioning obtained by the LAFA. We measured the total cost, the sum of the location update, and paging cost vs. the value of parameter K, which was employed in the LAFA.

Figure 8 shows the total cost in the rural environment. It can be seen that in the case of the total cost the effect of increasing the value of parameter K is just the opposite of that in case of the location update cost. The reason is that by increasing the value of parameter K, the size of the LA-s is getting smaller, so the paging cost is

Figure 9. The total cost vs. the value of parameter K (urban)



decreasing significantly. So the LAFA is not so effective anymore, but the CEREAL is still outperforming the other two partitioning methods significantly, in some cases over 50%.

Figure 9 shows the total cost vs. K parameter in the urban environment. It is the same case, the CEREAL decreases the amount of the total cost by 30-40%, and it does not depend on the value of parameter K.

Depending on our objective, we can deploy either the LA forming algorithm or the regrouping algorithm. If we want to decrease the location update cost, the LA forming algorithm is the solution, however if we want to decrease the total cost, we need to employ the regrouping algorithm.

CONCLUSION

An important benefit of optimized LA planning is preventing needless radio resource usage (Demirkol, Ersoy, Caglayan, & Delic 2004), but the most important is that we can support global QoS parameters, like signalling delay and delay variation, which can be critical in time sensitive services of the next generation mobile systems.

It can be achieved by reducing the signalling cost, which means that the inter LA movement must be minimized. The input of this algorithm was obtained by a mobility simulator developed by us that produces network information (base station transition matrix, incoming call distribution to every cell) in a realistic manner. We also proposed a cell regrouping algorithm, which uses the LA partitions obtained by our algorithm, like an initial step.

To evaluate the performance of our new scheme, we designed a rural and an urban environment in the mobility simulator, and with this database, we run the LA forming algorithm. Then we compared it with a randomly designed LA structure, examining the relation of the location update cost with an upper bound on the number of cells.

The simulation results show that the LA forming technique reduces the location update cost by 40-60%. The regrouping algorithm performs well if we want to decrease the total cost of our

system, it can reduce the total cost by 30-40%, sometimes over 50%. We recognized, by comparing the random algorithm and our LA forming one, that a significant reduction was attained in the signalling traffic that causes delay and delay variation, helping us improving QoS parameters in general.

Due to the difficulty of the problem, our future research plan is to use simulated annealing to obtain the optimal LA partitions, in reasonable running times. In this case, we will examine the minimization of the location update cost, subject to the paging cost, as an inequality constraint (using constrained optimization). Another research direction is to develop an optimization algorithm based on the inter-LA movements, which will help us to plan a hierarchical mobile structure, which results in the minimal signalling traffic.

Chapter 2.26
Market Configuration and the Success of Mobile Services:
Lessons from Japan and Finland

Jarkko Vesa
Helsinki School of Economics, Finland

ABSTRACT

This chapter introduces a novel analytical framework called Mobile Services Matrix (MOSIM), which is used as the basis of a comparative analysis between the Japanese and the Finnish mobile services markets. The results indicate that as the mobile industry shifts from highly standardized voice services towards more complex mobile data services, the vertical/integrated market configuration (i.e., the Japanese model) appears to be more successful than the horizontal/modular configuration (i.e., the Finnish model). A brief overview of the UK market shows that the leading UK mobile network operators are transforming the industry towards a more vertical, operator-driven market configuration. The role of national regulatory framework in this industry evolution process is discussed.

INTRODUCTION

There is a paradox in the mobile services industry in Europe today: Even though the industry will be experiencing a major transformation during the next few years, for the time being the business is going too well for the senior management of many telecom operators to take action to redefine their business models and strategies in order to be well positioned in the new era of mobile multimedia services (aka mobile Internet, mobile data services, or nonvoice services).

Take Finland, for instance. Once the Internet bubble burst and business risks that were built into the growth strategies of the leading telecom operators were realized, the growth-oriented senior management was replaced with new management teams with a strong focus in cost cutting and downsizing. Financial markets expected operators to clean up their balance sheets after notorious UMTS licence auctions and other

unsuccessful attempts to become serious players in the international mobile market. As a result of this development, Finnish operators have delayed their investments in new services and networks (for instance, the first UMTS service for commercial use was launched by TeliaSonera in October 2004, even though Finland was one of the first countries in Europe to allocate spectrum for 3G!) and sold those parts of their operations that are not considered to be their core business. Against this background it is easy to understand why the leading Finnish network operators opt for the current situation where they keep on making nice profits in the saturated market instead of actively seeking to change the competitive arena. Although this approach is understandable from individual companies' point of view, recently there has been much discussion as to whether this kind of risk-avoiding strategy will turn Finland into a yesterday's hero when it comes to actively building the brave new world of mobile services. Operators can rest on their laurels for a few more years, but the longer they neglect developing their business models for the competition of the future, the more painful process lies ahead of them. Some people within the industry have realized the destructive nature of the current price-driven competition in the Finnish market: a representative of TeliaSonera expressed his concern that many of the players in the mobile market are there to cannibalize the market with their aggressive pricing schemes, not to develop the market in order to secure healthy business also in the coming years (Tietoviikko, 2004). The industry seems to ignore the fact that the worst is yet to come, as new disruptive technologies such as voice-over-WLAN, WiMax, and free Internet telephone services such as the Skype service become increasingly popular in the coming years, especially now as eBay acquired Skype in order to enhance their online auction platform.

Unfortunately mobile operators are not the only ones sticking to old voice-centric business paradigm and earnings logic. Even the national regulatory authorities fail to see the need to adjust the regulation of mobile markets to the changes in technology and in the business environment in general. While the mobile phone usage has slightly increased (i.e., the minutes of use), in mature markets like Finland, the decrease in call tariffs has led to a situation where average revenue per user has remained flat or even decreased. Although 2004 was regarded as highly exceptional due to the introduction of mobile number portability in Finland, there is a widely shared view that call tariffs will continue to fall at a rate of 20–30%.

The current development in the traditional mobile voice market has made the leading operators to turn their eyes on nonvoice services. However, so far the European operators have not managed to turn mobile multimedia services into a similar success story as their Japanese counterparts. This raises the question why, despite the similarity in services and content offered, have nonvoice mobile services not taken off as expected? Based on a comparison of two very different mobile markets, namely Japan and Finland, this chapter argues that the lack of success of mobile Internet services in Europe is more a result of wrong business models and industry structure than it is about quality of individual services or products. As mobile services evolve from highly standardized and commodized voice-based communication services (i.e., person-to-person communication) towards the personalized and complex world of digital content and services (i.e., mobile multimedia or person-to-content type services), new challenges emerge also for the creation and delivery of mobile services. I argue that mobile data services represent a "complex good," which Mitchell and Singh (1996) define as "an applied system with components that have multiple interactions and constitute a nondecomsable whole." In a complex system like this, the overall performance depends on component performance, as a chain is only as strong as the weakest link. In the closely integrated and interrelated world of mobile Internet services, not only must all components meet users'

requirements, but all the elements of the service offering (i.e., networks, handsets, services, and content) must also work seamlessly together. As the analysis of the two mobile markets presented in this chapter will demonstrate, this is where Europe has performed much worse than during the previous paradigm shift in the mobile telephony industry, which was the transition to digital mobile networks in the beginning of the 1990s.

During the past 5 years, both Japanese and European mobile markets have been studied extensively. However, the focus of these studies is often technical (e.g., how various technologies used in handsets and networks have evolved during different generations of mobile telephony, or how technical standards have been adopted in various markets), or they have focused on macroeconomic issues (e.g., mobile phone penetration rates or how well competition works in different markets). In this chapter I will present a different approach that raises the level of analysis above the discussion of superiority of competing technical standards, which all too often overshadows more important issues. In fact, I argue that the European way of introducing new technologies to the market suffers from two mind-sets that are not optimal in the context of mobile services. The first one could be described as business reductionism. As Albert-László Barabási points out in his book *Linked*, there appears to be a widely accepted belief that "once we understand the parts, it will be easy to grasp the whole" (Barabási, 2003). By following the ideals of reductionism, some researchers have tried to understand the differences in the success of mobile markets by comparing various technologies used: What kind of markup language has been used? Are the mobile networks circuit or packet switched? How many pixels do cameraphones support? Unfortunately it looks like the dynamics of complex networked industries, such as the mobile services industry, cannot be explained simply by analyzing all the pieces of the puzzle separately. In all fairness I have to admit that this was the way I was thinking when I sat on a plane on my way to Tokyo to meet some of the key players of the Japanese mobile industry in October 2002. However, it did not take long to realize that there was something bigger than just technologies, protocols, and standards behind the success of mobile services in Japan, as we will find out later in this chapter.

The other ideal causing problems for the Finnish mobile market is that open standards seem to be the only goal worth pursuing, regardless the maturity of products and services offered. A good example of the "open-market thinking" that prevails in Europe was a conversation between a representative of J-Phone and some of my colleagues at the Helsinki School of Economics. When our Japanese guest presented the J-Phone business model where the operator controls all the key components of mobile services, several people in the audience raised the question whether this kind of model is acceptable. Their argument was that as the customers of J-Phone are not free to use other operators' networks, services, or content, this kind of model is not as elegant as the European open-market approach. Our Japanese guest asked why we Europeans always emphasize so much this question of openness and the freedom to move between every possible service provider's offering? Is it not possible that a consumer or business customer in some cases would prefer to deal with only one service provider, if that service provider offered high-quality services and content delivered in a seamless, easy-to-use way at a reasonable price? While being aware of the strong argumentation in favor of open markets and standards in economic theories such as network externalities, at least I could not help finding the Japanese concept attractive. Perhaps one reason for this reaction was the fact that I was still suffering from mental trauma caused by unsuccessful use of wireless application protocol (WAP) services. Without going into details in what went wrong in the launch of WAP in Europe, one could argue that the key players of the industry in Europe had probably too much faith in the power

of open standards, while in reality the products and services that were built on the WAP protocol were everything but standardized.

By combining the two assumptions that lie behind the widely accepted notion of what would be an optimal mobile market from the European perspective, we end up with something that could be described as "standards-based technical reductionism," which aims at free and efficient competition. It is easy to see that this kind of market would look very much like today's PC business (albeit there we are talking about de facto standards, thanks to the dominance of Intel and Microsoft). Although there are many excellent qualities in the market structure and product architecture of the PC industry, the analysis of mobile services market will demonstrate several reasons why simply copying the PC business model does not work for mobile services—at least not in the current phase of evolution. One of the key findings of this analysis of the mobile industry is that the optimal industry structure and product architecture is a function of time, that is, one should not make the mistake of presuming that a product/industry configuration that has turned out to be successful in some industries at some point of time in history would necessarily be the right alternative for another industry or another point of time, despite the fact that they may share some similar characteristics.

As the previous discussion indicates, the objective of this chapter is to offer an alternate approach into the analysis of the structure and dynamics of the mobile services markets. I will first present a new analytical framework that has been derived from the Double Helix model by Charles Fine (1998). This framework will then be used in the analysis of two very different markets—Japan and Finland. As the reasons for choosing these two markets will be explained in detail later in this chapter, it is simply stated here that Japan and Finland represent the two extremes of the continuum of contemporary mobile services business models. However, in order to better understand the dynamics of mobile market evolution, I will also present a brief analysis of the UK market, which represents an intermediate or hybrid model between the two extremes. The analysis shows that the UK market is moving towards a similar vertical and integrated market configuration as in Japan, whereas the mobile services market in Finland is stuck with a horizontal business model due to regulatory roadblocks. The results indicate that in a regulated industry such as mobile services, the operators are not always allowed to implement business models that would make sense business-wise. Furthermore, recent development in Finland shows that sometimes the key players of a given mobile services market are reluctant to drive the transformation of their industry due to strategic behavior. It is argued here that national regulatory authorities (NRAs) must have powerful vision of the kind of market structure and dynamics they are striving for.

These findings raise several questions: Is there anything the key players in a given market can do to change the market configuration towards a more favorable one? What are the implications of a given industry structure and product architecture for service providers and consumers? What can we learn by comparing various markets if they all are very different by definition (e.g., culture, history of mobile telephony, size of the market)? Hopefully this chapter will give answers to some of these questions—or even better, raise new questions about the interplay between mobile service development and delivery, and the structure and dynamics of the mobile industry within which these services are implemented.

The structure of this chapter is as follows. I will begin by presenting a novel model for the analysis of the two case markets. In section 3, I will apply the model to the Japanese mobile industry, and in section 4 the Finnish mobile market is analyzed by using the analytical model. Section 5 presents a comparison between the current status and future developments of the two case markets. Section 6 discusses the impact of market configuration on

the success of mobile services in a given market, and section 7 concludes the chapter.

THE MOBILE SERVICES INDUSTRY MATRIX

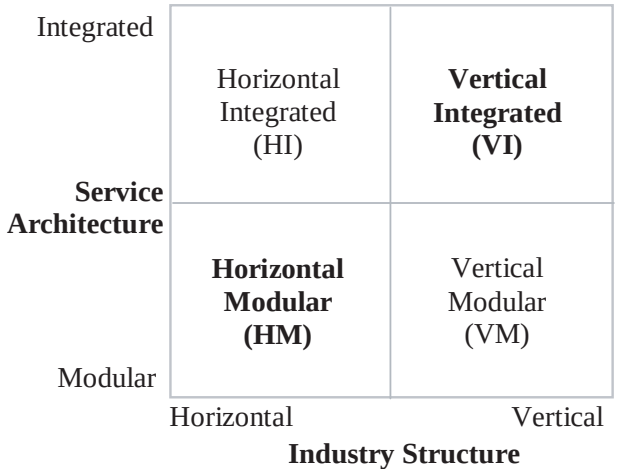
In recent years, a wide range of tools and methods have been used in the analysis of the structure and processes of the mobile and wireless industries. Various types of value chain analyses, cluster analyses, layer models, and business ecosystems approaches have become familiar to those of us who have followed academic research or market research in this field. While each of these models have certain good qualities, when applied in the context of mobile services industry they seem to be deficient in one respect—they are static by nature, that is, they provide a snapshot of an industry without giving much indication of what kind of development one can expect to see in the industry. I argue that given the magnitude of change currently taking place in the mobile industry (e.g., moving from a simple voice services to complex mobile multimedia services, and moving from closed circuit-switched networks to open packed-based IP-networks), new approaches are needed also in the research of this fast-moving industry.

One attempt to apply a new kind of approach to the research of the mobile industry was presented by Vesa (2003, 2004a) who applied the Double Helix model developed by Charles Fine (1998) in the context of the mobile services industry. Although the Double Helix model appeared to capture nicely the current trends in the mobile market, the model itself was criticized for lacking solid theoretical foundations. Some critics have even pointed out that the name "double helix" is not correct—a more appropriate name for the model would be the "Double Donut" or the "Pretzel Model"! Nevertheless, because the use of the Double Helix model in the context of mobile services has received also very much positive feedback, the matrix model presented in this chapter (see Figure 1) builds similar constructs as Fine is using in his model. However, in the Mobile Services Industry Matrix (MOSIM) the Product Architecture dimension has been replaced with Service Architecture in order to emphasize that despite of all the exciting technologies, the mobile services industry really is what its name claims it to be, a SERVICE industry. This line of reasoning is supported by recent statements within the service research discipline emphasizing the "nested relationship between service and goods" (Vargo & Lusch, 2004).

Let us take a closer look at the MOSIM presented in Figure 1. The matrix consists of two dimensions that are called Service Architecture and Industry Structure. The two extremes of the Service Architecture dimensions are defined as integrated service architecture and modular services architecture. Likewise, the Industry Structure of a given market represents either horizontal industry structure or vertical industry structure—or something in between. This last point highlights the fact that in both dimensions there can be, and very often are, various types of hybrid or intermediate industry structures or product structures (see Vesa, 2005, for an in-depth analysis of factors influencing product architecture and industry structure).

The matrix identifies four possible service architecture/industry structure configurations: (i) *Horizontal Modular* (HM), (ii) *Vertical Integrated* (VI), (iii) *Vertical Modular* (VM), and (iv) *Horizontal Integrated* (HI). The first two configurations, the Horizontal Modular and the Vertical Integrated, are the two extremes between which an industry cycles in "an infinite double loop" (Fine, 1998, p. 43). However, the MOSIM allows us to identify also two other possible combinations, that is, Horizontal Integrated and Vertical Modular configurations. In the following section, the MOSIM will be used in the analysis of the Japanese mobile services industry.

Figure 1. The Mobile Services Industry Matrix (MOSIM)



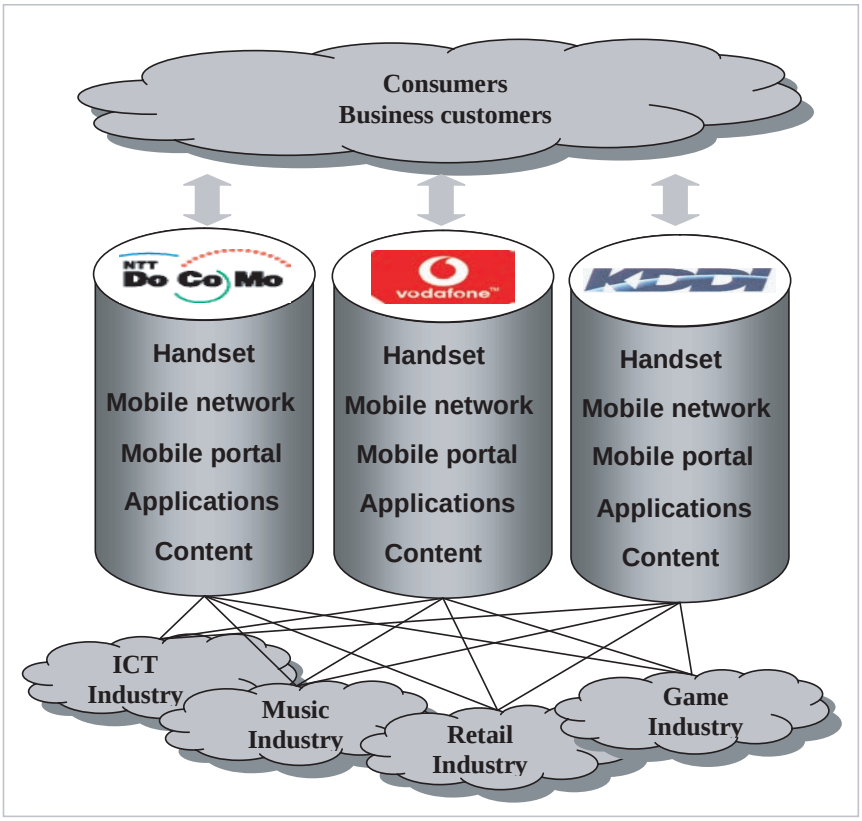
THE MOBILE SERVICES INDUSTRY IN JAPAN

There is a huge amount of academic and business research covering the various aspects of the Japanese mobile market (e.g., Baker & Megler, 2001; Funk, 2004; Kodama, 2002; Matsunaga, 2001; Natsuno, 2003; Vesa, 2003, 2005). Japan is considered to be one of the leading markets in the field of mobile Internet services: approximately 86% of the mobile phone subscribers (as of December 2003) also subscribe to the mobile Internet services, and over 20% of mobile operators average revenue per user (ARPU) comes from data access fees. For NTT DoCoMo the figures are even more impressive: almost 90% of DoCoMo's over 47 million subscribers are using the i-mode service. Furthermore, for FOMA user (the 3G service of DoCoMO), data ARPU is about 32%, which translates into over US$30 worth of data services per user each month (NTT DoCoMo, 2004). In addition the data access fees, the operators take 9–12 % of the revenue generated by content and services offerings by third parties.

In Japan, the industry structure is vertically integrated (see Figure 2) which means that mobile operators control directly or indirectly all different levels of value chain. Carriers act as wireless Internet service providers, access providers, mobile phone providers, retailers, and content aggregators (Baker & Megler, 2001). The Japanese mobile industry structure resembles the computer industry in 1975–1985 when the three largest companies (i.e., IBM, DEC, and HP) were highly integrated vertically (Fine, 1998). There is, however, one major difference: big part of the components used in the total service offering of the Japanese mobile operators comes from their partners.

In the Japanese mobile industry the competition is between business networks or ecosystems where the focal companies are the mobile opera-

Figure 2. Japan: Vertical integration with integrated product architecture



tors (see, e.g., Natsuno, 2003; Vesa, 2003, 2005). An excellent depiction of the Japanese mobile industry is the NTT DoCoMo case study by Kodama (2002), which describes the creation of a broad business network around DoCoMo's highly successful i-mode service. As Figure 2 demonstrates, the Japanese mobile operators are linking together several different industries such as the music industry and the game industry.

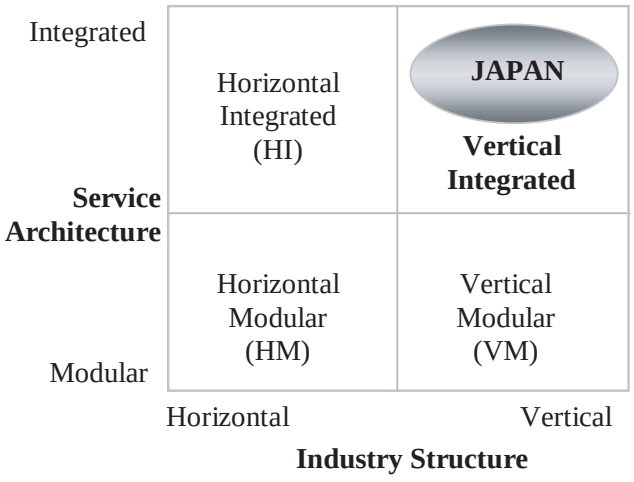
There seems to be an excellent match between the requirements of the next-generation mobile multimedia services and the traditional Japanese way of doing business. According to Hoshi, Kashyap, and Scharfstein (1991), one key component of the Japanese business environment is the concept of *keiretsu*, which is an industrial group that "coordinates the activities of member firms and finances much of their investment activity" (p. 34). Berger, Sturgeon, Kurz, Voskamp, and Wittke (1999) have named the Japanese business networks "captive value networks" that rely on dominant lead firms, i.e. suppliers of various elements of the mobile services (e.g., handsets, network technology, applications, content) are highly dependent on one or a few key customer firms. Lead firms often "urge affiliated suppliers to adopt specific

technologies" (Berger et al., 1999), as is the case in the Japanese operator-specific mobile networks and handset specifications.

The service architecture of mobile services is highly integrated in Japan. Mobile service offering consists of a handset, mobile network, and mobile portal (i.e., "a window" or "a door" to different kinds of mobile content and services) that are all closely integrated. Mobile phones are sold under an operator's brand and each phone model is designed to be used only in that operator's network. All three operators have their own mobile portal, which plays an important role in the mobile Internet business. Due to the limited screen size of a mobile phone and because of the huge amount of content available in mobile portals, it is very important how the links to various services are presented to the users when they access mobile Internet services. The last components of the Japanese mobile services business model are applications and content. Mizukoshi, Okino, & Tardy (2001) note that operators do not buy content from content owners or aggregators, nor do they create their own content, but they do control the content business through their certification process and billing service.

There are some disadvantages in the vertically integrated industry structure and integrated service architecture in Japan that have been identified in previous research. Perhaps the biggest disadvantage is that operators have to subsidize the price of the mobile phone—and the subsidy may be as high as 90% of the end-user price. Furthermore, mobile phone manufacturers are forced to develop and manufacture mobile phones that can only be used in one operator's network. According to Baker and Megler (2001), this increases the R&D and manufacturing costs in the Japanese system. It is important to keep in mind, however, that even the European "open and standardized" GSM world has been criticized for unfairness in the distribution of benefits resulting from standardization. As the CEO of a leading European mobile operator pointed out in his presentation in the 3GSM World conference in Cannes in February 2004, the only one to benefit from the fact Nokia manufactures over 100 million phones per year is the company itself—the benefits of

Figure 3. Positioning the Japanese market in the Mobile Services Industry Matrix



standardization remain within the walls of the mobile phone giant!

Due to the large domestic market of over 80 million mobile phone users, the Japanese operators have managed to reach a critical mass of users for their services, despite the lack of or limitations in the interoperability of the three commercial mobile networks in Japan (even though one could argue that at least from the technical point of view there are more than three mobile or cellular networks in Japan).

As Figure 3 demonstrates, the Japanese mobile services industry is positioned in the "Vertical/ Integrated" quadrant of the MOSIM. This concludes our brief overview of the Japanese mobile services market. Next we will examine what the Finnish mobile market looks like.

THE FINNISH MOBILE MARKET

Since the time Nokia introduced their first analog mobile phones and the state-owned telecom operator Telecom Finland (the predecessor of Sonera, which later merged with Swedish telecom operator Telia) opened their NMT (Nordic Mobile Telephony) network, Finland has been one of the world leaders of mobile telephony. The role of Finnish mobile market was also important during the launch of the digital GSM networks. Against this background it is easy to understand why the Finnish mobile market (despite the population of only 5 million people) is still considered to be an interesting subject for the research of the structure and dynamics of the mobile industry. The regulatory framework of the Finnish mobile market in particular receives much attention in different parts of the world, for reasons we will discuss later in this section.

The Finnish mobile services market is almost the opposite of the Japanese market. The industry structure in Finland is horizontal: the competition is taking place on each of the horizontal layers of the market, that is, operators are competing against each other, mobile phone manufacturers are competing against each other, and so forth

Figure 4. The horizontal and modular structure of the Finnish mobile market

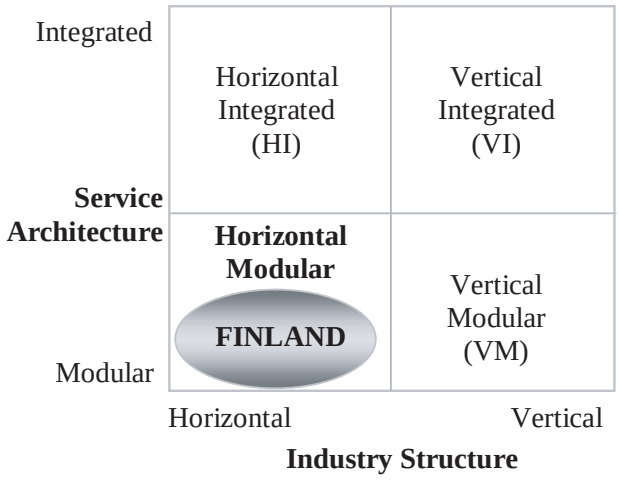
(see Figure 4). Finland is one of the few countries in Europe (along with Italy) that does not allow the use of so called SIM-lock, which prevents the users from switching to another operators network without paying penalties. In addition, the legislation in Finland prohibits mobile operators from bundling mobile phones and subscriptions—or more accurately, customers' decision to buy subscription must not affect the price of the mobile phone, in case subscription and mobile phone are sold at the same time. One of the implications of the contemporary regulatory framework is that mobile phones and mobile subscriptions are sold separately—and sometimes through different channels. An important element of the mobile business in Finland is so-called "finders fee," which operators pay to independent retail stores and chains (such as specialized stores selling only mobile phones, departments stores, and electronics and household appliance resellers) for each new subscriber. Therefore, it can be argued that the regulatory environment has a direct impact on the business models of the mobile services industry in Finland.

Handset subsidies and the bundling of mobile subscription and handset will be allowed for 3G handsets during a period of two years starting in the beginning of 2006. However, for the 2nd generation GSM handsets, bundling remains prohibited. The implications to the structure of the Finnish mobile services industry remain to be seen . The second largest mobile operator, Elisa (which has cooperative agreement with Vodafone), and handset manufacturer SonyEricsson would have preferred "the Central European" model that allows handset subsidies. The legislative authorities decided to maintain the existing legislation; in other words, operators are not allowed to subsidize the handset price. According to a representative of MINTC, authorities are prepared to reevaluate the situation if, for instance, 3G services, which were launched at the end of 2004, does not take off as expected.

As Figure 5 demonstrates, the Finnish mobile services industry is positioned in the "Horizontal/Modular" quadrant of the MOSIM.

This concludes our brief overview of the Finnish mobile services market. In the following

Figure 5. Positioning the Finnish market in the Mobile Services Industry Matrix



section we will focus on the differences between these two markets that represent the two extremes in the dichotomy introduced in the Double Helix model by Fine (1998) that has inspired the development of the MOSIM.

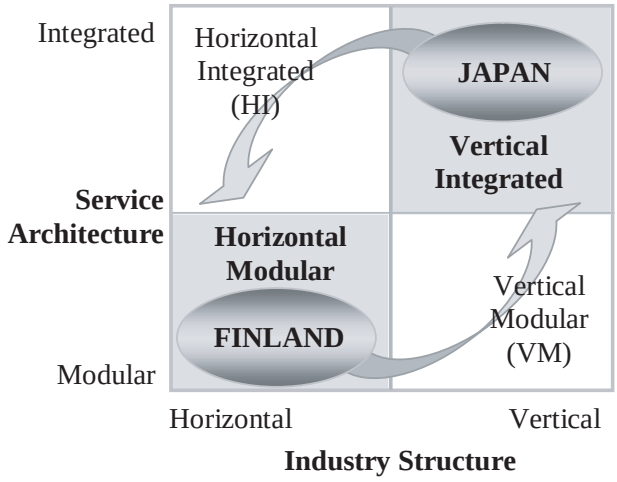
DIFFERENCES BETWEEN THE TWO MOBILE MARKETS

Next we will compare the structure and dynamics of the mobile services industries in Japan and Finland based on the MOSIM presented in section 2, and the analyses of the two markets presented in the previous two sections.

By now it has come very clear that the Japanese market (i.e., vertical/integrated configuration) and the Finnish mobile services market (i.e., horizontal/modular configuration) could not be farther apart from each other than what they are. This may not, however, be any permanent condition for neither of the markets. According to Fine (1998), neither vertical/integral nor horizontal/modular industry configurations are very stable as the forces of integration and disintegration are causing industry structures to oscillate between the two extremes in an infinite double loop. This led Fine to introduce the double helix of DNA as a metaphor when he wanted to describe the cyclic nature of industry evolution.

In Figure 6 the cycle between vertical/integrated and horizontal/modular is demonstrated by using the MOSIM. One of the benefits of the matrix approach when compared with the Double Helix loop is that it identifies the two types of intermediate market or industry configurations between the two extremes. The mobile services industry in a given country may evolve from horizontal/modular (HM) to vertical/modular (VM), for instance, if an operator chooses to use open and standardized product and service components, but wants to achieve more control in the market by integrating vertically upstream or downstream in the industry value chain, or even to different but related industries. Likewise, after moving from proprietary technologies to open standards, an industry may enter a configuration where industry structure becomes horizontal, but at the same time operators try to maintain an integrated service architecture. Later in this

Figure 6. The cycle between vertical/integrated and horizontal/modular configuration



chapter we will test the matrix model by adding a few more markets into the matrix.

Based on the analysis presented in this section, we can conclude that the industry structures of Japan and Finland are like day and night, or Yin and Yan. Next, we will try to see what is the impact of a given market configuration on the success of mobile services in the respective markets.

HOW SUCCESSFUL IS A GIVEN MARKET CONFIGURATION?

One of the objectives of this chapter is to study the relationship between an industry configuration (i.e., industry structure vs. service architecture), and the success of mobile services in a given market. In order to do this, we will next compare the key performance indicators (KPIs) of Japan and Finland. The assumptions behind this comparison are as follows:

- If industry configuration has a role in the success of mobile services, then there ought to be a significant difference in the KPIs of Japan and Finland because the industry configurations are practically the opposite.
- Success of mobile services can be measured by using the KPIs of the markets and the leading operators in the markets.

Table 1 presents some of the key performance indicators of the two case markets. The values presented here are not exact values but estimates

Table 1. Comparison of the Japanese and Finnish mobile services markets

Key Performance Indicators	**Japan**	**Finland**
Mobile phone subscribers (1,000)	84,3131 [1)]	4,880 [2)]
Mobile Network Operators	DoCoMo, KDDI, Vodafone	TeliaSonera, Elisa, Finnet
Industry structure	Vertical	Horizontal
Service architecture	Integrated	Modular
% of users using mobile Internet (excl. SMS)	***89%*** [1)]	**5%** [7)] (estimate)
ARPU US$ / user/ month	US$ 89[1)]	US$ 48 [3)]
Data ARPU % (incl. SMS)	***22 - 32%*** [4)]	**11-12%**
Non-SMS Data Revenue (Person-to-content)	14.3% [5)]	1% [6)]
Minutes of use (MoU)	219	157[3)]
Churn	1 – 1.5%[1)]	20 – 30 %[3)]

indicating the magnitude of a certain KPI (as all operators do not provide all the KPIs presented in this comparison).

What can we learn from the comparison of the KPIs of the Japanese and Finnish mobile markets presented in Table 1? Let us focus first on three items that are particularly interesting for the purposes of this chapter. As Table 1 shows, a huge majority of Japanese mobile phone subscribers use also mobile Internet services. For instance, over 89% of NTT DoCoMo's customers subscribe to the i-mode service (NTT DoCoMo, 2004). Unfortunately there is no such information available for the Finnish market, but according to some estimates the respective figure in Finland is less than 10%. What makes this comparison somewhat challenging is that in Finland SMS is used not only for person-to-person communication but also as a means of ordering ring tones, logos, wallpapers, and so forth, digital content to mobile phones. Premium rate SMS is also an important billing mechanism as operators do not offer any other micropayment services.

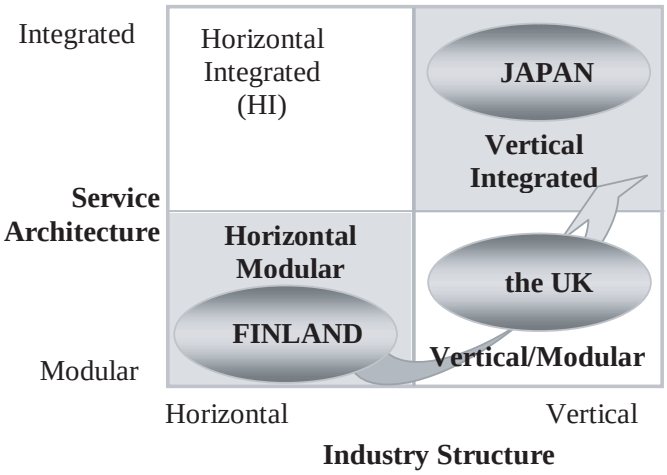
The second interesting item in Table 1 is the amount of data ARPU (average revenue per user) as a percentage of the total ARPU. In Japan data ARPU was 22% for Vodafone Japan's subscribers (mainly 2.5G users) and 32% for the subscribers of NTT DoCoMo's 3G services FOMA. In Finland data ARPU for the leading mobile operator Sonera was around 11–12% in Q3 2004. So despite the extensive use of SMS in Finland (for instance, the second largest operator's, Elisa's, subscribers sent on average 34 SMS messages per month; for Sonera this figure is below 30 messages per month), the Finnish operators are far behind the Japanese counterparts in making money with mobile data services.

The third item under scrutiny in this context is the amount of non-SMS data revenue, that is, the use of content over mobile networks (i.e., person-to-content services). Vodafone Japan reported in the end of the second quarter of 2004 that messaging represented 7.6% and data 14.3% of the total monthly ARPU. According to an estimate by a representative of a leading Finnish telecom operator, non-SMS data revenue in Finland is about 1% of the total ARPU.

Although this simple comparison of KPIs is not statistically relevant, it demonstrates the differences in the success of nonvoice mobile services in these two markets. Interestingly, both markets are considered to be advanced mobile markets—Japan because of the extensive use of mobile Internet services, and Finland due to high penetration rate of mobile phones and also because of the very low mobile phone call tariffs. It is also interesting that WAP services were introduced in the Finnish market roughly at the same time as NTT DoCoMo launched the i-mode service; however, while i-mode turned out to be a huge success story, WAP services failed miserably (although WAP technology is now starting to be an essential element of most mobile Internet services in Europe). Mobile networks in both countries were technically about on the same level although packet-based networks where first introduced in Japan. So if it was not about technology, timing, or people's willingness to adopt mobile technologies and services, why are mobile services much more successful in Japan and the gap seems to be growing? I argue that the vertical/integrated configuration of the Japanese mobile services industry has been more successful when the business paradigm is shifting from traditional voice-centric messaging-type services to content driven mobile Internet services.

Let us add one more market into our comparison. The UK market represents an interesting intermediary configuration between the Japanese and the Finnish markets. In the UK leading operators, such as Vodafone, mm02, T-Mobile, and Orange, have been building a new type of business model where mobile operators are orchestrating service delivery (i.e., moving from horizontal to more vertical industry structure) while maintaining more modular product architecture than the Japanese operators. If we add the UK market

Figure 7. The UK market in the Mobile Services Industry Matrix



into the MOSIM, we can see that we have now occupied a new quadrant of the matrix.

What we can see in Figure 7 is that the UK market is moving towards the vertical/integrated configuration, or the "Japanese model." This development is in line with the strategic statements by several leading European mobile operators who announced at the end of year 2002 that their goal was to increase operators' role in driving the mobile industry in the coming years. One of the reasons for this was the increasingly dominance of Nokia in the industry.

So how is the intermediate model of the UK doing, if we compare its success with Japan or Finland? The UK market is not even close to Japan but it has clearly advanced during the past 2 years. For instance, at Vodafone UK, data ARPU is close to 17% and the share of non-SMS data revenue is over 2%. If we compare these figures with the Finnish KPIs we can see that something has happened that has made the UK market more successful in the field of mobile services. Once again, I argue that this can be explained by comparing the differences in the market configurations.

DISCUSSION AND CONCLUSION

The objective of this chapter was to analyze the differences between the Japanese and Finnish mobile services markets by using the MOSIM. The matrix was derived from the Double Helix model developed by Fine (1998). The analysis revealed that the Japanese and the Finnish mobile industries represent very different kinds of market configurations: the Japanese market is a textbook example of vertically integrated industry structure, whereas the mobile services industry in Finland is currently in the horizontal and modular configuration. Our brief review of the UK market showed that there are also intermediate configurations between the two extremes. The transformation of the UK mobile services industry has been very fast, which indicates that

the industry clockspeed (Fine, 1996; Mendelson & Pillai, 1999) is high in the mobile services business. What is particularly interesting from industry evolution perspective in this analysis is the role of regulation in the evolution of the mobile services industry. Both the Japanese market and the Finnish market have stuck to their existing regulatory frameworks. In Japan, the national regulatory authorities did not open up the market for competition, whereas in Finland the regulatory authorities did not allow the use of SIM-lock and the bundling of subscription and handset that are typical characteristics of a vertical/integral market configuration (Vesa, 2004b). At the same time, the leading UK operators are transforming their business model towards a more vertical and integrated operator-driven business model as the regulatory framework in the UK does not prevent them from doing this. This approach seems to increase the use of nonvoice mobile services in the UK market, as the key performance indicators of the leading mobile network operators indicate. However, year 2005 appears to be a turning point both for the Finnish and the Japanese markets. As discussed earlier in this chapter, the Finnish government is in the process of allowing 3G-handset subsidies for a period of two years. At the same time, the Japanese government is in the process of opening the Japanese market for two to three mobile operators. This development in the Finnish and the Japanese markets illustrates the kind of oscillation between different market configurations described in the Double Helix model by Fine (1998).

This paper took a very challenging approach by carrying out a "macro-level" analysis of a fast-moving service industry. The analysis of two different markets that are almost the opposite of each other gave us the opportunity to identify the key characteristics of these two extremes of the continuum between horizontal/modular and vertical/integrated configurations. Even though this approach illustrates the structure and dynamics of the mobile services industry, it suffers from a well-known limitation of macro-level industry analysis: this kind of analysis is always very descriptive by nature, and gives little practical advice on how to solve the problems identified. I believe, however, that it is important both for business people and researchers who are involved in the mobile business to pay attention also to the structure and dynamics of the mobile services market where they develop and market their services. Experiences from the Japanese and the UK market indicate that a key player with enough market power (e.g., NTT DoCoMo in Japan or Vodafone in the UK) can succeed in reshaping the entire industry towards a more favorable industry configuration. There is, however, one precondition for this: the regulatory framework must not prohibit this kind of natural evolution of the industry, otherwise there is a risk that the development of mobile market is halted. The challenge for national regulatory authorities is to have the wisdom to see beyond the wishes and demands of the dominant players that may be stuck with the business paradigms of the past. In Japan the key question is how to make sure that the regulation of the mobile services industry evolves as the mobile phone market is becoming mature and new 3G technologies are being implemented. For the Finnish authorities a major challenge is to analyze whether regulatory framework that worked well in the highly standardized GSM voice market is still viable as the business moves towards more complex mobile multimedia services.

Chapter 2.27
A Mobile Intelligent Agent-Based Architecture for E-Business

Zhiyong Weng
University of Ottawa, Canada

Thomas Tran
University of Ottawa, Canada

ABSTRACT

This article proposes a mobile intelligent agent-based e-business architecture that allows buyers and sellers to perform business at remote locations. An e-business participant can generate a mobile, intelligent agent via some mobile devices (such as a personal digital assistant or mobile phone) and dispatch the agent to the Internet to do business on his/her behalf. This proposed architecture promises a number of benefits: First, it provides great convenience for traders as business can be conducted anytime and anywhere. Second, since the task of finding and negotiating with appropriate traders is handled by a mobile, intelligent agent, the user is freed from this time-consuming task. Third, this architecture addresses the problem of limited and expensive connection time for mobile devices: A trader can disconnect a mobile device from its server after generating and launching a mobile intelligent agent. Later on, the trader can reconnect and call back the agent for results, therefore minimizing the connection time. Finally, by complying with the standardization body FIPA, this flexible architecture increases the interoperability between agent systems and provides high scalability design for swiftly moving across the network.

INTRODUCTION

Many people nowadays use mobile devices such as personal digital assistants (PDA) or mobile phones to access information through the Internet. In addition, they desire to have the ability to

participate in e-business anywhere and anytime via their mobile devices. Current e-business applications, such as business-to-consumer (B2C) or Internet-based shopping, are typically developed over the Web for human-computer interaction. These applications require that users must login the intended Web sites from their personal computers or public terminals. Also, users often need to visit lots of sites and are always involved in a time-consuming process. To address these challenges, several wired agent-based e-business systems have been proposed. Kasbah (Chavez & Maes, 1996), for example, is an electronic marketplace where buying and selling agents can carry out business on behalf of their owners. Nevertheless, these systems do not satisfy the users' mobile demand due to their lack of wireless channels.

This article proposes a feasible architecture that combines agent mobility and intelligence for consumer-oriented e-business applications. It allows a user to create a mobile, intelligent agent via a mobile device, and then launch the agent to the Internet to perform business on the user's behalf. The aspect of mobility enables our architecture to support the agent's migration and the user's mobility (the ability to conduct e-business via mobile devices anyplace and anytime). The mobile agent will migrate from market to market, communicating with different trading agents to find the most appropriate one. Once an appropriate agent is found, it will inform the user of the results. This architecture complements the current Web-based, Internet systems by adding the wireless channel of mobile agents. Our current work focuses on lightweight mobile agents which act on behalf of consumers and participate in consumer-to-consumer (C2C) e-business applications. However, the architecture can be extended to business-to-consumer (B2C) or business-to-business (B2B) applications, as discussed later in the article.

Since personal software agents essentially need to communicate with other agents (to accomplish their designated tasks), they have to comply with a set of standards concerning the agent communication language and the protocols to be used. Although there is currently no universally accepted set of standards for developing multi-agent systems, the Foundation for Intelligent Physical Agents (FIPA), which aims at providing one language commonly understood by most agent-based systems (FIPA, 2006), is obtaining a growing acceptance. With FIPA becoming a de facto standard in this field, the architectures such as JADE (Java Agent Development Environment) have become available to allow for the implementation of a FIPA-compliant multi-agent system such as our proposed architecture (Chiang & Liao, 2004).

It should be noted that mobile devices suffer not only from limited battery time, memory, and computing power, but also from small screen, cumbersome input, and limited network bandwidth and network connection (Wang, Sørensen, & Indal, 2003). The proposed architecture, by making use of mobile agent technology, offers a solution to those problems. That is, after creating and initializing a mobile agent to act on the user's behalf, a user can disconnect the mobile device from the server. The user only needs to reconnect later on to recall the agent for results, hence minimizing the use of resources. In addition, mobile agent technology also addresses such challenges as increased need for personalization, high latency, demand for large transfers, and disconnected operation (Kotz & Gray, 1999).

The remainder of this article is organized as follows: the second section introduces background knowledge and related work. The third section illustrates the proposed architecture. The fourth section shows an implementation of the proposed architecture. The fifth section discusses some existing problems and future works. The sixth section concludes the article.

BACKGROUND AND RELATED WORK

Mobile Agent Paradigm

An intelligent agent is a piece of software, which differs from the traditional one by having such features as being autonomous, proactive, social, and so on. One of these characteristics is mobility, that is, the agents' ability to migrate from host to host in a network. Mobile agents are defined as programs that travel autonomously through a computer network in order to fulfill a task specified by its owner, for example, gathering information or getting closer to the required resources to exploit them locally rather than remotely. A mobile agent is not bound to the system on which it begins execution, and hence can be delegated to various destinations. Created in one execution environment, it has the capability of transporting its state and code with it to another host and execute in the same execution environment in which it was originally created. Several mobile agent systems have been designed in recent years. Telescript (White, 1996) is the first commercial mobile agent system developed by General Magic. Telescript provides transparent agent migration and resource usage control. Aglets from IBM (Lang & Oshima, 1998) is also a mobile agent system based on the concept of creating special Java applets (named aglets that are capable of moving across the network). JADE (Bellifemine, Caire, Trucco, & Rimassa, 2006) is one of the agent development tools that can support efficient deployment of both agents' mobility and intelligence in e-business applications. As a middleware implemented in Java and compliant with the FIPA specifications, JADE can work and interoperate both in wired and wireless environments based on the agent paradigm. JADE supports weak mobility; that is, only program code can migrate while no state is carried with programs. NOMADS (Suri et al., 2000) supports strong mobility and secure execution; that is, the ability to preserve the full execution state of mobile agents and the ability to protect the host from attacks.

Recently, mobile agents have found enormous applications including electronic commerce, personal assistance, network management, real-time control, and parallel processing (Lange & Oshima, 1999). Kowalczyk et al. (2002) discuss the use of mobile agents for advanced e-commerce applications after surveying the existing research. There are many advantages of using the mobile agent paradigm rather than conventional paradigms such as client-server technology: reduces network usage, introduces concurrency, and assists operating in heterogeneous systems (Lange & Oshima, 1999).

Related Work

Mobile agents have been recognized as a promising technology for mobile e-business applications. The interest of developing mobile agent systems for mobile devices has increased in recent years. Telescript describes a scenario in which a personal agent is dispatched to search a number of electronic catalogs for specific products and returns best prices to a PDA from where it starts (Gray, 1997). An integrated mobile agent system called Nomad allows mobile agents to travel to the eAuctionHouse site (http://ecommerce.cs.wustl.edu) for automated bidding and auction monitoring on the user's behalf even when the user is disconnected from the network (Sandholm & Huai, 2000). They aim at reducing network traffic and latency.

Impulse (2006) explores a scenario in which e-business meets concrete business through a system of buying and selling agents representing individual buyers and sellers that carry out multiparameter negotiation and running on the wireless mobile devices. Impulse deploys personal agents on mobile devices to help users seek agree-

ment on purchase terms. However, these personal agents are directed to move online to participate in negotiations, and hence resulting in potentially long-time connection with the Internet. We also think that the Impulse system was designed with a single communication protocol for all agents. This presents drawbacks due to the heterogeneity of exchanged information and leads to an inflexible environment, which can only accept those agents especially designed for it. Agora (Fonseca, Griss, & Letsinger, 2001) is a project conducted at HP Labs to develop a test-bed for the application of agent technology to a mobile shopping mall. A typical scenario consists of mobile shoppers with PDAs interacting with store services while in the mall, on the way to the store, or in the store itself. The Zeus agent toolkit, developed by British Telecommunications, was used to implement all agents in the Agora project. Only the infrastructure agents speak the FIPA Agent Communication Language (ACL), causing the architecture to conform partly to FIPA, although more effort in conformance is needed. The purpose of the Agora project is to gain experience in agents' communication protocols and to realize the significance of architectural standards.

It has been shown that modern agent environments such as JADE could be easily scaled to 1,500 agents and 300,000 messages (Chmiel et al., 2004). Thus, it is now possible to build and experiment with large-scaled agent systems. Moreno et al. (2005) use JADE-LEAP (JADE Lightweight Extensible Agent Platform) to implement a personal agent on a PDA. This agent belongs to a multi-agent system that allows the user to request a taxi in a city. The personal agent communicates wirelessly with the rest of the agents in the multi-agent system, in order to find the most appropriate taxi to serve the user. IMSAF (Chiang & Liao, 2004) is an architecture designed to fulfill the requirements of Impulse-introduced mobile shopping and implemented using JADE-LEAP tools. LEAP can also be used to deploy multi-agent systems spread across mobile devices and servers; however, it requires a permanent bidirectional connection between mobile devices and servers. Considering the current expensive connection fees for cell phones, such a required permanent connection is not affordable for consumers in practice.

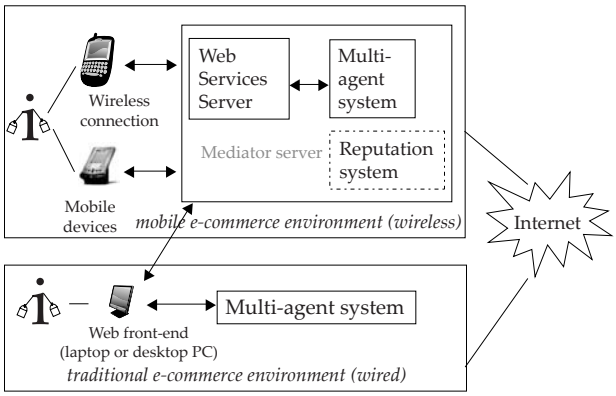
In contrast to the above works, we are motivated to propose a mediator-based architecture that attempts to enable users' wireless participation in several e-marketplaces through their mobile devices. The mobile agents can move across the network and perform trading tasks on behalf of their users when the users are disconnected from the network. We believe that it is important to consider the limitations of mobile devices, such as low-battery, low bandwidth, high latency, limited computing ability, and expensive connection fees. The fact that consumers in our physical world may need to access the worldwide markets and distributed e-business environments requires the agents to operate in heterogeneous and dynamic environments as well as to talk a common language. By complying with the FIPA specifications, the proposed architecture provides an interoperable solution to allow users dynamically to connect to the network by means of their mobile devices only when needed. Also, the mobile devices will not suffer those limitations mentioned above. In addition, the benefit of using mobile agents to a user becomes more obvious in our architecture if the user has a mobile phone and is interested in minimizing expensive connection costs. The next section explains the architecture in more detail.

SYSTEM ARCHITECTURE

Overview

Figure 1 shows a distributed C2C wireless e-business environment and a traditional wired e-business one. A consumer can connect a mobile device, such as a PDA or mobile phone, to the mediator server through wireless connection and then send a request for creating a mobile buying

Figure 1. Distributed e-business environment



or selling agent to undertake a specific business task (e.g., auction bidding) on the user's behalf. A personal agent that resides on the mobile device is needed to interact directly with the consumer and to consider the consumer's personal preferences. Considered as a true representative of the consumer, the personal agent represents the consumer's interests and allows the consumer to have a choice of dispatching either a buying or a selling agent. The mediator server sits in the fixed network and provides services such as generating mobile agents according to consumers' requests. After being created, the mobile agents will autonomously travel to multiple agent-based servers on the Internet. The agent-based servers offer places for selling and buying agents to meet and negotiate with one another. The proposed mediator server contains two main components: the Web services server, which facilitates mobile agents to interface with other agents, and the multi-agent system, which manages the agents and plays the role of a marketplace similar to an agent-based server. An additional component, a reputation system, will be necessary in our architecture. Using this reputation system, agents could sign binding contracts and check user's credit histories and reputations. The trust problem will be further studied in future research (e.g., Jøsang & Ismail, 2002 present a Beta Reputation System). Also, the mediator server provides a Web-based interface, and as shown in Figure 1, a consumer can also connect a laptop or a desktop PC to the network and launch an agent to execute on the mediator server.[1] In this article, we focus on the electronic trading of second-hand products for owners of mobile devices.

The main idea is that a consumer will request the mediator server to create a buying or selling agent and then dispatch it to agent-based servers on the Internet. The main operation that occurs in an agent-based server is price negotiation where buying agents negotiate price with selling agents. According to the consumer's preferences, the buying agent may travel to different e-market sites known by the white-page agent[2] to seek goods, when the consumer desires to conduct a global multiple markets comparison. The W3C's XML schema specification (www.w3.org/XML/Schema) provides a standard language for defining the document structure and the XML structures'

data types. The consumer's preferences can be represented in an XML format. In a real business situation, we would have to ensure that messages are reliably delivered to the mediator server from the personal agents. Although this communication protocol's reliability is not detailed in our architecture currently, we could use a reliable transport at the very least, such as Reliable HTTP (HTTPR) (Todd, Parr, & Conner, 2005), for the communication between the personal agents and the mediator server. Another consideration is to encrypt the communication. Encryption technologies can also help ensure that even intercepted transmissions cannot be read easily.

A Scenario of Our Architecture

To understand the environment best, let us consider a typical scenario taken from daily life, where two hypothetical customers, named Mary and Tom, try to participate in an eBay-like auction. Mary wants to sell her used Sony MP3 player. At her office, she initiates a selling agent from a PDA, through a wireless LAN connection with the mediator server in the building. Then this selling agent lives in the server and waits for potential shoppers. Due to some unpredictable event, Mary may have to leave her office and cannot access the selling agent via her PDA (as there may be no available wireless LAN network coverage). However, she will be able to reconnect later on.

Haphazardly, Tom enters his buying preferences into his Java-enabled mobile phone, trying to buy a second-hand Sony MP3 player under a maximum price. The personal agent on his mobile phone establishes a connection with the mediator server and asks the server to launch a mobile buying agent according to his preferences. Then Tom disconnects his cell phone from the server. The mobile agent knows where and how to migrate, as instructed in the migration itinerary. As days pass, while this buying agent is roaming around the Internet, it enters into Mary's mediator server and searches for services provided. After the negotiation between the selling agent and buying agent, they reach an agreement on the item and price. With that, the buying agent will return to its host server and send a SMS (Short Message Service)-based notification to the personal agent running on Tom's mobile phone, about the potential seller gathered from the Internet. Also the selling agent sends an e-mail-based notification to the personal agent running on Mary's PDA. Finally, things left to Mary and Tom seem to be simple and easy since they could have either the cell phone number or the e-mail address from the information reported by their personal agents, respectively. As we have seen, mobile consumers only need a small bandwidth connection twice, once for initiating a migrating mobile agent and once for collecting the results when the task is finished.

Architecture Description

We explain how the whole system works in this section. Figure 2 illustrates the system architecture and the operation process. As shown in Figure 2, mobile devices are supported by personal agents and connected to the mediator server via a wireless connection. A personal agent is a static agent running on a mobile device and offers a graphical user interface (GUI) for its user to communicate with the system. The mediator server is connected to the Internet where other mediator servers or other FIPA-compliant systems exist. In the mediator server, a servlet answers any requests from the personal agent and is linked to the behavior of a proxy agent[3] in charge of handling the requests. The proxy-agent interfaces with the servlet and constructs a bridge between the Web service server and the multi-agent system. Each instance of the behavior[4] connects not only to the AMS agent (Agent Management Service as defined in FIPA, i.e., the white-page agent mentioned above), asking for the creation of a buying or selling mobile agent in the multi-agent system as well as providing a response, but also connects to the

agent DF (Directory Facilitator as defined in FIPA, i.e., the yellow-page agent), retrieving the list of agents advertising services with the DF. In this architecture, the multithreaded-servlet server is mirrored by a multibehavior proxy agent to allow for handling multiple requests in parallel.

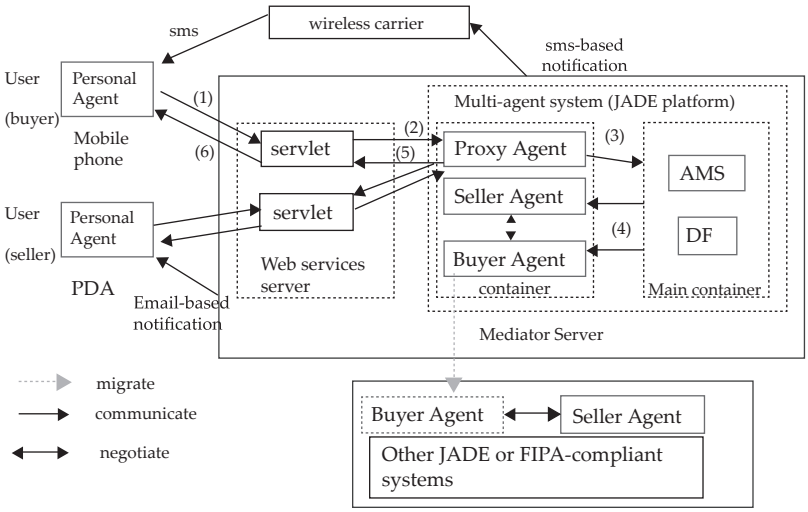
As illustrated in Figure 2, the procedures from (1) to (6) depict how a buying or selling mobile agent is created by a user according to preferences:

1. At the first step, the user configures the preferences via the personal agent (residing in the mobile device). The personal agent then sends an XML-based request to the mediator server.
2. An instance of the servlet accepts the request and communicates with the proxy agent.
3. The proxy agent cooperates with the AMS agent who lives in the main container of the JADE platform to create a buying or selling mobile agent.
4. If the buying or selling agent is created successfully in the container, it might be mobilized to other systems to undertake the user's task.
5. and (6) The personal agent receives a response from the proxy agent via the servlet and informs the user of the relevant mobile agent being created.

The above is an asynchronous process after which the user can disconnect from the network at will. Even if the user decides to disconnect from the network, the user will still receive an SMS-based notification from the mediator server via an interface with the wireless carrier, or an e-mail-based notification from the mediator server via an interface with a mail server, as long as the user reconnects to the network.

The mediator server provides the required support for the creation of mobile agents, messaging among agents, agent migration facility, collaboration, protection, destruction, and control

Figure 2. System architecture and process



of mobile agents. Mobile agent platforms such as JADE have been proposed to provide the supporting environment. Obviously, any multi-agent system can be used here as long as it provides the required support.

Different Types of Agents in Our Architecture

The following agents co-exist in our architecture: personal agents, proxy agents, buying or selling agents, yellow-page agents, and white-page agents. Among them, only buying or selling agents are mobile agents, while personal agents and proxy agents are stationary agents. Both the yellow-page and white-page agents are fixed on a component of the mediator server. Details of these agents are described as follows:

A personal agent is a stationary agent that runs on a user's mobile device and provides a graphical interface to allow the user to configure a mobile buying or selling agent (from the mobile device). When starting the personal agent on the mobile device, the user can choose either to initiate a new mobile agent or to recall a previous mobile agent. One may argue that such a personal agent is nothing more than an interface. From the agent's viewpoint, however, the personal agents are able to autonomously communicate with the proxy agent which is running in the mediator server.

A proxy agent is also a stationary agent which links the multi-agent system to the Web service server. It is one of the agents that is always up and running in the multi-agent system. The proxy agent cooperates with the AMS (white-page) agent to create a mobile buying or selling agent for each user. There is only one proxy agent per mediator server due to its unique multibehavior ability.

A yellow-page agent (such as the DF agent in the JADE platform) provides the service of yellow pages, by means of which an agent can receive information about available products or

Table 1. Attributes of a mobile agent

Attribute	Description
Agent type	The agent type that a user can select, that is, either a buying agent or a selling agent
Agent server	The configuration of the mediator server address.
User id	The user identification which can be email address, cell phone number, or IMEI (International Mobile Equipment Identity).
Quantity	Quantity of the predefined product.
Price	For a buying agent, this is the maximum price that the agent can bid: for a selling agent, this is the minimum price that the agent can accept.
Current Price Inquired	For a buying agent, this is the best price offer colledted from the Internet.
Lifetime	The total time an agent can be away before being recalled or terminated.
Mobility	Specification of whether a user desires to enalbe the agent's migration ability (i.e., in the context of a local, single or global, multiple market comparison).
Server Activity Time	The time an agent can spend on each server before migrating ot another.

find other agents providing necessary services to achieve its goal. A white-page agent (like the AMS agent in the JADE platform) represents the authority and provides naming services. It stores information about addresses and identifiers of all agents in the system. In our architecture, sellers have permission to advertise their products; and buyers are allowed to query the sellers which post the products they are looking for. Selling agents update yellow pages by publishing their services via the yellow-page agent. Buying agents query relevant services from the yellow-page agent. Both buying and selling agents update white pages by registering in or deregistering from the system. They communicate with each other via querying agent's information from the white-page agent.

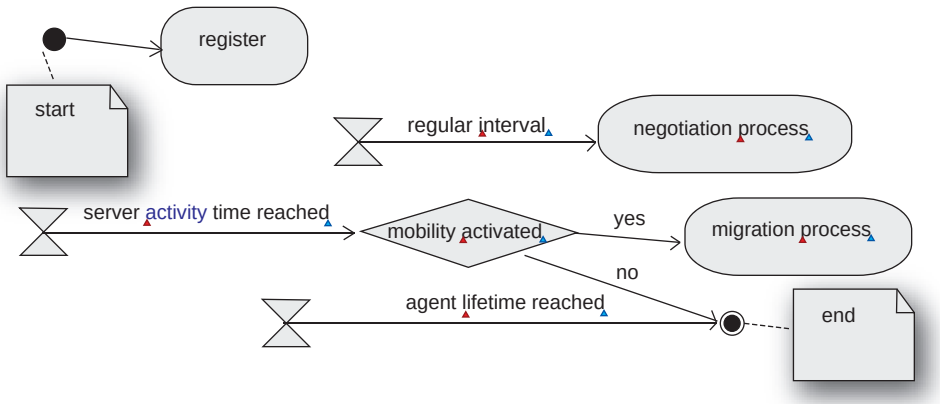
Both buying and selling agents are mobile agents, which are also called *service agents.* A service agent is the counter part of a personal agent and is involved in the migration from host to host on the Internet. A service agent first negotiates with other service agents in the same host mediator server before migrating among multiple Web sites to talk to other service agents, provided that they can talk a common language.

To demonstrate a useful mobile agent system, we present a prototype for buying and selling agents, with attributes depicted in Table 1. This means that a user will configure a mobile buying or selling agent on a mobile device, precisely according to the characteristics in Table 1.

Behaviors of Mobile Agents

As illustrated in Figure 3, a mobile (buying or selling) agent starts with its registration in the system and ends with a timeout of its lifetime. There are three time events that indicate the behaviors of a mobile agent: (1) the agent starts its negotiation process at a regular interval (e.g., every minute); (2) the agent starts its migration when activity time per server is reached; and (3) the agent ends its life cycle when its lifetime is exhausted. An argument may arise; how can one be sure that the mobile agent will be terminated according to the parameter and lifetime, as users prefer? This parameter may be changed by a third party (including the mediator server). The assumption we made is that the mobile agent can be protected from the attacks (e.g., from

Figure 3. Activity diagram of mobile agent



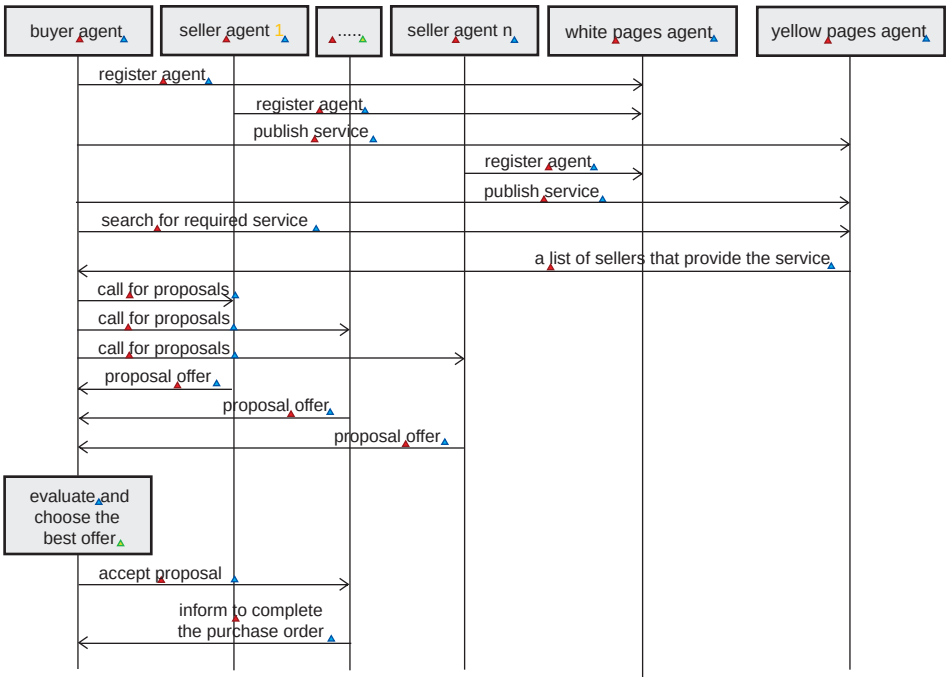
the host or other agents) once a future security mechanism is imposed on our architecture. (The security problem is discussed in the Discussion and Future Work section.)

Negotiation Process

The proposed interaction between agents complies with the FIPA-Contract-Net Protocol (FIPA, 2006). This protocol allows a buying agent (initiator) to send a call for proposals (CFP) to a set of selling agents (responders), evaluate their proposals, and then accept the most preferred one (or even refuse all of them). Both initiators and responders should register in the system before they negotiate with each other.

In this article, we consider a classical situation in which a selling agent offers a single item to the highest bidder (similar to eBay), and the simplest type of bid is an offer to buy or sell one unit at a specified price. As shown in Figure 4, the buying agent sends a CFP to all the available selling agents (obtained from the yellow-pages service). After receiving the message, a selling agent can send the buying agent a proposal with the price for the product. If the product is not available or sold, it does not need to send any proposal. The buying agent will place a purchase order if the offer price is within the maximum price that the customer has specified. Results of price negotiations are sent back to the personal agent and showed in a graphical interface to the user. Since the system is fully asynchronous, an intention to make a purchase does not have to lead to a successful transaction. By the time the offer is made, other buying agents may have already purchased the last available item.

Figure 4. Negotiation process



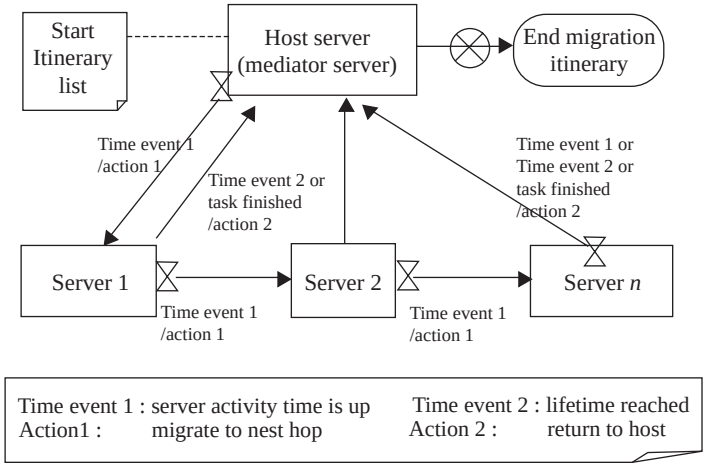
Agent Migration

The general process of migration is depicted in Figure 5. An agent starts its migration from its host server (i.e., the mediator server) with the itinerary list acquired from the host. We assume that there are *n* servers, which will be visited by the agent in sequence. In each server, two time events happen resulting in two actions respectively: if the agent reaches its lifetime, it will return to its host where it was created, and then end the migration process; if the agent exhausts its server activity time, it will migrate to the next server. Additionally, before the agent migrates to the next server, it should also make the decision if it has fulfilled the task at the current server. As we know, a task is finished when an agent receives an acceptable offer from another agent. The migration process actually describes a scenario of price comparison (finding a price less than a buyer's reservation price for buying, or searching for a price greater than a seller's reservation price for selling). The agent may access its host server repeatedly during its lifetime and updates its itinerary list every time when visiting its host server. One interesting problem here is how the mediator server maintains the itinerary list that includes a series of service-providing servers to be visited by the agent. Curbera, Duftler, Khalaf, Nagy, Mukhi, and Weerawarana (2002) state that "several individual companies and industry groups are starting to use 'private' UDDI directories to integrate and streamline access to their internal services" (p. 90). UDDI (Universal Description, Discovery and Integration) (UDDI, 2006) enables businesses to publish service listings and to discover each other. We assume that the white-page agent can interact with the UDDI server to obtain other service-providing servers' addresses (the feasibility of this function will be further studied) and therefore mobile agents can update the itinerary list during their migration. Only the mobile agents, which are originally created in this mediator server, are allowed to access this resource (a list of servers).

System Implementation

We have implemented a simple prototype to evaluate the concepts proposed in our architecture,

Figure 5. Agent migration process



using the Java programming language. Figure 6 shows the screenshots of a personal agent and a JADE-based multi-agent system, respectively. The personal agent was developed as a J2ME MIDlet[5] application that offered a graphical interface for its user to initiate or recall the mobile agent, and to dialogue with the mediator server. The mediator server played an important role in our architecture, running a Tomcat Apache Servlet Engine on a JADE platform. JADE is an open-source with good scalability, one of the best modern agent environments compliant with FIPA. As shown in Figure 6, there are two containers on the JADE system, Main-container and Container-1. Main-container holds the basic management agents defined by FIPA (AMS, DF, and RMA, which manages the GUI of the JADE platform). The proxy agent, buying agents, and selling agents run in Container-1. We can deploy the mediator-based architecture in one or several PCs.

The Web services architecture communications are based on JSR172, J2ME Web services, which include two independent parts: the JAX-RPC and JAXP. XML is chosen as the standard way for clients to interact with backend servers so as to use the remote services. J2ME JAX-RPC APIs subset solves how to access the SOAP/XML Web services and JAXP APIs subset solves how to

Figure 6. Screenshots of a personal agent and the JADE platform

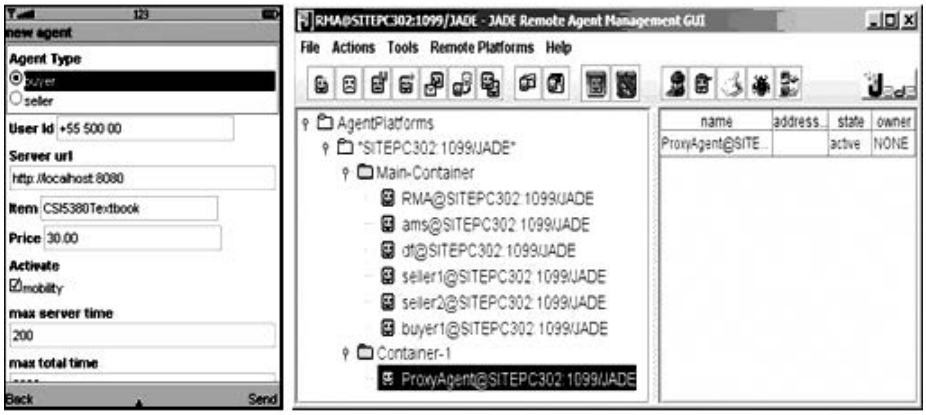


Figure 7. Experiment environment

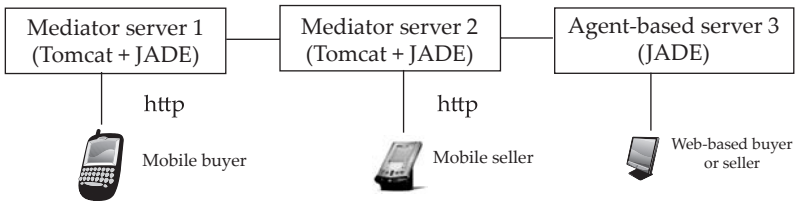

process the XML messages. Messages exchanged by agents in the multi-agent system have a format specified by the ACL language defined by FIPA for agent interoperability.

As shown in Figure 7, we deployed three servers in the Local Area Network, installed J2ME MIDlet in two mobile phone simulators, provided one GUI for the Web-based seller, and simulated a simple used-item electronic trading scenario similar to the one we described in A Scenario of Our Architecture section previously. The mobile phone emulator is a tool provided by the Sun J2ME wireless toolkit 2.2. Both mediator servers deployed the Tomcat server and the main container of JADE platform was initialized. The third computer played the role of an agent-based marketplace on the Internet. For the buyer's emulator, the user activated the mobility of the buying agent, but it was not the case for the seller's emulator. We observed the following results:

- Mobile users can connect to mediator servers via HTTP and initiate mobile buying or selling agents in the mediator server.
- Mobile users do not need to instruct their mobile agents of what to do after configuring their preferences.
- Mobile users can add new items anytime and relevant mobile agents will be created to handle the trading of these new items respectively.
- Mobile users can kill their mobile agents to cancel their tasks by sending instruction to their personal agents.
- Mobile agents are active in their servers within the specified server activity time and then migrate to other servers.
- Buying agents can reach agreements with selling agents when the required item and price are matched. Mobile users then receive text messages from their agents, displayed on the screen of the simulators.
- Mobile agents end their life cycles when finishing their tasks.

As confirmed by the experiments, mobile users connect to their servers only when they need to add new items or to cancel their tasks. This obviously results in such benefits as reduced bandwidth utilization, increased battery life for mobile devices, and no complicated computation conducted in mobile devices. Also, mobile agents can move to various servers to negotiate autonomously, and mediator servers can accept mobile agents from outside their systems. This feature enables users to participate in multiple markets on the Internet.

In particular, we observed the migration process of a mobile agent. Mobile agents should be active in their servers within a specified time and migrate among the servers. Thus, we developed a scenario where we supposed that a buying agent started from Server1 and continued searching for the required product or service in Server2 and Server3. We set up two parameters for this mobile agent: Maximum server active time was set to 100 seconds and total lifetime was set to 850 seconds. As expected, the buying agent contacted the other agents in Server1 and then migrated to Server2 after approximately 100 seconds. Similarly, the buying agent communicated with other agents in Server2 and then traveled to Server3. The same things happened in Server3. Because there were no more sites to be visited, the buying agent migrated back to Server1, ending its first round of migration. The second round was started since the total lifetime was not reached. We assumed that no sellers offered the required product or service to this buying agent. With the time elapsed, the buying agent was in its third round and roamed into Server2. At this stage, the buying agent used up its lifetime of 850 seconds and predicted an ending of its life cycle. Therefore it migrated back to the host Server1, even though the third round trip was not finished. In another scenario, we used the same parameters for the buying agent, except that the total lifetime was enlarged to 1,000 seconds. The difference was that we dispatched a selling agent in Server2 at

the moment the buying agent was ready to launch its third round trip. This selling agent offered exactly the service that the buying agent needed. As we expected, the two agents met and reached an agreement after negotiating with each other. This experiment confirmed that after completing its task, the buying agent migrated back to Server1, regardless of its remaining lifetime that had not yet been exhausted.

DISCUSSION AND FUTURE WORK

In this article, we propose a feasible mobile agent architecture that assists users in C2C e-business. It enriches the resources for users to perform comparison shopping activities at the point of purchase. Users' mobile devices connect to the network only when needed, thus making efficient use of limited bandwidth and reducing the network traffic. In addition, it helps cell phone users save money from their expensive bills. At any time, users may add items via their personal agents and specify their preferences such as time limit and preferred price for trading. Through the negotiation process between mobile buying and selling agents, users also gain valuable information for making trading decisions.

Our proposed architecture is extensible: On the one hand, XML-based communication is used to enhance extensibility; on the other hand, the architecture could be easily extended to B2C, or even B2B business models. That is, not only individuals but also business companies can be attached to the architecture. With mobile phones and PDAs already being used as extended enterprise tools, business companies, such as retailers and suppliers, can publish their products and/or services on their servers via mobile devices. As long as these businesses take part in our architecture parties, they could benefit from the automatic discovery of other business partners. Also, it is possible for businesses, especially for retailers, to sell their products to potential buyers in the manner described in the proposed architecture as an extra way to their traditional ones. In this sense, our architecture is an integration model of C2C, B2C, and B2B e-business. Nonetheless, using mobile devices for complex tasks can be quite frustrating (e.g., difficult to enter data), so probably people will not use it. An idea is to incorporate targeted messaging or advertising into our model, where businesses could send a message to users who are physically located in their vicinity. Agents could negotiate a transaction, and the buyer would already be located nearby to complete the purchase and pick up the item.

Currently, we present a conceptual framework that needs to be refined. Using this work as a starting point, we have outlined a number of future research directions:

1. Negotiation protocols do not have to be hard-coded into the agents. Instead, mobile agents can adapt to any intelligent negotiation strategies when they arrive at a new remote location. Thus, our architecture paves the way for future research in which more general architectures can be explored to allow mobile agents to participate in a variety of negotiation protocols, such as factor negotiation (price, quality, delivery time, etc.), electronic contracting, and so on. Currently, the negotiation strategy module consists of only a purchase determined by price (agents seek a preferable price by a fixed amount). FIPA defines auction protocols (e.g., Dutch and English auctions) as well as simpler strategies such as fixed pricing, fixed pricing with a discount, and so on. We will add them into the negotiation protocols in our future research.
2. Items are described only by their names. Obviously, other attributes, such as color, age, terms of warranty and delivery should also be considered. We believe that ontolo-

gies can help to solve this problem. It should be noted that the small screen of mobile devices will bring inconvenience to users when they specify many attributes of an item. A possible solution is to make use of the persistent memory of mobile devices to store the users' preferences.

3. Mobile agent technology currently has some limitations, such as identity management, fault tolerance, protection of agents, and resource security. These limitations have brought up some concerns about the practical utilization of mobile agents. For example, in the area of security, e-business applications are often involved with money and thus users may hesitate to use mobile agents, unless mobile agents are secure enough to be trusted.

In the situation presented in this article, the mobile agents representing different buyers or sellers migrate over the Internet and then execute themselves on remote computers. These mobile agents are thus exposed to open environments and may become vulnerable. Since the mobile agents execute on unknown computers and interact with unknown agents, a reliable security infrastructure is vitally needed for the design of the system. The mobile agents must be able to deal with situations where they have been shipped off to the wrong address or to a hostile environment (Neuenhofen & Thompson, 1998). Listed below are some possible security concerns:

- Malicious mobile agents can try to access services and resources without adequate permissions. In addition, a malicious agent may assume the identity of another agent in order to gain access to platform resources and services, or to cause mischief or even serious damage to the platform.
- Mobile agents may suffer eavesdropping attack from other mobile agents. A malicious agent can sniff the conversations between other agents or monitor the behavior of a mobile agent in order to extract sensitive information from it.
- Mobile agents may suffer alteration attack from malicious hosts. To execute the agent and update its state, the host must definitely be capable of reading and writing the agent. A malicious host may steal private information from the agent or modify the agent to compute the wrong result or to misbehave when it jumps to another site.

Current research efforts in the area of mobile agent security adopt two different perspectives (Kotz, 2002): First, from the platform perspective, we need to protect the host from malicious mobile agents (such as viruses and Trojan horses) that are visiting it and consuming its resources. Second, from the mobile agent perspective, we need to protect the agent from malicious hosts. There are many mechanisms to protect a host against malicious agents. Digital signatures and trust management approaches may help identify the agent and evaluate how much it should be trusted. The malicious host problem, in which a malicious host attacks a visiting mobile agent, is the most difficult problem. We found in the literature some works on powerful techniques such as Sandboxing and Proof-Carrying Code (PCC). Sandboxing (Wahbe, Lucco, Anderson, & Graham, 1993) is a software technique used to protect a mobile agent platform from malicious mobile agents. PCC (Lee & Necula, 1997) introduces the technique in which the code producer is required to provide a formal proof that the code complies with the security policy of the code consumer. Therefore, we envisage that the security of mobile agents is an important issue that will encourage techniques and mechanisms for e-business in the future.

CONCLUSION

We propose in this article an e-business architecture that allows traders to do business at remote locations by means of mobile intelligent agents. Our architecture, which adheres to standardization efforts in the multi-agent field such as FIPA paves a possible way towards a near future when mobile buying (and selling) agents can smoothly travel among different agent-based marketplaces to carry out tasks on their users' behalves. Our purpose of presenting this idea is to improve our understanding of the value of mobility and to encourage the conceptual construction of a global community. We do not claim that buyers and sellers around the world would have to buy into this to make it work, and that worldwide C2B e-commerce would be revolutionized thereby. In practice, however, we hope that our work would be useful on a smaller scale and lead to new investigations that may result in new solutions to the problems we addressed. Our proposed architecture, aimed at providing new capabilities for advanced e-business solutions, employs an approach that integrates intelligent and mobile agents. Intelligent agents can provide automation support for decision-making tasks, while mobile agents can extend that support by allowing users to participate in several marketplaces in a networked e-business. We believe that intelligent and mobile agent technology is also a promising solution to the problems of low speed, high latency, and limited computing ability that the current wireless network is facing.

ABSTRACT

This chapter introduces a framework for designing, distributing, and managing mobile applications that uses and updates information coming from different data sources (databases and systems from different organizations) for helping mobile workers to perform their job. A summary of the state of the art in relation to mobile applications integration is presented. Then, the authors describe the appropriate organizational context for applying the integration framework proposed. Next, the framework components and how the framework is use are explained. Finally, the trials performed for testing the mobile applications architecture are discussed, presenting the main conclusions and future work. Furthermore, the authors hope that understanding the concepts related to the integration of mobile applications through the presentation of an integration framework will not only inform researchers of a better design for mobile application architectures, but also assist in the understanding of intricate relationships between the types of functionality required by this kind of systems.

INTRODUCTION

Many workers in current organizations perform their activity in mobile environments. Sellers, architects, doctors, veterinarians, and so forth perform the most part of their work outside an office, many of them in cities or at rural and remote areas. Moreover, in many cases, the information required for mobile workers comes from different information systems and databases owned by different organizations or providers, so it is necessary to provide mobile workers with devices (handhelds, pocket PCs [personal computers], tablet PCs, etc.) with software systems that employ user interfaces appropriate for this kind of devices, and with the capabilities for accessing and updating several information systems.

In order to solve this problem, an integration framework, called DAVINCI, has been defined. DAVINCI is a framework for providing mobile workers with mobile software applications to query and update information coming from different and heterogeneous databases.

The DAVINCI project was first tested with the main aim of developing a solution to help veterinarians performing in-field sanitary inspections in cattle holdings across European Union countries; DAVINCI was tested by veterinarian services from Spain, Bulgaria, Latvia, and Czech Republic.

During these trials, we identified that one of the main advantages of the DAVINCI architecture is its capability to be integrated together with different European databases for animal health controlling (for instance, EUROVET in Bulgaria or SIMOGAN in Spain registering cattle census and movements). DAVINCI also permits the development of new data warehouse systems compliant with the previously cited regulation, providing large economic costs savings. On the other hand, DAVINCI is easily adaptable to procedures in different countries, each with a singular culture and organizational structure regarding the responsibilities for livestock sanitary control.

STATE OF THE ART

Mobile computing devices (smart phones, PDAs (personal digital assistants), tablet PCs, or notebooks) increasingly include integrated wireless capabilities. Wi-Fi (wireless fidelity, 802.11) access points for wireless connectivity have appeared everywhere. Moreover, a growing number of complementary wireless networking standards, such as wireless personal area networks (802.15) and wireless metropolitan area networks (802.16), has evolved. In this sense, the users, who take their devices everywhere, expect their software applications to run as they do in the traditional network environment available at their offices.

To achieve such functionality transparently, however, these applications must meet a new set of requirements and support a specific set of capabilities related to the following.

- Provision of intelligent roaming capabilities to enable users to work without interruption, even when network connections are disrupted
- Exploitation of multiple network interfaces in a single device or the ability to select the most appropriate connection, for example, when two or more connections are simultaneously available
- Synchronization of databases by caching contents to local devices through asynchronous connections
- Access to data and applications on diverse devices through similar user interfaces
- Conservation of power at the operating-system level and maximization of performance

To implement mobile required functionality, application architects and developers have attempted to work around such problems without the benefit of development environments, application programming interfaces (APIs), or third-party

middleware solutions that are tailored for mobile environments.

The tools that are available to application architects and developers to provide this functionality are as follows.

- Mobile-application architecture guides
- Mobile-computing application servers

Mobile-Application Architecture Guides

The purpose of mobile-application architecture guides is to provide basic principles to design and develop mobile applications, facilitating the understanding of the high-level issues around mobility and mobilized software architectures.

This kind of guides identifies the primary capabilities required of mobile applications, such as efficient resource management, comprehensive context management, encoding, view consistency, extended policy and security functionality, durable storage, and reliable messaging.

Examples of mobile-application architecture guides are the following:

- *Intel® Mobile Application Architecture Guide* (Intel Corporation, 2006)
- *Mobile Applications: Architecture, Design, and Development* (Lee, Schell, & Scheneider, 2004)

Mobile-Computing Application Servers

Mobile-computing application servers are software programs that run in a server and provide the following functionality.

- Application-level logic that handles business functions involved in a particular organization and its integration with back-end database or business application systems
- Presentation services for the mobile client device (handheld computers, notebooks, PDAs, etc.). This is also called GUI (graphical user interface) in some cases, though some handhelds are more like older text terminals than PCs. It includes breaking the messages into smaller chunks, filtering redundant information, and even logically compressing the data.
- Transaction services, in some cases including multithreading for heavy volumes and persistency
- Application programming-level interfaces with specialized communications protocols

Actual implementations of an application server vary from one vendor to another. Some application servers are generic Web servers with an SDK (systems development kit) or API capability to pull data from enterprise database systems and send them to browser-based client software on a handheld device.

Depending on the heritage of the vendor and its core expertise, you can categorize application servers in the following broad classes.

- Generic application servers with a Web-based SDK, for example, Netscape, Microsoft, Sun, SilverStream, and BEA, may have support for handheld devices and wireless networks strapped onto the basic application server
- Database vendors' application servers, for example, Oracle 9i and Sybase's iAnywhere application server
- Data synchronization vendors, for example, Puma, Synchrologic, and Extended Systems
- Specialized Mobile or Web computing application servers, for example, IBM's WebSphere
- WAP-centric application servers, like Nokia's WAP Server

- E-mail-centric application servers, for example, Microsoft's mobile Information server and the EdgeMail application server

DAVINCI INTEGRATION FRAMEWORK'S MAIN CHARACTERISTICS

Our work applies many of the principles presented in the mobile-applications architecture guides to provide a framework for information systems integration in mobile working environments, paying special attention to some problems that are not well-solved by commercial mobile application servers, related to the following.

1. Provide standardized ways (independent from the vendor) to accomplish the following:
   - Define the mobile application's user interface and establish the data to be managed with this application.
   - Ship the user interface definition and data required to manage mobile applications.
   - Process the user interface definition and data to present mobile applications to the user.
2. Facilitate the development of mobile applications that integrate data coming from the following.
   - Different databases that are stored in different DBMSs (database management systems)
   - Other existing systems that have been programmed in different languages and operative systems

   This reduces the time, effort, and cost required for the development phase.
3. Optimize communications capabilities by accomplishing the following.
   - Reducing the size and number of the messages interchanged between servers and client devices
   - Increasing the possibility to adapt the mobile applications integrated to several different communication architectures
   - Recovering automatically the interrupted data messages
   - Selecting the optimal communication channel depending on the available bandwidth and the economic costs associated

Moreover, the integration framework should be deployed in different technological infrastructure coming from different vendors.

INTEGRATION FRAMEWORK WORKING CONTEXT

Before beginning with the detailed description of the integration framework, it is necessary to analyze some of the basic concepts of the working context related to information systems integration in mobile and remote settings. These concepts are the geographic area, zone of work, protocol, campaign, and workers in the field.

- **Geographic area:** This is a geographic zone that includes geographic locations (represented as geographic coordinate points) where the information management tasks are initiated. For example, in the business related to veterinarian control of pets and cattle, a geographic area could be a region of a country. In the business of the population censuses, a geographic area could be a town or a district of a large city.
- **Work zone:** This is a concrete point within a geographic area that will be visited by

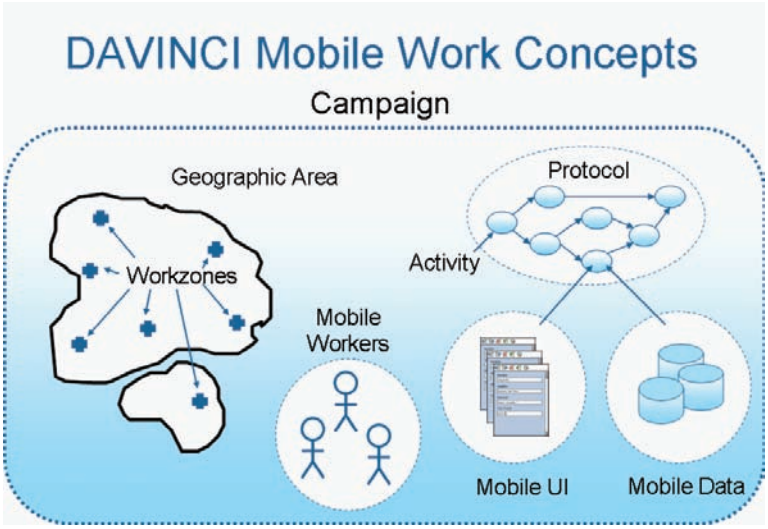
the field workers to perform their concrete tasks. For example, in the business related to veterinarian control of pets and cattle, the work zones could be each one of the cattle holdings and farms to visit. In the business of the population censuses, the work zones could be the streets or buildings of a town or a district of a large city.

- **Mobile workers:** They are the people in charge of performing concrete tasks in the assigned work zones. For example, in the business related to veterinarian control of pets and cattle, the mobile workers will be the veterinarians employed to perform the cattle and pet inspection on a farm. In the business of the population censuses, the mobile workers will be the people employed to visit each family to fill in the census forms.
- **Campaign:** A campaign is the grouping of a set of tasks of the same type that will be performed by mobile workers in several work zones and geographic areas using the same procedure.
- **Protocol:** It is the work procedure used in a work zone by a mobile worker to satisfy the objectives established in the campaign definition. In the scope of this integration framework (DAVINCI), a protocol is implemented by means of a set of applications or forms that the worker should complete or execute.

Each DAVINCI application is composed of a set of tasks or activities linked using a precedence sequence. Each one of these tasks is implemented by a form that accesses (external and/or internal) databases and updates the pertinent information through the mobile devices used by mobile workers. The forms should be defined using the standard of XForms.

The sequences of forms that define the campaign protocol configure the mobile user interface. Using this user interface, the mobile workers will

Figure 1. DAVINCI mobile work concepts



be able to manage (querying, modifying, inserting, and deleting) the data concerning each protocol task. These data will be stored in local databases, physically located in the mobile devices. In order to relate the data shown by the form and the data stored in the database, a file, named modelmapper, should be defined. These modelmappers define the relation between each one of the fields of the form and the concrete field of the local database, and the way (SQL statements) to access and update the data.

According to the concepts presented below, the integration framework works with general concepts, so this architecture is able to be applied to different business areas with very few enrichments and/or modifications.

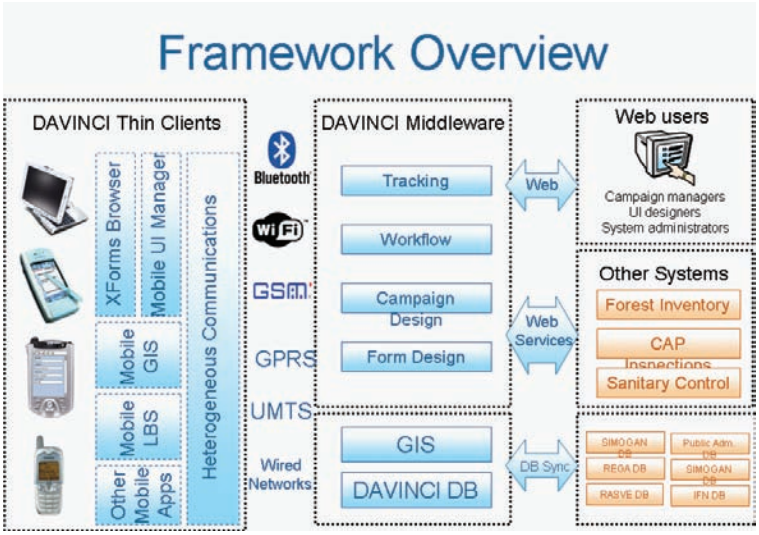
The integration framework will only store generic data on geographic areas, work zones, and mobile workers: concretely, its internal identifier, name, description, and an identifier or code assigned in an external database that contains extended information related to the concrete business area related to the tasks to be performed by the mobile workers. For example, the data to gather by a veterinarian in a work zone (cattle holding) will be different than the data collected by a questioner in a family house related to a population census.

For access to these extended data that will be stored in external databases, DAVINCI uses a specific data access module denominated DBSync.

INTEGRATION ARCHITECTURE

In order to provide support to this working context, the integration architecture suggested is based on client-server architecture, with a main module of communications and a message dispatcher, allowing the integration of any new service that is designed for a concrete area of business through its connection to the message dispatcher. Following this philosophy, DAVINCI'S integration architecture is organized in three levels, as it is shown in Figure 2.

Figure 2. Integration framework overview



a. DAVINCI provides a user interface (Web interface) for defining the process that should be used by the mobile workers and the connection of this process with the mobile software applications to be used for its consecution.
b. The core services are grouped in DAVINCI integration middleware, which permits the definition of mobile applications for performing several types of mobile work without a strong effort in software programming. These applications are defined by means of the user interface specification using XForms language (a standard for defining multimodal and multidevice user interfaces), and the specification of the information sources (server, database, table, and fields) for each user interface element (labels, text boxes, combo boxes, etc.) and the policy for selecting and updating the concrete data of a form.
   DAVINCI middleware also permits the use and adaptation of several software components for accessing and integrating heterogeneous databases that could be merged for providing the information necessary for a concrete mobile software application.
   This middleware also permits one to distribute the assignments to each mobile worker available, send the application and data for using the software application to perform the work assigned, and receive the data obtained as a conclusion of the work.
c. Moreover, DAVINCI provides some client components (currently developed for pocket PCs) that permit the following.
   - The communication with the middleware for receiving the information by the applications and data used and updated
   - The use of DAVINCI mobile applications with voice and pointing interfaces, providing access to additional capabilities related to location- and geographic-information-based services

The following sections describe these three levels in detail.

Integration Middleware

The components that permit the definition of the user interface of the final integrated user applications (Mobile UI Designer) and the components to access heterogeneous databases (DBSync) should be customizable; that is to say, in the standard version of DAVINCI, the core functionalities of these components are provided, but it is necessary to develop simple additional components to provide the full functionality needed in the final solution of the concrete sector.

Other components with full functionalities, related to the design of campaigns, the assignment of individual work to the mobile staff, and the synchronization of data and applications between the server and the mobile devices, are provided in the standard version of DAVINCI, so they do not have to be modified or enriched in any case.

Customizable Components

These components should be applied to adapt and use the integration framework in a concrete business environment.

Web Interface

The Web interface provides the required functionalities related to campaign design, the assignment of work (in terms of geographic areas or work zones) to each mobile worker, and controlling the advance of the work corresponding to a campaign.

Next, the main functionalities of the Web interface are presented in a detailed way.

- **Design of campaigns:** The design of a campaign consists of the specification of certain items.
  - The tasks to perform
  - The steps to follow for each task
  - The selection of the geographic areas and/or work zones where the mentioned tasks should be performed

  As we said previously, a protocol is implemented by an application (or set of forms) to complete or execute. Each application is composed of forms, each of them representing a task of the protocol. The forms are presented in sequence, representing in this way the precedence required among the protocol tasks. Once the forms are designed and the work assignments are planned, the forms and the related data are sent to mobile workers' devices. The above-mentioned forms are designed using the XForms standard. The

Figure 3. Campaign registration form

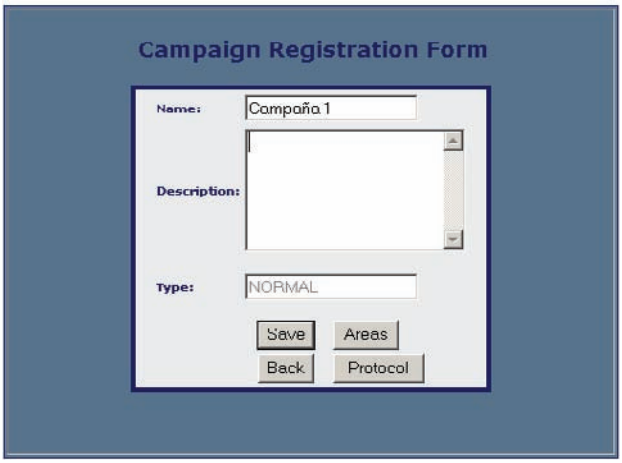


Figure 4. Workers' assignment form

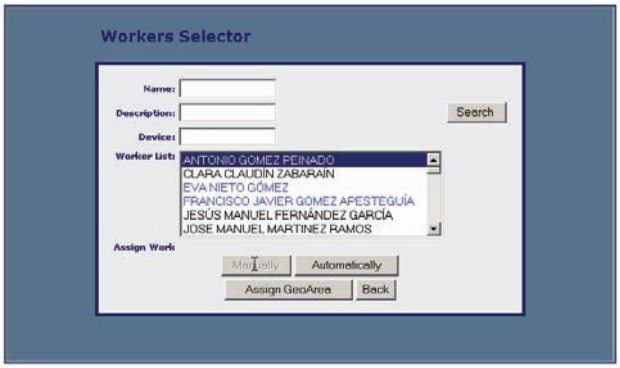

query and update functions to process the data related to the forms are specified in the modelmappers files related to the forms.

- **Campaign work assignment:** Once the campaign has been designed, it is possible to begin the assignment planning. The work assignment consists of the determination of the workers assigned to a campaign and selecting the geographic areas or work zones that mobile workers have to visit to perform the campaign task. Moreover, the Web interface permits the campaign manager to fix the concrete dates to perform the tasks, configuring the agenda of the mobile workers.

  Once the work has been assigned to each available mobile worker, the campaign manager should send the assignments obtained to mobile workers; so, the integration framework sends, through a message-center server component, to the mobile workers' devices the forms definition, modelmappers

Figure 5. Work-zone selection form

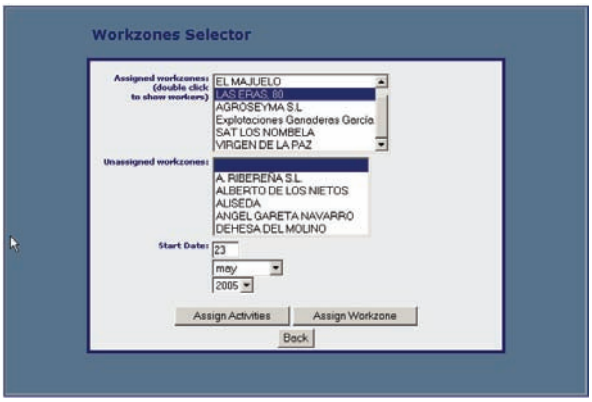

Figure 6. Campaign query form

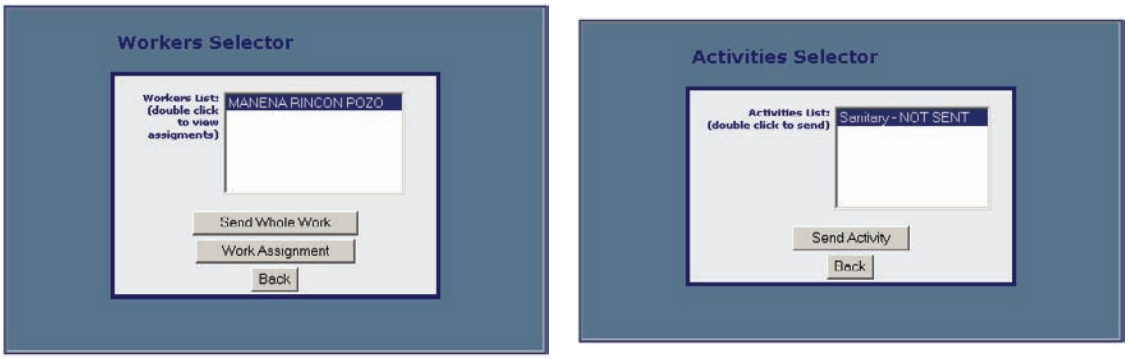

Figure 7. Work-zone selection form

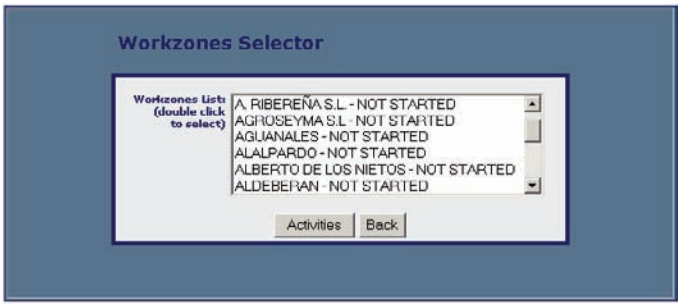


files, and necessary data to perform the campaign tasks.

At any time, the allocations to the workers can be modified as long as the work in the work zone to reassign has not begun yet.

Also, the planning of a campaign could be consulted about at any time.

- **Control of the state of the work:** DAVINCI offers the required functionality to control the advance of the campaign work at any time. To achieve this aim, the work zones assigned to each mobile worker is consulted and, for each one of them, the advance degree is calculated through the information sent by the mobile applications at the completion of each protocol task in every work zone and stored in the DAVINCI internal database.

  In addition, the integration framework allows the placement of the mobile workers in order to control their availability to receive new assignments. According to the accessories installed in the mobile workers' devices and the coverage of wireless communications in the zones where they are, the location processing will be based on GPS (Global Positioning System) positioning algorithms (without cell-phone coverage) or GSM provider positioning services (with cell-phone coverage).

Mobile UI Designer

The main purpose of this component consists of helping mobile-application integrators to design mobile applications using the XForms standard, preparing them for their introduction into the DAVINCI integration framework.

This component has not been developed yet. Temporarily, we are using any XML (extensible markup language) editor that is able to process XForm schema. Concretely, during DAVINCI's deployment in the European veterinarian sector, the editor used has been XMLSpy.

The activities required for this purpose are as follows.

1. Design of the forms of the mobile applications following the XForms standard
2. Creation of the modelmapper file containing the rules of insertion, modification, deletion, and consultation of the information of each form and each data item presented in it

DBSync

This module is in charge of the communication and synchronization of data between the integration framework (DAVINCI) and any other system to connect.

DAVINCI works with a set of generic concepts that are easily adaptable to concrete concepts in external systems. For example, if we are processing work zones, which are the places where mobile workers perform their tasks, the DAVINCI integration system only stores the identifier of the zone and the extended information; the properties of the concrete business area are stored in an external system that is conveniently connected.

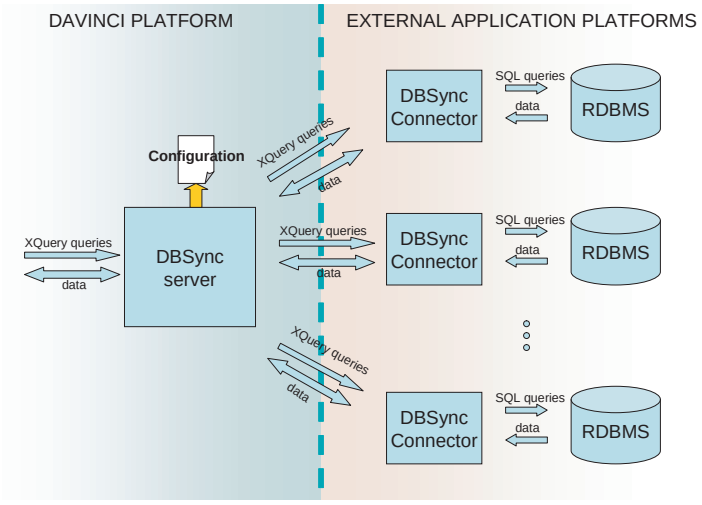
Moreover, DAVINCI applications will work with data stored in external systems and databases for recovery and modification of the business area information.

Next, DBSync's main functionalities are presented in a detailed way.

- **Get extended info:** In this use case, additional information is requested about any of the DAVINCI main subjects.
  - Work zones
  - Geographic areas
  - Campaigns
  - Workers

  The DAVINCI data model holds very little information about these elements in a generic way. Applications may need to show to the user more detailed data just for information purposes. The data obtained by using this use case is not modifiable by DAVINCI middleware, and DAVINCI does not handle them in any way but for showing it to the Web interface user in the suitable place.
- **Query data:** Several DAVINCI middleware components will need to obtain data from the data sources integrated in order to send it to the clients for showing and updating. That data are queried in a generic way by using this use case.

Figure 8. DBSync architecture



- **Update data:** Several DAVINCI middleware components will need to update or insert data in the data sources integrated in the DAVINCI platform. That data usually come from data capturing applications used by workers. A certain format is specified to transfer data from clients through DAVINCI middleware to the original data sources.
  The DBSync architecture is shown in Figure 8.
  DBSync is composed of a server that interacts with the other DAVINCI modules needing data synchronization. The DBSync server uses different DBSync connectors to access different data sources integrated with the DAVINCI platform. The data sources can be located in geographically separated points, and can make use of different relational database managing systems (RDMS). There is no limit on the number of DBSync connectors that can be used by the DBSync server.
- **DBSync server:** The DBSync server obtains the access data needed to reach the connectors from configuration, but the data can also be obtained dynamically.
- **DBSync connectors:** A DBSync connector is in charge of communicating with the DBSync server and performs the required operation regarding data querying and updating. Each connector handles one RDMS and can have its own policies about data updating and handling.

To integrate a new data source into the DAVINCI platform, it is necessary to complete the following steps.

1. *Define the data managing policies that will be used on the data source.*

The data updating and querying policies to be used on each data source are to be defined by the owner of the data source. The DAVINCI platform will provide new data and queries in the format specified above through the DBSync server, however it does not specify the way in which that data are to be updated and the queries are to be performed.

The following aspects are to be considered in order to design the data managing policies to be applied by the DBSync connector.

- Data may be overwriting when new data that has been captured by DAVINCI clients are updated in the data source. The DAVINCI platform does not perform any data storing or auditing, thus the DBSync connector should be able to manage data overrides in a consistent way with the data source. For instance, critical data should not be overwritten by new data if there is not a previous check, and historical data might be kept in order to roll back to previous states of the data source.
- Security procedures might be implemented in order to prevent unauthorized access to data or modifications. This depends on several factors such as the physical location of the data source, the connectivity of it with external threats, or application security requirements.
- There may be the need to dynamically modify the data access policies. If there is that need, configurable mechanisms can be implemented for being able to change data managing policies at run time.

2. *Implement and deploy a new DBSync connector to enable the DBSync server to access to data source.*

A new DAVINCI DBSync connector module must be implemented when a new data source is integrated into the DAVINCI platform.

The connector must expose a Web service in order to communicate with the DBSync server.

The data managing policies used by the connector to access its own data source are not restricted and are up to the particular implementation of each DBSync connector.

The connector Web service must be accessible from the DBSync server through HTTP (hypertext transfer protocol) or HTTPS. It can be deployed at any platform able to fulfill that requirement. There is no restriction about the technologies (programming language, platform operating system, applications server, etc.) used to implement and deploy the connector due to its Web service (SOAP, simple open access protocol) interface with the DBSync server.

An implementation using the same technologies as the rest of the DAVINCI middleware is provided for reference. It is built using the Java programming language and deployable on any J2EE-compliant application server; JBOSS was used during the development stage.

Box 1.

```
- <q:query xmlns:q="http://www.w3.org/XQuery">
  - <q:flwr>
    - <q:for>
      - <q:forAssignment variable="b">
          <q:pathExpr>T_WORKER</q:pathExpr>
        </q:forAssignment>
      - <q:forAssignment variable="a">
          <q:pathExpr>T_DEVICE</q:pathExpr>
        </q:forAssignment>
      </q:for>
    - <q:where>
      - <q:binaryPrefixExpr name="AND">
        - <q:binaryPrefixExpr name="LIKE">
            <q:pathExpr>b/WR_NAME</q:pathExpr>
            <q:constant datatype="xsd:string">Fran</q:constant>
          </q:binaryPrefixExpr>
        - <q:binaryPrefixExpr name="AND">
          - <q:binaryPrefixExpr name="!=">
              <q:pathExpr>b/WR_ID</q:pathExpr>
              <q:constant datatype="xsd:decimal">0</q:constant>
            </q:binaryPrefixExpr>
          - <q:binaryPrefixExpr name="=">
              <q:pathExpr>a/DV_ID</q:pathExpr>
              <q:constant datatype="xsd:decimal">0</q:constant>
            </q:binaryPrefixExpr>
          </q:binaryPrefixExpr>
        </q:binaryPrefixExpr>
      </q:where>
    - <q:return>
        <q:variable name="WR_ID" />
      </q:return>
    </q:flwr>
  </q:query>
```

The DBSync module receives Xqueries in order to collect information from the database. That kind of queries achieves a high-level abstraction over SQL sentences in such a way that the same query could be applied over different types of databases (SQL Server, Oracle, etc.).

FLWR is the subset of the Xquery standard that will be used by DAVINCI modules. This standard defines five operations that could be defined in Xquery.

- *For* creates a variable that represents the table and associates it to a variable.
- *Where* filters the query using data from tables selected in *for* expressions.
- *Return* specifies the node set of the output document with variable references. After a *for-in* expression completes the iteration, *return* delivers the query result document.

There is one more operation offered by the FLWR standard, denominated *let*. However, this operation is not necessary to offer the functionality required by server modules of DAVINCI.

An example of a FLWR expression could be as shown in Box 1.

The result of this FLWR expression through a parser would be this SQL sentence.

SELECT WR_ID FROM T_WORKER b, T_DEVICE a WHERE b.WR_NAME LIKE 'Fran' AND b.WR_ID != 0 AND a.DV_ID = 0

In this case, the FLWR parser has been developed for MS SQL Server Database in such a way that the syntax of the SQL sentence is specific for that database server.

The DBSync module has an implementation of certain capacities of the FLWR standard. Through that implementation, a new connector developed for the DAVINCI platform will be able to transform a FLWR request into an SQL sentence for SQL Server Database.

Fixed Server Components

These components should be installed in a server machine with a connection to the client devices. They provide full capabilities of the integration framework, so they do not have to be modified or enriched in any case.

Campaign Designer

This module encapsulates the functionalities for the management of campaigns and the protocols assigned to them.

Next, the campaign designer's main functionalities are presented in a detailed way.

- **Campaign design:** This functionality consists of one of the following.
  - Selecting an existing campaign to modify its geographic areas and protocols
  - Creating a new campaign and selecting the corresponding geographic areas related to the campaign in which one will work in that campaign.
- **Protocol design:** This functionality consists of one of the following.
  - Selecting an existing protocol, and adding and/or deleting activities. Moreover, for each activity, the application or form to complete is able to be changed
  - Creating a new protocol, defining the general information of each activity and the precedence between the protocol activities, and assigning a mobile application or form to each activity.

Work Planning

Next, the work planning component's main functionalities are presented.

- **Assign and unassign mobile workers to geographic areas:** The first step in the work planning component consists of determining the workers who will perform tasks in each one of the geographic areas assigned to the campaign.
- **Assign and unassign work zones to mobile workers:** Once the workers are assigned to the different geographic areas, this function allows selecting from the mobile workers of a geographic area the concrete person who is going to visit each work zone.
- **Send the assigned tasks:** Once the tasks in the concrete work zones are assigned, the integration framework provides functions to send the assigned tasks to each mobile worker. This information shipment is composed of the mobile applications to run during the tasks in the work zones assigned, the list of the mentioned work zones, and the extended information that is required to run the applications correctly.

MobileUI-Server

This component receives the orders (initiated by the user through the Web interface operations) sent by the campaign designer and work planning components, transforming them into the messages adapted for its shipment to the corresponding component in the mobile worker's device.

Moreover, MobileUI-Server processes the messages of data and requests sent by the corresponding component in the client side of this integration framework.

Next, the MobileUI-Server component's main functionalities are presented.

- **Application shipment:** This operation consists of looking for an application assigned to the worker, assembling the message to notify the client of the need of this concrete application, and sending the application to the client, which is in charge of verifying if this application is installed or not. If the application is not installed, the client will sent a new message asking MobileUI-Server for the files corresponding to the new mobile application to install.
  Moreover, this function collects the required extended data for running the application sent correctly, and sending them to the client side by means of the appropriate messages in order to be stored correctly in the corresponding mobile databases.
- **Forms request:** When a mobile device asks for the installation of a new application, MobileUI-Server sends a message with the description of the XForms documents that compose the required application.
- **Modelmappers request:** The process is similar to the comments for the forms request, being initiated by the same event of the installation of new applications in the client side, but in this case, the files sent correspond to the files that link the form fields to the local database fields.
- **Data request:** The process is similar to the comments for the modelmappers request, being initiated by the same event of the installation of new applications in the client side, but in this case, the information sent corresponds to information items to be inserted in the local database.
- **Data modification:** The purpose of this function consists of the synchronization of already updated information by the server to the client in order to permit the use of undeprecated information by the mobile workers to perform their tasks correctly.

In order to obtain this intention, whenever the server detects the modification of information shared by several mobile devices, a message to the affected devices, with the sentences to substitute the deprecated information with the valid one, is created.

eSignatureServer

This module is responsible for verifying the information signatures generated in the mobile devices to check their validity.

MessageCenter-Server

This module centralizes the communication between the different modules installed in the central integration server, considering that the communications server is the module that, in the server side, represents the mobile workers' devices.

When a server service sends a message to another server component, MessageCenter-Server redirects it considering that the information directed to a mobile device will be redirected to the communications server, which will send it to MessageCenter-Client (the message manager that is continuously running in each mobile device).

In addition, the shipment of messages between modules can be programmed, so in this case, the shipment is executed at a planned moment. In case of nonprogrammed messages, they will be sent as rapidly as possible.

MessageCenter-Server's main functionalities are as follows:

- Send a programmed message
- Send a list of programmed messages
- Send an instant message to other server component
- Send an instant message to a client component
- Start MessageCenter-Server
- Register new service

Communications Server

This module is in charge of managing the communications between the client and server in the server side, handling a queue of messages to send, reconstructing the messages received from the mobile devices, and sending them to Message-Center-Server, which is responsible for redirecting them to the corresponding server service.

The communications server's main functionalities are the following.

- Send a message to a client
- Receive message from client

Fixed Client Components

These components should be installed in each mobile device to be used by a mobile worker. The client components provide full capabilities for using and managing the mobile applications that are in the scope of the DAVINCI integration framework, so they do not have to be modified or enriched in any case.

Communications Client

This module is in charge of managing the communications between the client and server in the client side, handling a queue of messages to send, reconstructing the messages received from the server, and sending them to the message center, which is responsible for redirecting them to the corresponding component.

Next, the communications client's main functionalities are presented.

- **Send a message to the server:** When the message center has any message to send to the server, the mentioned message is introduced in a queue for its later shipment.
  The shipment will be made at any moment depending on the availability of the communication channels of the device (Bluetooth, GPRS, wired connection, etc.) and on the priority of the message to send.
  Internally, the message queue is stored in a database to avoid losses produced as a consequence of possible falls of the system.

- **Receive message from the server:** When the module of communications has received a message from the server, the messenger center is notified of this circumstance and is responsible for redirecting the message to the corresponding component.

MessageCenter-Client

This module centralizes the communication between the different modules installed in the mobile device, considering that the communications client is the module that, in the client side, represents the central integration server.

When a client component sends a message to another client component, the MessageCenter-Client redirects it considering that the information directed to the server will be redirected to the communications client, which will send it to MessageCenter-Server (the message manager in the server part).

In addition, the shipment of messages between modules can be programmed, so in this case, the shipment is executed at a planned moment. In case of nonprogrammed messages, they will be sent as rapidly as possible depending on the amount of messages in the queue and the state of communications channels.

MobileUI-Client

The MobileUI-Client component is formed by five differentiated subcomponents.

- Forms Viewer (XFormster)
- Forms Server (MobileWebServer)
- Forms Processor (XFormsModule)
- Data Access Control (MuiData)
- Applications Controller (MuiDataManager)

The dynamic collaboration between these subcomponents, with the rest of the modules of the side client, is shown in Figure 9.

The interaction begins when the DAVINCI server sends to the mobile device the applications to be installed. As it has been described previously, the messages interchanged among a concrete client and servers are provided by the communications client that is one of the services handled by the message center, as it is shown in Figure 10.

When a message of a new application is received, ClientMessageCenter redirects it to MuiDataManager, which is in charge of managing the installations of new applications, the downloading of data from the server, and the modification of the updated data to the server. The forms (written in XForms) are stored in a specific repository, the data mapping files (modelmappers) are stored in another separated repository, and finally the data are stored in a local database.

For the management of the applications' data, an independent module called MuiData, which encapsulates the logic to manage data sources, is used, so it is possible to change easily the format of the data sources to another format (i.e., text files, XML files, etc.); replacing the MuiData component with another makes it able to process the new format.

On the other side, the mobile worker, when using DAVINCI mobile applications, interacts with the forms browser, called XFormster, to navigate between the forms that compose the mobile application. This navigation implies interaction with a forms server, called MobileWebServer, which is in charge of process the forms; this is illustrated in Figure 11.

The mobile Web server works with a set of APIs that processes different types of requests created and initiated by Web pages. In this case, the corresponding API to process requests of XForm forms will be the XFormsModule. This module is in charge of gathering the data sent from the Web form to the Web server, searching the modelmapper file corresponding to the mentioned form, and updating the data in the local

Figure 9. MobileUI-Client collaboration diagram

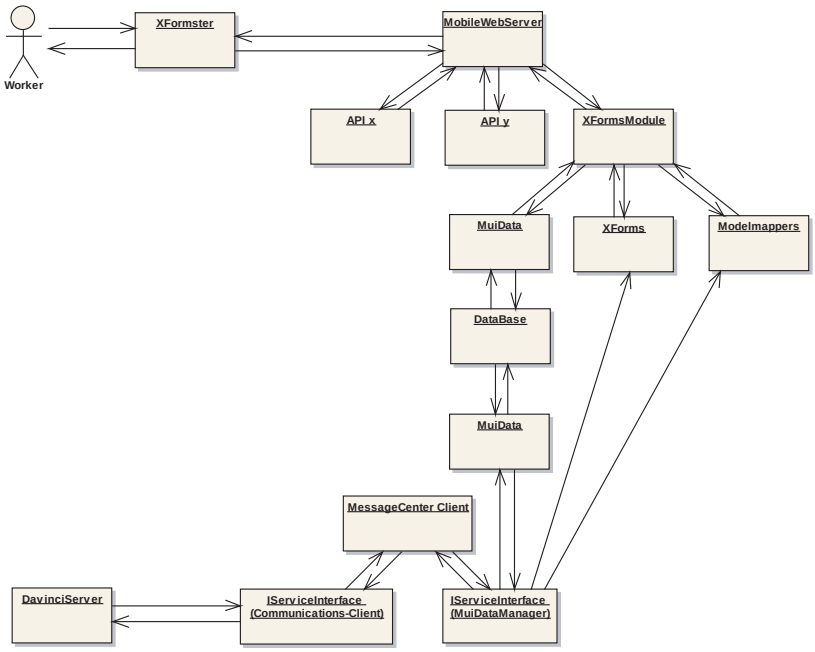


Figure 10. MuiData collaboration diagram

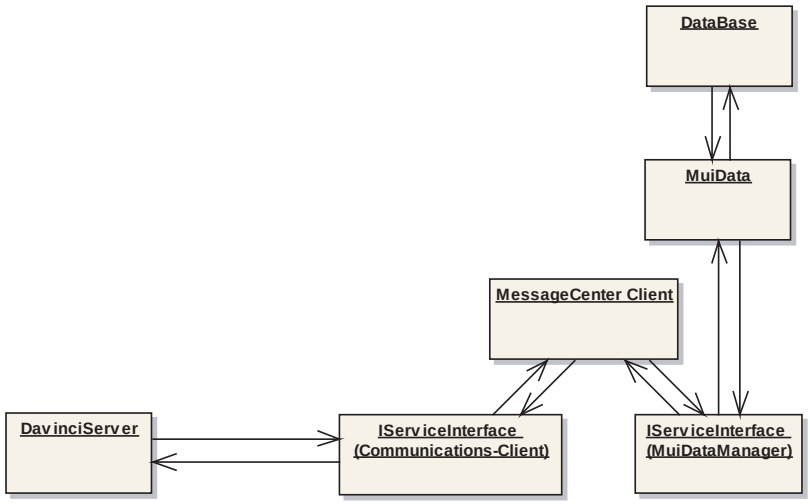

database according to the rules specified in the modelmapper file.

Moreover, XFormsModule is also in charge of searching for the form that should be presented to the user as a consequence of any command processes being used for this purpose, displaying the new information according to the rules specified in the modelmapper file of the new form to show.

The forms browser has the user interface displayed in Figure 12.

Navigation between the different forms will depend on the specific design and the purpose of each mobile application implemented.

eSignatureClient

This module is in charge of signing electronically the data generated by the mobile worker during the protocol application in a work zone and sending the signature to the central server for its verification and storage.

Figure 12. XFormster user interface

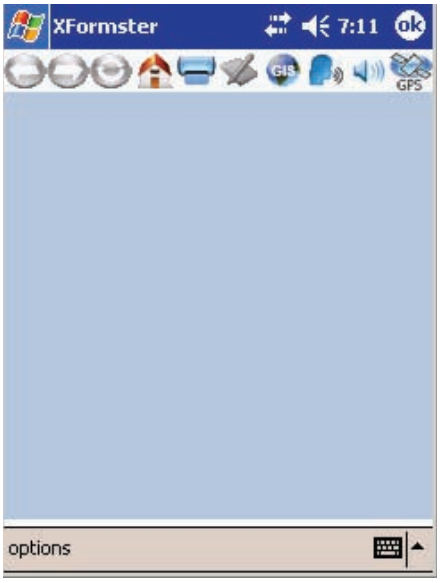

Figure 11. XFormster and MobileWebServer collaboration diagram

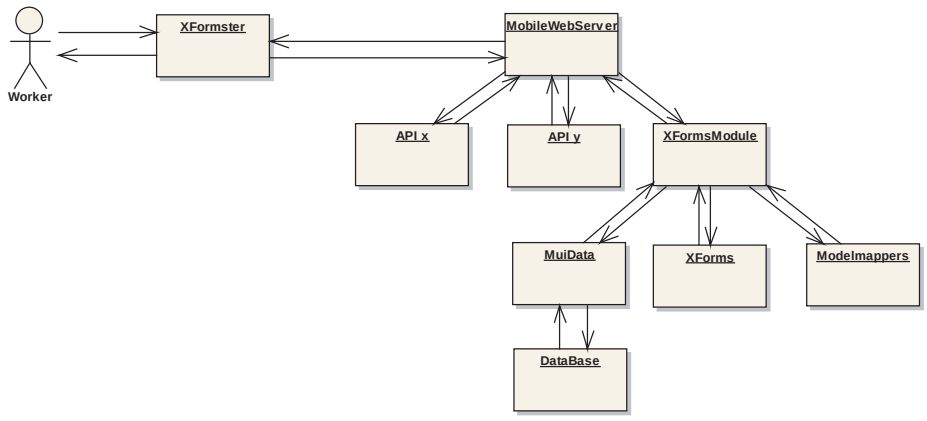


VoiceUI

The VoiceUI component is in charge of providing the capability to handle XFormster forms by means of voice processing; that is to say, using the VoiceUI component, mobile workers are be able to handle the DAVINCI mobile forms using commands introduced by speaking.

The voice processing interface allows the user to introduce values for form fields and execute the commands provided by command controls provided by the form, even the activation of the main functionalities offered by XFormster.

Print Manager

This module allows printing of any of the forms shown by the XFormster forms browser of the MobileUI-Client component. The print manager uses the Bluetooth port to communicate with the printer in order to send the printing jobs.

When the user decides to print through XFormster, the print manager extracts the information of the labels and fields to be printed, and then prints and transfers them to a flat text document.

Mobile Geographic Information Viewer (Mobile GIS)

This module allows the visualization of cartographic images and the presentation of information relative to parcels or enclosures defined on the shown cartographies.

Mobile GIS (Geographical Information System) is launched from the browser of MobileUI-Client's XFormster, but due to Mobile GIS's complexity and the size of the screen of some pocket devices, the cartographic information appears in a new window in order to not saturate the XFormster window; otherwise, the window to visualize GIS information would be totally unmanageable.

Positioning Component (LBS)

This component is responsible for obtaining and handling the geographic position, in terms of coordinates, of DAVINCI mobile workers. This positioning component allows one to handle geographical, cartographic, and UTM coordinates, and to work with WGS84 and ED50 data.

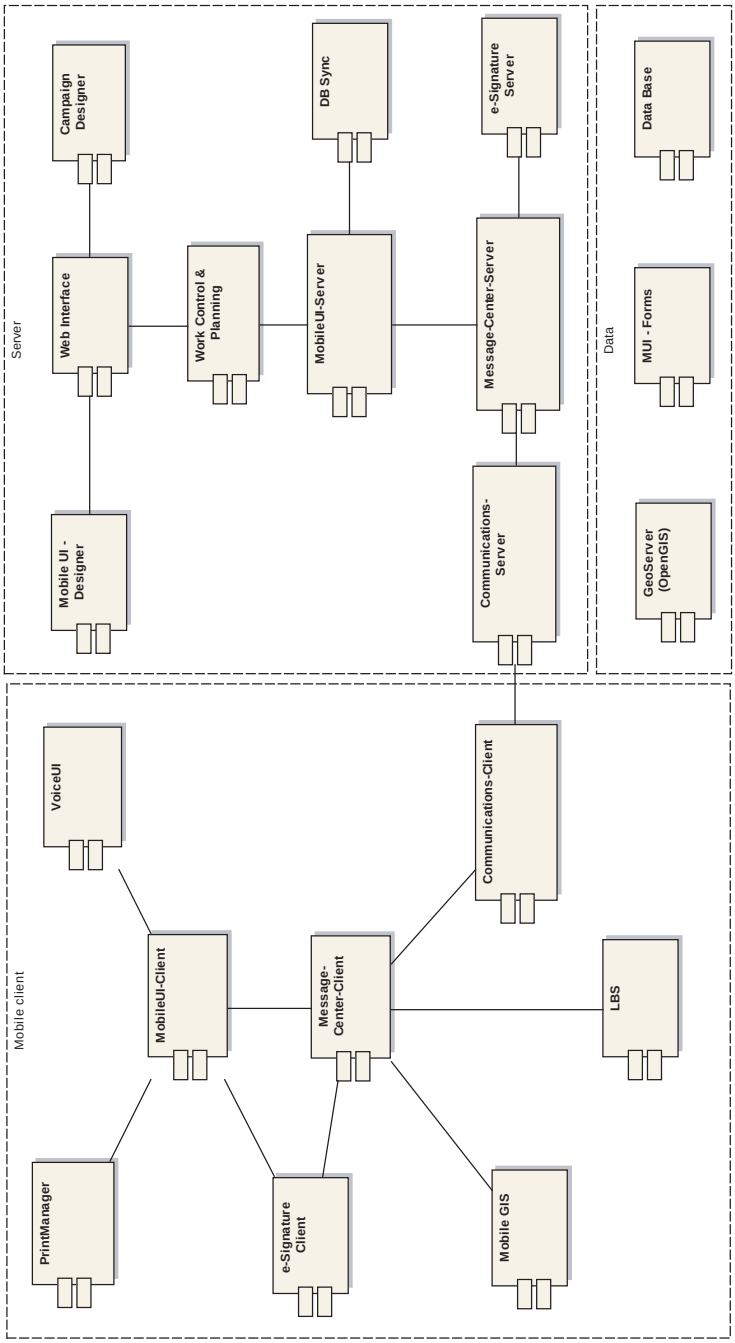
A detailed diagram of DAVINCI integration components is shown in Figure 13 using UML (unified modeling language) syntax.

STEPS TO USE THE INTEGRATION FRAMEWORK

If an organization wants to use the DAVINCI integration framework for the management of the applications used by its mobile workers, it is necessary to perform the following tasks.

1. Install and configure the server components of the integration framework in a server able to be connected to client devices with the configuration. The server machine should have installed any J2EE-compliant application server and an RDMS. Our trials were done using JBOSS and Microsoft SQL Server (this database only manages the internal data required by the integration framework).
2. Install and configure the client components in the devices that will be used by the mobile workers. The configuration is different depending on the mobile device's capabilities. This is the most complicated task because there are several exceptions and special cases related to each device vendor and model. The effort of this task could be reduced by using the same model of mobile device.
3. Define the data managing policies that will be used on the data source used to obtain

Figure 13. Integration framework architecture



and update the data managed by the mobile applications.

4. For each mobile application to deploy, it is necessary to do the following.
   - Define, design, and implement the forms of the mobile applications using the XForms standard, preparing them for their introduction into the DAVINCI integration framework. This task could be done with any XML editor that can process XForms, for example, XMLSpy.
   - Define a modelmapper that contains the information of the graphical control used to show any item of the information, and the rules to query and update the mentioned data.
   - Implement and deploy a new DBSync Connector to enable DBSync Server to access the data source.
5. Design each company campaign using the Web interface of the integration framework.
6. Define the protocols that are assigned to the campaigns, and assign a form to each protocol activity.
7. Plan the work of each campaign, assigning the job to any available mobile worker.

Then, the applications and the required data are automatically sent to the mobile workers.

As each mobile worker performs his or her job, the integration framework automatically updates the information in the data source in accordance to the data managing policies established in Step 3 of this section.

When a mobile worker has new assignments, the integration framework sends the new data and, if required, a new mobile application to enable the worker to perform the job.

SYSTEMS INTEGRATION IN EUROPEAN VETERINARIAN SECTOR USING DAVINCI

Trials Purpose

The objectives that should be satisfied by means of the realization of DAVINCI trials and technology transfer activities consist of validating the improvements and technological innovations using DAVINCI in real working environments.

The main aspects validated were as follows:

- Capability of integrating the data provided by DAVINCI with Spanish and Bulgarian cattle exploitations and livestock-movement databases. This objective allows checking the effectiveness of DAVINCI for integrating information systems of different nature.
- Reduction of costs and effort spent in relation to the new mobile applications development.
- This validation was carried out by gathering related data on the necessary time to develop mobile applications to help veterinarians perform information retrieval, and updating tasks related to the cattle sanitarian control program.
- Improvement of the ergonomics and veterinarians' comfort when performing the activities related to sanitary controls and clinical inspections. To fulfill this purpose, the effectiveness, efficiency, and ergonomic conditions for those carrying out the inspections were analyzed in detail. This analysis was performed by the veterinarians completing some evaluation questionnaires about the subjective estimation of these aspects.

Trials Scope

Trials have been performed in four European countries (Spain, Latvia, Czech Republic, and

Bulgaria) during the experimentation activities of the European-Commission-funded project called Advanced Management Services for Inspections and Sanitary Interventions in Cattle Holdings through Mobile Technologies (IPS-2001-42057).

The most efficient strategy for achieving the trial objectives was performing separate trials and technology transfer activities in Bulgaria, Spain, Latvia, and Czech Republic.

The reason for this separated approach is based on the existing differences between the infrastructures already present in each country.

In Spain, there is an information system for cattle-exploitations registering and livestock movements managed by each autonomous community and coordinated by the central government. The databases in the system satisfy the requirements in Directive Number 1760/2000 of the European Parliament. Also, in Spain there are standard GISs that are accessible by the project, so we will allow the checking of all of the project's required functionalities.

In Bulgaria, although there are databases for cattle exploitation and livestock movements, they are not standardized according to Directive Number 1760/2000 of the European Parliament. On the other hand, DAVINCI cannot use the standardized systems of the Bulgarian GIS to satisfactorily prove the GIS capacities provided by the project.

Trials in Spain

A voice recognition system was tested in a small ruminant bleeding activity because the time saved with small ruminants is by far greater than the time estimated for large ruminants. The voice recognition system will be useful for some veterinary activities on the ground, but experience shows that the time saved in a bovine bleeding job using this technology is not as profitable as in small ruminant practices. For this reason, sheep control programs were selected for this trial.

The bleeding of large animals will be done using pocket PCs. There is a reason for this choice. In the case of large animals, more activities have to be performed and the use of a pocket PC, with all the functionality that it is able to provide, facilitates the job for these activities. The objective of this demonstration is not only the use of those devices on bleeding activities, but also to become conscious of the limits and capabilities of the use of technological devices on the ground in an unclean environment.

Figure 14. Trials execution in Spain

Figure 15. Trials execution in Czech Republic

Figure 16. Trials execution in Bulgaria

Trials in Bulgaria, Czech Republic, and Latvia

Bulgaria believes that the approach to separate the demonstration from the prototypes is reasonable for a better evaluation of each one of them.

The use of a voice recognition system, no matter whether being used on small or large ruminants, is of significant interest for us, but due to some limitations on the languages that can be used in such a system, the demonstration of the technology could be limited to Bulgarian project coordinators reviewing the Spanish prototype.

Although the mobile mapping system was tested in Spanish trials, we believe that this component will be of significant importance for us during the monitoring of culicids vectors on bluetongue disease, a disease with great epidemiological significance for Bulgaria and the region. Along with that, the application of restricting measures could be tested for a geographical area in case of a disease outbreak. All those activities could be done in a lab with all the data that we have—digital maps, data from culicid traps, and

so forth—and we believe they are going to be sufficient for testing a prototype for the mobile mapping system.

Trials Activities

In order for the testing routines to be able to provide a comparable set of conclusions, a common process for the trial development has been established by DAVINCI. The necessary activities to meet the established trial objectives and the desired technology transference are the following.

1. Definition of the trials scope
2. Determination of the region and holdings to be visited during the trials, looking for concrete parameters
3. Selection of the participants in the prototype testing activity
4. Configuration of the mobile devices' hardware
5. Preparation of trial evaluation materials
6. Performance of the cattle sanitary control activities
7. Trials evaluation

CONCLUSION AND FUTURE WORK

The main success factor of DAVINCI does not lie in obtaining a system that provides a highly optimized performance, but in the automation of manual procedures, achieving acceptable performance. Moreover, it has been detected that the performance displayed is not optimal, but since it copes with minimal required performance, the fundamental objectives of the project are fulfilled.

As a summary, it may be said that the results obtained from the trials allow us to state that the main improvements brought about by DAVINCI are the following.

- The effort necessary to develop mobile applications to gather and/or consult livestock sanitary information has been reduced by up to 43.43%. The absolute value (in working hours) of this reduction will depend on the size (measured in function points) of the intended application.
  Nonetheless, it ought to be taken into account that the success mentioned has been produced in a limited context of a quite restricted set of mobile applications based on simple formularies, without complex displaying elements such as dynamic lists or tables, with simple access to databases not joining different data sources.
  Thus, this effort reduction is so far applicable to the development of simple mobile applications in terms of the insertion, modification, and consultation of data coming from a single data source.
- The economic costs needed to integrate mobile applications with existing systems and databases for livestock sanitary information management has been reduced by 9.03%.
- The average time to publish the data relative to a cattle holding has been reduced by up to 2.6 days, decreasing from 64.84 hours in the previous situation to 1.14 hours when using DAVINCI.
- DAVINCI easily adapts to the field working proceedings of different countries, with different cultures and organizational structures.
- The DAVINCI framework should adapt easily to technology changes in communications or to new mobile devices being used to perform fieldwork.
- The performance and easiness of mobile device configuration is acceptable, allowing the veterinarian to effectively carry out the field tasks.
- The communication components of DAVINCI are adaptable to several different com-

munication infrastructures, allowing one to effectively resume interrupted messaging due to uneven communication coverage. Thus, the information transmitted through the available bandwidth is optimized.

However, it is necessary to perform, in the immediate future, an optimization process of the obtained solution, introducing, among others, the following improvements.

- To extend the set of available controls to be used by DAVINCI mobile applications, allowing the usage of more complex formularies with complex information, displaying elements such as dynamic lists and tables, and allowing simultaneous access to different data sources (joins)
- To carry out, keeping in mind the improvements of the available controls for mobile applications, a larger set of studies to assess the reduction of effort and time needed to develop mobile applications within DAVINCI
- To study and define algorithms allowing the broadening of coverage time, and thus lowering the number of messages that have to be resumed due to loss of communication with the coverage currently offered in rural environments by communication providers
- To improve the ergonomics and ease of use of the central components for in-field resource management
- To improve the ergonomics and ease of use of the mobile applications developed under DAVINCI, paying attention to those aspects related to input data validation and helping with the completion of less common tasks
- To provide the veterinarian with a mobile device that allows her or him to perform the fieldwork without the need to undergo configuration changes, such as battery changes, during the activities
- To improve the performance of DAVINCI's voice recognition system so that it consumes less resources and is less sensitive to noise while not lowering the speed for voice processing

Chapter 2.29
"It's the Mobility, Stupid": Designing Mobile Government

Klas Roggenkamp
Dipl. Designer Electronic Business, Germany

ABSTRACT

This chapter looks at mobility and the term government to describe influencing factors for the process of designing mobile government. A detailed review of perspectives on mobility and a subsequent examination of the government term is given to reach a better understanding of what mobile government can be. Furthermore, four questions are refined which are aimed at helping to first justify and assess a possible m-government service and second to classify this service in a given context. By focusing on mobility as a key component of mobile government, the author hopes to aid developers and researchers alike with designing new and better mobile services within the public sector.

INTRODUCTION

Mobile government as a subject of debate, research and actual services is gaining momentum within the field of electronic government. The number of mobile phone users is exceeding the number of fixed line phones and, though at a slowing pace, is still growing. With the recent roll-out of mobile broadband data services such as UMTS or Wireless LAN, one gets the idea that we are still just looking at the tip of an iceberg.

So far, e-government has allowed for a faster, more convenient and often value-added delivery of public services. It has started a regrouping and rethinking of processes in many administrations, helped to create a new and improved access to various services, and also supported citizen participation in political processes. Even where it is not obvious to "front-end users" like citizens, e-government has in many cases boosted the more efficient gathering and processing of data. Information and communication technologies in governmental organizations have reduced cost, redundancies, and errors, thus speeding up the handling of services.

Nevertheless, mobile technologies, however unknown their real value still is, will take this development to an even higher level. Not only are such mobile services promising more efficiency,

faster and less erroneous processing of data, but also an improvement of service as a whole through direct contact with citizens. "As painful as e-government transformations have been, the challenges of dealing with an always-on society and workforce will be even more daunting. Service delivery, democracy, governance and law enforcement will all be affected" (Di Maio, 2002).

Mobile government by itself can still be considered in its "infancy" (Zálešák, 2003)—when it comes to governmental organizations we can assume a "transitive state" (Kushchu & Borucki, 2004, p. 830). The services currently considered to deserve the label mobile government range from W-LAN in public buildings to stand-alone mobile applications. They depend on, utilize, or incorporate features of mobile technologies. In-between these two extremes, we can observe a vast variety of services such as mobile information via SMS, mobile tickets for parking or trains, and alike. Hence, it is rather unclear what we talk about when we actually refer to mobile government.

The definitions given in the literature vary slightly. Some describe m-government as "a functional subset of all-inclusive e-government" (Arazyan, 2002) respectively saying, that technologies used for m-government "are limited to mobile and/or wireless technologies" (Llalana, 2004) in comparison with e-government. To others, m-government is "a complex strategy for efficient utilization of all wireless devices" (Zálešák, 2003) with the goal of "improving benefits to the parties involved in e-government" (Kushchu & Kuscu, 2003).

Defining m-government as a form of mobile business, some see it as a connection between Internet and mobile communications offering context-dependent and highly individualized information and not huge amounts of data (cf. Frischmuth & Karrlein, 2002, p. 15). By ruling out mobile yet stationary interaction as well as random wireless connections, m-government is considered restricted to public mobile services that need time-critical information access (cf. Thome, 2003).

If an application fits one of these definitions or if it falls short of certain features is a debate of its own and shall not be the issue here. Whether one talks about mobile government, mobile e-government, or mobile public services is a semantic issue. The process of planning, developing, designing these service offerings is, however, important. In this process, several sets of interests need to be aligned to allow for a coherent offering in the first place.

We will look at mobility, government, and the scope of connotations to each term with the aim of describing factors to be considered in the design process of such a mobile service in the public sector. Requirements toward mobile services from both sides will be detailed and combined.

As a first step, the following second part will review the term mobility from a technological, economical, and sociological perspective. As a result, a set of questions will be derived to pinpoint issues to consider in the context of being mobile.

To gain a more comprehensive understanding of the involved parties, the third part will subsequently examine the government term. By separately looking at the organization, the actors, and the processes, the scope of this term becomes clear. To what extent these subsets and their goals can be combined will be discussed alongside a brief description of important challenges.

Following these separate considerations, part four will discuss the interaction of mobility and government and thus give an overview of factors to consider when thinking about mobile government. This will be concluded with an outlook into future developments.

MOBILITY PERSPECTIVES

Mobility in a general sense is understood as a form of *being mobile*. The adjective "mobile"

goes back to the Latin word "mobilis", meaning *movable*. In this sense, mobile objects are capable of moving or being moved.

Depending on the context, in which the term is used, its implication is variously extended. These differences lead to distinct approaches how to deal with mobility, how to become mobile, or how to support being mobile. For example, the question "Are you mobile?" does not ask for the status of someone being physically movable but for the subjects *ability to move* from one place to another in a more social context. Maybe the asked person has obligations that do not allow leaving ("I'm stuck here"), thus making him immobile, at least for a certain amount of time. It could also be asked, whether someone is mobile in a sense of *willing to move*.

The title of this article states the importance of understanding the concepts of mobility how to properly deal with them. Obviously mobility is one of the key features of mobile government of whatever kind, depending on the starting point of planning such a service, the issues considered as key problems are rather different. Between the fields of information science, economics, and sociology, we can observe very distinctive perspectives on mobility (see Hess et al., 2005; Kakihara, 2003; Urry, 2000). As a result, each comes to its own conclusions which are often not easy to align. From the technological viewpoint, dealing with mobility is primarily concerning shared computing and distributing data. Even though this also includes allowing end users to move more or less freely, this is dealt with in a very different manner compared to economical or sociological debate. Vice versa questions asked by social sciences on for example the reason to be mobile at all, or the needs while being mobile are constrained to this field. Yet again, financial aspects of mobility can hardly be found, neither in the sociological nor the technological handling of mobile topics.

Technological Perspective on Mobility

The current debate on mobile government (and more generally mobile services) on the one hand and a supposedly mobile society on the other is in part due to the availability of certain mobile technologies. No matter if it is mobile hardware (such as a PDA or a mobile phone) or mobile networks and protocols to use them (such as GSM, UMTS, W-LAN), we have to consider certain issues alongside mobility that enable us to actually create and use mobile services.

The underlying technologies are dealing with four basic concepts of mobility, of which at least three are of primary concern (Hasan, Jähnert, Zander, & Stiller, 2001):

- device mobility;
- user mobility;
- service mobility; and
- session mobility.

Device mobility deals with the continued access to services while being spatially mobile, that is, moving from one physical location to another. This access can be granted via locally limited Wireless LAN access points. Other standards include concepts of handing over connections between access points, as is the case for mobile phone networks based on standards such as GSM. The reach of the device and the general possibility to roam a broader area thus depends on available networks, and of course on the hardware itself.

Assuming that a user is mobile without physical constraints, *user mobility* from this perspective refers to location- and device-independent service access. Pre-requisite is an appropriate means of identification. Again, a common example would be the mobile phone network which is utilizing the subscriber identification module (SIM) to identify a user within the network.

With *service mobility* comes the idea of access anytime, anywhere. More appropriately one should add "anyhow" to this often cited paradigm since this concept includes the idea of service delivery regardless of device and user specific settings (see Perry, O'Hara, Sellen, Brown, & Harper, 2001). Implementations allowing for service mobility are currently hard to find—neither GSM nor UMTS or W-LAN includes the capability to provide a certain service irrespective of device and user. There are, however, approaches to offering seamless services, which automatically suit themselves (e.g., to available bandwidth of a network (FOKUS, 2000)).

The *session mobility* describes the capability of starting, pausing, and resuming a user session while switching between devices and/or services. The session itself is considered as a relation between distributed service components which integrates needed resources. None of the available communication systems allows for session mobility, yet (Hess et al., 2005).

Current mobile communication technologies particularly allow for the mobility of device and user and thus enable the growth in this field. On the path from mobile to ubiquitous computing, however, also the latter two concepts need to be fully included. As for now, some services (also in the field of government) are mobile when considering scalable and adapting front-end interfaces as a means of serving this goal. Nevertheless, offering truly mobile services in this sense can only be attained by solving technical and most of all security issues. To what extent session mobility really is an issue for mobile government has to be questioned. Secure and reliable service delivery—independent of respectively adaptive to an available device and the available network type and bandwidth—surely is of concern in the case of more complex transactional services.

Economical Perspective on Mobility

Whereas the previously discussed technological perspective on mobility takes a device- and service-based approach, the economical perspective can be described as focusing on the intersections between a business process and mobility. Within a typical business process, there are three steps to consider, each of them open for a different perspective of including mobile aspects:

- the value chain;
- market transactions; and
- mobile goods.

Looking at the influence of mobility within *the value chain* the question is raised how mobile services can contribute to the process of value creation. Mobility can affect the efficiency and effectiveness, embracing mobile technologies and thus directly offering support to employees working in a mobile setting can create added value. Typical examples can be found in the areas of field work (Rossado-Schlosser & Hacke, 2002); in a government setting this would include police forces (Bazijanec & Pousttchi, 2004). Apart from directly supporting a mobile workforce, the implementation of mobile machine-to-machine communication (e.g., radio frequency identification (RFID)) can allow for the substitution of certain human-bound sub-processes by directly connecting objects with their environment respectively the organizational information processes (Hess et al., 2005). When properly implemented, both approaches can reduce operational cost and errors while possibly speeding up processes as a whole.

As part of *market transactions*, that is, the exchange between a business (or government) organization and a buyer respectively customer (or citizen) mobility becomes an issue as part of hindering, complicating, or yet demanding mo-

bility (Khodawandi, Pousttchi, & Winnewisser, 2003). Within this setting, mobility can lead to an increase in transactional cost. Through the implementation of mobile communication, these costs can be reduced in the same way as is true for the internal value creation (cf. Kaspar & Hagenhoff, 2003). Striking examples for the effective use of mobile services in this field are, among others, services offering critical information prior to the initiation of a transaction. These may be just accessible via mobile network and device or actually allow for location-dependent information. After this initiation phase the actual transaction can be supported within a mobile context, for example, by enabling mobile payments. Following the transaction mobile services can allow for specialized CRM-methods, either simply by addressing a customer directly or by allowing for a mobile feedback channel.

Furthermore, mobility becomes an issue when dealing with or creating *mobile goods*. In the context of this chapter, this shall only span mobile information goods. Here we can observe a vast variety of goods which are merely a piece of software being delivered to mobile devices, anyhow very successful: ring tones, mobile games, and other mobile entertainment services. Considerably more complex and less intrusively marketed, another field for mobile services as a good of its own is offering adaptive, context- or location-aware information, for example, tourist guides, maps, or real-time information on public transport (see Turowski & Pousttchi, 2003, p. 181).

From this focus on business processes, one can identify general economical issues connected with mobility and ways to theoretically surpass obstacles due to it. In some cases, this perspective can actually help to identify possible new markets connected with or created by mobility, mobile services, and mobile users.

However, assuming that services will be used as planned in up-front business would mean ignoring user behavior. Not only is it inevitable to convey the gains to the prospective user. As a matter of fact, these gains need to be identified. A simple monetary equation, however promising, simply falls too short. This is all the more valid in a government setting where there are not only competing access channels or behavioral obstacles within an organization, investments have to be legitimized to a critical public and in the context of budgets constraints.

Sociological Perspective on Mobility

The *sociological perspective* on mobility is dealing with the description of mobile contexts and needs to be connected with these situations. Concerning mobile communications, we can add the more explicit question about reasons to use a certain service.

On a general level, there is a distinction made within this perspective as to what kind of mobility is applicable or rather, what types of mobility can be found. We can distinct three types:

- physical mobility;
- social mobility; and
- virtual mobility.

"Perhaps the most widely adopted usage of mobility is that of people in terms of geographical movement" (Kakihara, 2003, p. 39). This type of mobility is to be called *physical mobility*, meaning going from one place to another. To more closely define this mobility, it shall be characterized by the mode of movement respectively the overcome distance (Kristofersen & Ljungberg, 2000). Local mobility best describes "wandering" within a building or a local area. "Visiting" one place and then moving to another location extends the locally bound movement. The opposite of wandering in this sense is "traveling", describing a state of moving from one place to another by using a vehicle

of some kind. Gerstheimer and Lupp (2001) also consider the separation of mobile and fixed locations, the first matching the mode of "traveling", the latter the modes of "wandering" and "visiting" (p. 67). In general, physical mobility serves a certain purpose connected to getting from A to B. As a consequence, the process of moving is of primary concern for the moving subject, rendering other side-activities secondary. Where there are slots of attention for such activities, tools and services involved need to adapt themselves or the result of their involvement to a given setting and needs thereof. Traveling by car does not allow for interaction such as typing on a keyboard or visualizing complex content. However, voice interaction might be as well a solution as simplified displays within the sight of the driver.

Social mobility on a macro-level describes the permeability of a society between pre-defined societal levels. On a micro-level, the term refers to the ability of an individual to change roles in reaction to external influences and contexts (see Goffmann, 1967; Ling, 2000). Each physical movement leads to a change of context, if just related to surrounding people (e.g., being with friends as opposed to being with colleagues). A different social context is also attributed to physical location itself—the most general distinction being that of public and private places (Agre, 2001). To visualize this, one might think of a youth among his friends or with his parents. Assumed and fulfilled roles vary in the same way as we would for instance imagine when riding the bus or spending the evening in a comfy chair at home. With the social role played, a behavioral change can be observed, concerning language, volume of speech, even posture or clothing can be implicitly affected.

Resulting from networked and more often also location-independent communications we were able to experience the rise of what Castells (2000) calls a "network society". This new sphere is untying physical location and the range of activity of involved people, along with all due implications. This so called *virtual mobility* has a broad impact on many areas, leading to new behavioral patterns and expectations. On top of the virtuality offered by Internet communication as a whole, mobility extends the grasp of this even further. The consequences of this have been described by many authors (among others Agre, 2001; Geser, 2003; Ling & Yttri, 1999).

As a consequence of virtual mobility—especially in conjunction with mobile communications—it can be observed how, on the one hand, the social context is being more detached from the physical one. On the basis of a mobile communication channel, a mutual virtual but private space can develop between two communication partners, regardless of the fact that they might be physically located in the middle of a crowded public space.

On the other hand, just due to the option of such a virtual presence, the perception of actual physical co-presence emerges. Ling (2000) has shown how this perception develops within a youth group whose members are not all in the same location at the same time, however the absentees are perceived to be part of the actual group activity because they can be contacted wherever they are. Similar observations have been made concerning mobile workforce (Kakihara, 2003; Vincent & Haddon, 2003). Pica and Kakihara (2003) talk about a "duality of mobility". Interpersonal ties may be weakening due to the ease of having ephemeral contact which can be fit into idle times throughout a day. The same opportunities may result in more persistent communication relations for the effects of virtual mobility stated earlier, namely the perception of virtual co-presence.

Nevertheless, especially the sociological perspective leads to the conclusion that many of the topics connected to mobility should be considered as constantly evolving. Certainly, norms influencing and influenced by mobile user behavior are steadily changing. We just need to consider the general perception of using a mobile phone. A few years ago, public use of a mobile

phone was considered snobbish. These days the opposite is true: not having a mobile phone is often considered to be awkward. Usage of voice services (i.e., telephony) and other mobile services (i.e., data) is also subject to so called social shaping—not only the patterns of usage but also the perception of the use, the user, and services as a whole keep developing (see Palen & Salzman, 2002). Hence, it is rather short-sighted to plan and design services merely from the technological or economical perspective.

Bringing these three mobility perspectives together reveals a set of questions which cannot be answered by solely taking one isolated perspective into consideration.

The main goals of the different perspectives (Figure 1) are the creation of technological solutions for mobility, the economical assessment of possible business processes in regard to, above all, efficiency and value creation as well as the reflection on social preconditions and interdependencies of technology and everyday life and work.

At the intersection of technology and economy, the key questions to ask would be:

- Which are potential added values?
- (How) Can the range of old products be extended?
- What are possible new goods?

The combined perspective of economy and sociology lead to questions in the manner of:

- What are current user needs?
- How can these needs be transformed into accepted products?

When connecting sociology and technology, questions arising are:

- How technologically feasible are user wishes/needs?
- What are the interdependencies between technological solutions and usage?
- How can technology adapt to these needs/ interdependencies?

In sum, the result would be a mobility cycle with which the goal to make sense of mobility

Figure 1. Main research goals and open questions of different perspectives (Hess et al., 2005)

Perspective	Goal	Open Questions
Technological	• Development and improvement of new technologies and applications	• Business models and user behavior
Economical	• Services and business models to support business processes and development and roll-out of mobile goods	• Technologies to translate and implement business models • Forecasting user acceptance and adoption
Sociological	• Social pre-requisites for the adoption of new technologies and applications • Implications of new technologies for society	• Creation and designing new technologies and application • Economical strategies, business models, and value chains

as a feature of mobile communications can be attained. In this cycle, the possibilities of technology will be shaped into applications and services appealing to users and also offering added value to providers.

However simplified and generalized the previously-made statements are, they do show possible ways to combine the three different perspectives on mobility in general and on dealing with mobile communications in particular.

GOVERNMENT PERSPECTIVES

After having brought forth a more detailed image of mobility and dealing with mobile communications, this chapter will approach the term "government" in a similar manner. By taking into consideration the particular connotation of this term, we will derive key aspects of developing services for mobile government. Even when it seems evident what might be mobility issues, it is yet unclear whom this shall serve, who and what is crucial within the field of government when planning a certain service.

From a semantic viewpoint, government as a collective term consists of four main elements:

- the (political) system,
- organizations within the government system,
- the processes of governing,
- the actors constituting government.

In Figure 2, showing the relation between the elements, we see that the *system* is the framework in which people being administered by "a" government are located, as well as the governing organizations. Since the system itself has a rather normative character, it is of less importance when dealing with mobile government.

More important is the governing element, the *organizations* performing within the superior system, compliant to given values and norms as well as pursuing and enforcing them. The distinction between a government and administrative branch is merely functional; from the current point of view, this distinction shall also be neglected. Of interest is the single organization as a whole, supposedly acting as one instance in relation to other organizations and preliminary elements (citizen, businesses).

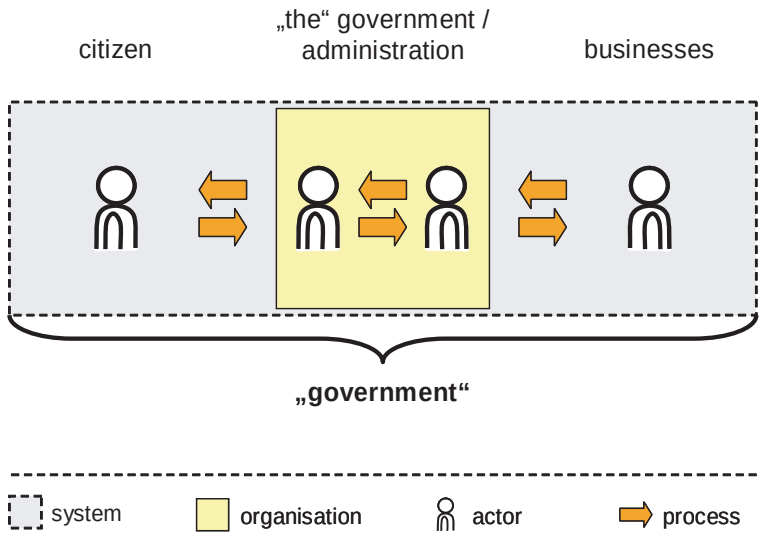
The *processes* of governing describe the actual ways of interaction between these active elements. Usually, there are certain procedural requirements which have to be met by effected participants. In general, these are available in form of laws and regulations, determining how a process is to be run, who is involved, which resources are required, and what the possible outcome is.

Involved *actors* within government constitute the governing authority, implicitly legitimizing its existence. The set of actors include the citizen as the basic part of the system, sometimes also acting as a representative of a business or as an employee or representative of a governmental organization.

In this setting, electronic government describes using ICT in the interaction of the named governmental elements, thus including m-government. To provide a rough distinction between e-government and m-government, it shall be understood here, that of course mobile government mainly extends electronic government, but at the same time, it adds mobility as a new feature, allowing for new, genuine mobile services. Whether mere extension or true innovation, m-government is dealing with mobility in the context of government, especially but not primarily with mobile technologies as a means of service delivery.

When designing a mobile government service, at least one part of the elements of government described earlier is mobile. Depending on what is being mobilized, different requirements have to be met. Of general concern are certain specifications set out by the system, possibly the availability of services to the whole public, thus often creating the problem of competing access channels. Recent

Figure 2. Elements of government



research (Pew Internet & American Life Project, 2004) reveals that multi-channel government is needed and wanted on the one hand, while on the other it decreases or at least consumes some of the efficiency gains by reducing the overall number of transactions within one channel, and requiring the support of parallel infrastructure. By adding yet another channel to the already available multiple channels (paper/forms, telephone/call centre, Internet/Web sites), it can be assumed that this issue will not be solved too easily. Thus, where there are several access channels for the same process, investment and roll-out strategies for new services have to closely monitor current capacities, and consider competition between available means of communication and effective demand. This competition issue is more relevant in the case of dealing with external parties (most likely citizen) than it is for internal exchange. In the latter case, it can be assumed that offerings are less prone to allow for diversity, due to the opportunity to simply impose standards in a top-down manner.

Since we are discussing the inclusion of mobility as a feature of a mobile government service, we have to take a closer look at the government elements who actually are mobile or to whom mobility is of importance. In the same way as we previously identified different perspectives on mobility, it will now be described how the different elements deal with mobility in the context of mobile government.

Process Requirements

The processes of government are the link between actors and organizations. In the context of mobility, one can think of many features of mobile communications which might be useful for governments. However, since government processes are rather formalized, they need to integrate many preconditions, with security being

just one. The challenge for mobile government is thus combining formal, procedural requirements with opportunities of the technologies.

From a more distant perspective, we have to first understand that a process consists of several steps. It is initiated by some kind of triggering event. This can be mobile, for example, a transaction being initiated in response to a mobile context.

Then there is the actual process, involving certain logic as to who is responsible, what resources are needed, and what decisions need to be taken. All of these can be *mobilized* as well. Decision makers can be linked to other participants via mobile communication channels, allowing for on-the-spot decisions or feedback when and where it is needed. Resources can be requested or procured in a similar manner. The final product itself may also be delivered using mobile technologies. Information as a product might be passed on to a mobile device, or the process result might trigger a new follow-up process, equally mobile.

As to whether or not a service can be made mobile is not only depending on the fantasy of a designer, but also on formal requirements imminent to the process. The question is thus a rather specific one and cannot be discussed in detail here.

Nevertheless, there are some general properties to a government process offering a generic guideline. First of all, a dominance of informational process can be assumed, that is, most of the transactions are based on information exchange and information processing. Depending on the content, especially the processing of information is more or less sensitive and time-critical. The complexity can differ, too, as well as the form of presentation.

The information focus is connected to the fact that general conditions for government processes are comparability, legal validity, and binding character of results (e.g., a decision on your taxes is based on your income, not on the mood of the decision maker; the decision is binding but can be legally challenged). The process itself is governed by law and usually processed along an organizational and functional path. Though these criteria still need to be detailed for each application, they offer assistance for the design process.

As is true for any government service, the formal requirements have to be matched with what is technically possible. A general method for such a matching process for mobile communication has been set out by Gerstheimer and Lupp (2001; see also Roggenkamp, 2004, p. 864). Notwithstanding this, describing what is feasible within the possibilities of technology and requirements of government processes is just the starting point. Designing mobile government must not be constrained to analyzing what can be mobilized. Furthermore, it is imperative to identify how and where additional value can be created, for the individual user as well as the providing organization.

Organizational Willingness

Different to a business organization, an organization in the public sector is acting in a kind of monopoly—the customer (in this context being a citizen, a business, or other governmental actor) cannot choose between different providers of public services. There usually is just one police, one local administration responsible, and so forth. In addition, a government organization is not seeking a rent of a financial kind; instead, it needs to legitimize its actions and existence towards the public, whom it is supposed to serve.

Thus, when it comes to the question as to whether, how and for what and whom an organization should rethink and re-organize its way of "doing things", a dilemma is surfacing which needs to be solved: external pressure and internal opposition. The common driver for implementing new technologies is external pressure: the demand for more and more efficient services, technologically enhanced process-handling as well as improving the public perception of an

organization respectively of the people in charge. Hence, technology is often implicitly imposed on an organization as a response to this pressure. A supposedly *new way* most often simply transfers the *old way* of doing things into the digital world. Replacing a paper-form by a Web site in fact leads to gains in productivity and cost reductions. Gora (1996) concluded that traditional organizations are insufficiently incorporating possibilities of ICT.

According to a recent survey of European public sector organizations (Net Impact, 2004) structural changes within the organization are in most cases made in response and not prior to the implementation of technology (p. 30). This results in lower gains in productivity as would have been achievable the other way around. The problem government organizations have to deal with is that "technology has evolved to a point where it is more difficult to change human behavior than it is to get the technology to do what you want" (p. 33). While there is external pressure to change, there is internal opposition hindering these changes. A description as to why this opposition occurs and how it arises has been thoroughly given by Borins (2001) and less detailed but focused on mobility issues by Kushchu and Borucki (2004). At this point it shall be of more interest how an organization can estimate the scope of this dilemma, especially in the course of designing mobile government.

While considering process requirements, it has already been roughly outlined how to identify processes. The task of an organization is to find out where stakeholders actually are confronted with mobility. From this deduction potentials for mobile services to be successful can be identified: from a productivity perspective to deal with internal opposition (by offering an enhanced mobile working environment) and with external pressure (by improving overall outcome).

Taking the previously-made statements about economical perspectives into account, we can identify three fields of action as starting points:

- internal processes (value chain);
- transaction processes; and
- government products (as results of the earlier-mentioned).

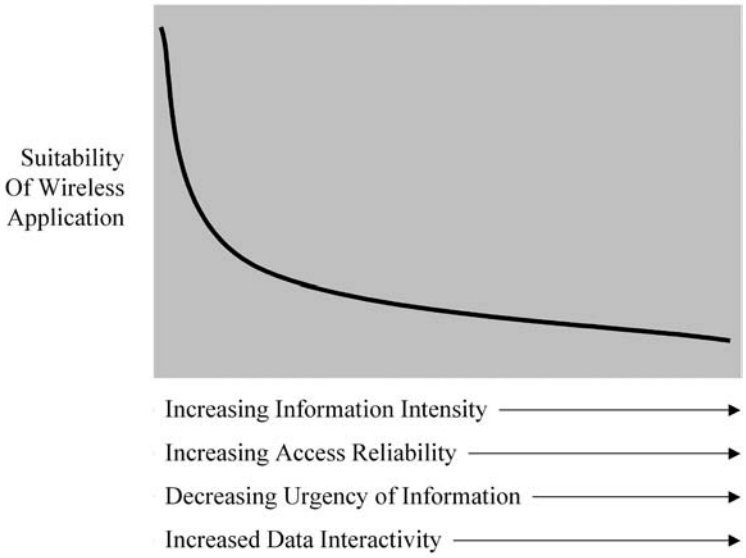
A whole set of possible services in the various fields of government has been described by the Centre for Public Service Innovation (2003) based in South Africa. Since there are already quite a few services available (see Zálešák, 2003), it should be a manageable task to identify applicable service proposals. As a method to assess whether and when an organization should consider implementing a certain service, Chang and Kannan (2002) have identified four relevant factors: the "extent of mobility in the target segment, information access needs, security/privacy requirements of the application, and technology readiness of the target segment" (p. 32). By joining the first three factors they generate an indicator for the sophistication of technology to meet certain requirements. In relation to the technology readiness, the actual question to be considered from the organizational perspective, they create a matrix (Figure 3) with which possible services can be ordered in a timely manner.

Of course, each organization which is considering mobile government services, as an option to invest in, needs to create a more detailed depiction of what it actually needs as well as an outline of why it needs a mobile service.

Concerning the fact of technology readiness—describing an attitude towards technology and not the mere competence to use it—will vary from one organization to the other, also from one department or team to another. By taking a step-by-step approach, the readiness can improve with each project. Generally speaking, as experience grows, so will the readiness to accept a new service (see also Davis, 1989, on perceptions of technologies).

When considering mobile service, it has so far been made clear that problems for an organization

Figure 3. Matrix for suitability of mobile services (Chang & Kannan, 2002, p. 21)



will most likely arise from within: in the form of internal opposition. By approaching more and more sophisticated services to deal with mobility in all fields of a government organization one step at a time failures can be avoided or at least contained.

Nevertheless, to legitimize an investment in mobile services, the value created has to be clear to the providing organization and its stakeholders. Where there is an overall strategy for service creation, criteria to assess and prioritize possible services in compliance with superior goals are easily found. In general, however, a real improvement has to be proven, for example, by pilot implementations. Mere feasibility of mobilizing the processes is one thing to be shown here, but also the feasibility of integrating the service into existing backend structures and more so into communication structures within an organization.

While the value of each service will often be easily assessed, the willingness and ability to realize potential gains through mobile services in common processes is the key from the perspective of an organization. Otherwise, even the most promising mobile added values would be just that: promising.

User Acceptance

We have so far looked at feasibility of mobile government services and discussed organizational willingness. Now we will focus on user acceptance as the main driver for the success of a service. The situation, into which mobile government will be deployed, can usually be described as competitive as there are other access channels to certain services. Thus, it is inevitable to consider why a user is lead to adopt a service.

User acceptance can be described as a product of user behavior in relation to the available technology and a given environment. Davis (1989) has described perceived usefulness and

perceived ease of use as the main influences on user acceptance of information technology (p. 320). As a consequence thereof, to achieve user acceptance the development of these perceptions need to be dealt with.

Methods in this field reach from standard quantitative approaches simply asking about how services would be or are perceived to explorative approaches of shadowing users. The latter are able to find out more about actual usage patterns and social shaping factors (see Vincent & Haddon, 2003). From the research we learn that for mobile communication the usage patterns are influenced by the "representation" (Churchill & Wakeford, 2002) of a service, meaning the image being drawn by suggesting value (based on supposed usage). This image is usually framed by the reaction of the individual environment of a prospective user, considering norms and general values.

This leads a user to the initial decision to get to know a service—to test it. During this "learning phase" previously formed expectations determine the subsequent, repeated usage, allowing for new experiences. Important at this stage is not only typical front-end usability but a more generic feeling of actually being able to control and, to a certain extent, to understand functions offered by the used technology. Palen and Salzman (2002) have described four dimensions important at this point, of which at least two are within the reach of government.

Hardware, being the first dimension, roughly covers the device used for accessing a service. On such a device, a set of *software* is controlling user flows. The *netware* is the connection of hard- and software with mobile technologies' functions. This is surrounded by the *bizware*, consisting of all sorts of customer support and customer relation.

For a government organization offering mobile services, the points to connect into this structure would mainly be the net- and bizware, offering services and supporting their usage.

Following the state of acquainting with a service, the user individually explores the opportunities offered, possibly seeking new patterns of usage, as well as feeding back his experiences to his environment. At this point, but also in the initial phase, we can observe what Vincent and Haddon (2003) call "social shaping" of mobile technology: the creation and reassessment of value expectations, changing usage and behavioral patterns as well as overall norms defining how to properly behave, use, and consider certain mobile services.

The choice to use a mobile service, as is the case for any ICT, is thus guided by the perception of use and the actual use. User needs, more so the evaluation of a service to meet these needs is crucial for its success. Yet, research has also shown (cf. Pew Internet, 2004; Vincent & Haddon, 2003) that a typical user will not only make smart choices about the technology to use, but he will often consider the appropriateness of a means from a functional (reflecting the actual service) and a social (reflecting the outside perception) point of view. Furthermore, often parallel structures are maintained, for backup purposes or to meet requirements of unexpected situations. This is related to trust on the one hand, to a somewhat haptic experience on the other (Perry et al., 2001). In both cases, the biggest challenge for mobile information access is a paper-based process, for mobile interaction services the challenge is the fixed line phone (see also Vincent & Haddon, 2003). Since government services are most often based on trust (especially when exchanging sensitive personal or corporate information) while allowing for several channels of interaction, this issue should be thoroughly considered.

Nevertheless, trust can be built (by experience), whereas complementary services as a first step will lead to substituting less helpful stationary services in the long run.

By assessing needs more closely, the impact of the previously-named issues can be softened.

In general, mobile business services consider a user in a certain situation, and come to conclusions about his needs by deconstructing the individual context (see Gerstheimer & Lupp, 2001; Roggenkamp, 2004).

For existing services to be mobilized, this is helpful, though not fully leading to conclusions. Because of this, a different method of looking at user needs shall be introduced to extend this perspective.

Before, one has to distinguish between need in the sense of wishing for something and need in the sense of demand, connected to the willingness to trade resources to satisfy this demand. Hence, the needs we will talk about now are of the latter type, considered from the supply side.

Governments offer certain services in pursuit of meeting common rules and fulfilling assumed tasks. This "supply" can be characterized (Figure 4) as to what kind of interaction it offers: information, communication, or transaction. Second, the intention of a service can be defined: whether it is aimed at following a user, thus allowing him to be mobile. Or whether it is aimed at guiding a user, thus supporting his mobility. Finally, we can consider the dependency of user and service, being connected due to time, location, or person.

With each aspect, it can be estimated as to how sensitive a service is, and how much it relates to situations which are mobile. An assessment of how a service will be perceived can be based on the results of this description.

From the initial description of influences on user acceptance, the second relevant issue for government is user experience. As has already been mentioned for organizational willingness, a step-by-step approach seems to be appropriate in the course of entering the field of mobile services. Not only can the providing organization adjust to demands of mobility, the actual users too can familiarize themselves with mobile government and explore technology, services, and functions available.

Finally, an issue not to be underestimated is the overall perception of mobile government. We have to bear in mind that mobile communications are currently most often used for purposes of social connectedness, whereas we also see mobile services most successful when offering entertainment and tools to customize the personal item "mobile phone". Against this background, it has to be proven that mobile government is more than supposedly helpful SMS or more intrusive government officials with remotely trustworthy devices that seem to reveal and collect by far too much sensitive data. Electronic government has reached a point where the extreme perceptions reaching from subversive Internet-based liberation to data-gathering "big brother"-like organizations have diffused into something convincingly useful, that can be utilized as needed. The biggest changes have occurred within the backend infrastructures.

Figure 4. Describing a service to identify resulting needs

Interaction level	Intention of a service	Dependency user/service
• Information • Communication • Transaction	• Follow user/ allow for mobility • Guiding user/ supporting mobility	• Time • Location • Role/Person

Since mobile government is, due to its mobility, doomed to take place far more in public spaces, the positive images have yet to emerge, the general perceptions yet need to be formed.

THINKING ABOUT MOBILE GOVERNMENT

When thinking about mobile government, the following four general questions should lead the way on to a definition of an aspired service. Also, they are supposed to help identifying beforehand, if and where there are flaws in the concept and actual message connected with a service and its goals.

What is Being Mobilized?

Reviewing existing m-government, it becomes obvious that the scope of services awarded this label is wide, to be distinguished by their primary function and their reach.

To answer this question, initially it needs to be defined whether the main goal is offering mobile access to some data source or if a service is supposed to be a genuine mobile application (or more likely something in-between, but tending to one side or the other).

Whereas mobile access most often means getting rid of wires, the being-mobile is part of the functionality of a full-scale mobile application. Services such as geographical or tourist information are a case in point, since being stationary bound impedes their value dramatically. The reach of a service in this context is considering geographical limitations, whether a service is limited to a single location, a region or whether it reaches even beyond. From this initial evaluation, we can derive possible bearing technologies applied for transmitting, accessing, or delivering services in question.

The second part of this evaluation dealt with needed/offered complexity, sensitivity, and criticality of a service. Referring to the earlier-identified process elements, we can look at:

- triggering events,
- control mechanisms,
- resources, and
- resulting products and recipient,

as able to be mobilized, as well as consequences thereof. Triggering a process is probably less complex than governing it. With the recipient being mobile, embedded within a certain context, and depending on the product being possibly presented mobile, there are particular problems to be dealt with for each element.

Why Mobile?

This rather broad question is supposed to lead to name driving forces behind the creation of mobile services. The case of actual, focused public demand is found rather seldom. Hence, we can conclude key motives to be efficiency, effectiveness or political goals. Furthermore, when looking at the purpose of mobilization, the mobile value being *expected* should be directly addressed. When an answer cannot be easily found here, it should be doubted that targeted users will be convinced. Less so, when they are actually obliged to cover extra cost (connection fees, infrastructure, etc.). Nevertheless, the opposite situation of being instantly able to state exact and conclusive reasons is no guarantee for success, for initial user adoption.

Are there Alternative (not Mobile) Services Available? Will Existing Services be Replaced?

Based on the already found answers, this subject should be quickly covered. The mere existence of an alternative to a mobile service puts the question of expected added values attributed to such

a service back on the agenda; especially when these alternatives are maintained.

Competing with other communication channels, the mobile channel covers certain areas of use, namely social and private ones. Therefore it is appropriate to ask whether and why the mobile alternative should be better.

Nevertheless, the data on the not-mobile services can help to assess how to improve it, and how to transfer this into a mobile context. Also, it can be better identified who would actually be served, and how often.

What is the General Agenda? Who will Benefit?

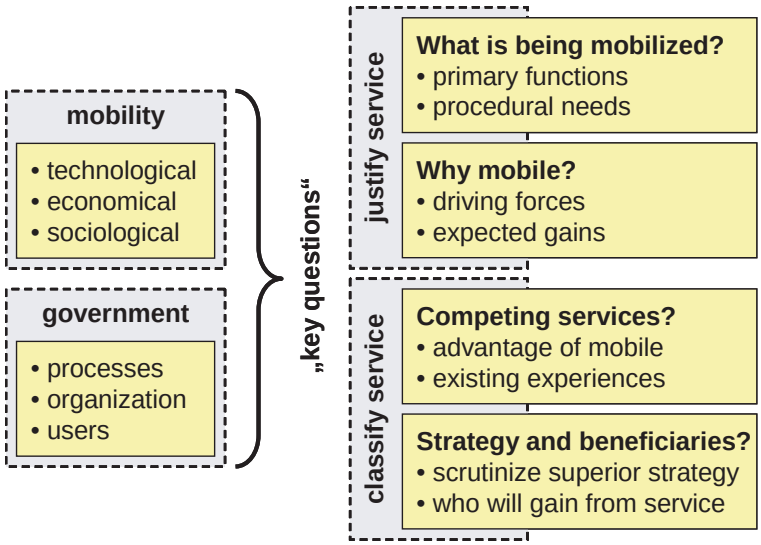
This third version of the "Why mobile?" question is asked separately, because it scrutinizes the superior strategy of a providing organization. Naming those who will benefit is especially important when a service is deployed into a kind of monopoly, as we find to be predominant in most of the public sector.

An individual cannot choose with which organization it prefers to do government business, however, in many cases it can choose how it wants to do it. By identifying those who gain advantages by a mobile service it can also be determined who will have to cover any additional cost.

CONCLUSION

In the course of this chapter, the term mobility has been described as the key component of mobile government. Three (technological, economical, and sociological) different perspectives have been shown along with goals connected to their respective view. The combination of these perspectives has helped to identify key issues to be considered when dealing with mobility. With the description of these views, it is possible to develop a mobility cycle which combines questions of technological feasibility with economical demands and user needs.

Figure 5. Key questions when designing mobile government



Focusing on the elements of the government term, it has further been described how process requirements, organizational willingness, and user acceptance can influence mobile government services. Also, a rough distinction between e-government and m-government has been provided, stating that mobile government mainly extends electronic governments, but considering mobility as a new feature, new services become possible which do not fit in a narrow view of e-government being a digital way of service-delivery.

Resulting from the previous dealing with mobility perspectives and the elements of government, four questions (Figure 5) were identified which ought to be dealt with when conceptualizing and designing mobile government.

The questions are supposed to guide developers through the process of designing mobile government services: First by helping to define and justify scope and content of a service. Second, the service can be classified and reviewed in its context, by assessing the possible competition it might face and by naming its beneficiaries.

OUTLOOK

Leading to a more generalized debate on mobile government, it is yet unclear whether mobile services in the public sector should be seen as something completely different that "traditional" services, or if we need to amend our evaluation criteria just a little.

All in all, most of the mobile services can be reduced to "old-fashioned" online services, based on existing backend infrastructure, with only significant differences being the *feature* mobility, to be understood as an add-on.

However, the debate on mobile interaction points out that the addition of "mobile" as a feature and important component of a service (including all the technological functions like localization, etc.) lead to changing behavior; the expectations toward the public sector are affected while the boundaries of public and private are diminishing.

Similar things have been said on the peak of the online hype and following the invention of the World Wide Web, just a few years ago: *virtual democracy* was expected by many commentators. However, the debate developed from euphoria to disillusionment—the drastic expectations of an Internet-based revolution did not come true. This notwithstanding can we observe changes in behavior and perception among users. Also, we have to recognize the changes on the government side, which is now looking for the creation of better services. Even the most pessimistic evaluation of mobile services in the public sector has to acknowledge the sustainable effect on users and providers alike.

Apart from the common criteria of service assessment, such as cost and quality, the potential of location-independence and other features of mobile technology have yet to be understood in all their impact.

Mobile government is not per se something new or even special. Due to the technological features and more so due to mobile users, it is an issue growing to become more and more important. And that is enabling and supporting mobility.

Chapter 2.30
Design of Government Information for Access by Wireless Mobile Technology

Mohamed Ally
Athabasca University, Canada

INTRODUCTION

As the world becomes mobile, the ability to access information on demand will give individuals a competitive advantage and make them more productive on the job and in their daily lives (Satyanarayanan, 1996). In the past, government information was presented by government employees who verbally communicated with citizens in order to meet their information needs. As print technology improved, government information was, and still is in many countries, communicated to citizens using paper as the medium of delivery. Because of the cost of printing and mailing printed documents and the difficulty of updating information in a timely manner, governments are moving to electronic delivery of information using the Web. Currently, governments provide digital service to their citizens using the Web for access by desktop or notebook computers; however, citizens of many countries are using mobile devices such as cell phones, tablet PCs, personal digital assistants, Web pads, and palmtop computers to access information from a variety of sources in order to conduct their everyday business and to communicate with each other. Also, wearable mobile devices are being used by some workers for remote computing and information access in order to allow multitasking on the job. It is predicted that there will be more mobile devices than desktop computers in the world in the near future (Schneiderman, 2002). The creation of digital government will allow the delivery of government information and services online through the Internet or other digital means using computing and mobile devices (LaVigne, 2002). Also, there will be more government-to-citizen and government-to-business interactions. Digital government will allow citizens, businesses, and the government to use electronic devices in order to communicate, to disseminate and gather information, to facilitate payments, and to carry out permitting in an online environment (Wyld, 2004). Digital government will allow citizens

to access information anytime and anywhere using mobile and computing devices (Seifert & Relyea, 2004).

BACKGROUND

According to O'Grady and O'Hare (2004), mobile computing will become the major computer usage model of the future. This will be possible since the digital divide is decreasing due to wireless access, increasing use of mobile devices, decreasing cost of Internet connections and computer technology, and transparent access of computer systems. Governments need to take advantage of technology-literate citizens and design and make available information for citizens to access government information digitally from anywhere and at anytime. This is important, since citizens expect the same level of service that is being given by businesses that are providing services and information anywhere and anytime (Dawes, Bloniarz, Connelly, Kelly, & Pardo, 1999). Users need just-in-time information for the job and in the community. The use of wireless mobile devices will facilitate access of government information from anywhere and at anytime. Also, computing is becoming ubiquitous, where citizens will work from anywhere and access government information from many networks using wireless mobile devices (Huber, 2004; Perry, O'Hara, Sellen, Brown, & Harper, 2001).

Before the use of mobile devices to access government information and design of information for mobile access are discussed, it is important to examine the information processing required when citizens access digital government information. Citizens acquire government information at many levels. At the lowest level, citizens may want to be aware of what is happening in government, so they will read the information in order to be informed. For example, some citizens may want to know the changes made to tax regulations. At the next level, citizens and businesses may want to access government to apply the information to complete everyday tasks. For example, some occupations require that businesses and citizens follow approved safety procedures when completing tasks. This requires comprehension and application of the information. At the highest level, citizens and businesses may want to critically analyze, synthesize, and evaluate government information for research purposes. To achieve this, citizens will have to access government information from many sources through ubiquitous computing using mobile devices.

USE OF MOBILE DEVICES TO ACCESS DIGITAL GOVERNMENT INFORMATION

There are many benefits to the use of mobile devices to access digital government information. According to a recent report by the European Commission (2004), digital government can provide better quality public service, reduce waiting time for information and service, lower administrative costs for businesses, and allow higher productivity for the public. Using mobile devices will allow citizens to access government information from anywhere and at anytime. With the use of wireless mobile technology, users do not have to be connected physically to networks in order to access information, and the mobile devices are small enough to be portable, which allows users to take the devices to any location to send and retrieve information. For example, a worker in the field who requires specific government regulations while completing a task can use a mobile device to access the information just in time. If government regulations in a field change, the government can update the digital information to allow individuals and businesses to access the current information immediately. In addition, a worker in the field can use a mobile device to contact a government employee remotely and to request specific information for immediate use.

Mobile devices have many benefits for accessing government information; however, there are some limitations of mobile devices of which designers of government digital information must be aware when designing information for delivery on mobile devices. Some of the limitations of mobile devices in delivering government information include the small screen size for output of the information and the small input devices for accessing the information (Ahonen, Joyce, Leino, & Turunen, 2003). Designers of information must be aware of these limitations when designing government digital information for access by mobile devices and must design for ease of use. Rather than scrolling for more information on the screen, users of mobile devices must be able to go directly to the information and move back and forth with ease. Information should be targeted to the users' requests when they need it and should be presented efficiently to maximize the display of the information on the mobile device screen. The interface of the mobile device must be appropriate for individual users and the software system should be able to customize the interface based on individual user's characteristics.

Designing Government Digital Information for Mobile Devices

As the evolution of delivery medium of information changes, so does the strategy for processing the information. According to Grudin (2004), prior to writing and print, most information access and interaction were done by listening, memorizing, and speaking. With the print medium, information acquisition strategies were reading, analyzing, and writing. As government information becomes digital, acquisition strategies include searching, synthesizing, and constructing. Designers of government information for mobile devices must design for the new information acquisition and interaction strategies.

Most government information tends to be text-based, which takes longer for users to process and interpret. This is because past government information was designed for printing on paper for delivery to citizens. Designers of digital government information must use the capability of the computer to present information visually as well as textually in order to facilitate efficient processing and acquisition of the information. According to Paivio's (1986) theory of dual coding, information storage and retention is enhanced when information is represented both in verbal and visual forms. Presenting material in both textual and visual forms will involve more processing, which will result in better storage and integration of information in memory (Mayer, Fennell, Farmer, & Campbell, 2004).

In addition, because of the limited display capacity of mobile devices, government information must be designed for display using rich media such as audio, video, pictures, and graphics. Tabbers, Martens, and van Merrienboer (2004) found that for Web-based multimedia information, students who received visual cues to pictures scored higher on an information retention test compared to students who did not receive the cues for the pictures. According to cognitive psychology, information acquisition is an internal process, and the amount retained depends on the processing capacity of the user, the amount of effort expended while reading the information, the quality of the processing, and the user's existing knowledge structure (Ausubel, 1974). These have implications for how government information is designed for mobile devices. Designers must include strategies that allow the user to activate existing cognitive structure in order to conduct quality processing of the information. Mayer, Dow, and Mayer (2003) found that when a pedagogical agent was present on the screen as information was narrated to students, students who were able to ask questions and receive feedback interactively performed better on a problem-solving transfer test compared to students who only received on-screen text with no narration. It appears that narration by an intelligent agent encouraged deep processing, which

resulted in better information acquisition and higher-level information processing. This suggests that government should use audio to present government information to citizens.

Guidelines for Designing Government Digital Information for Mobile Devices

Chunk Information for Efficient Processing

Designers of government materials for mobile devices must use information presentation strategies to enable users to access and process the information efficiently because of the limited display capacity of mobile devices and the limited processing capacity of human working memory. Information should be organized or chunked in the form of information objects of appropriate and meaningful size to facilitate storage and processing in working memory (Ally, 2004).

Adapt the Interface to the User

To compensate for the small screen size of the display of the mobile device, the interface of the mobile device must be designed properly (Ally, 2004). Mobile access to government information requires interface designs for multi-mobile device access and intelligent agents to adapt the interface to the user (Nylander, Bylund, & Boman, 2004). The interface can be graphical and should present limited information on the screen in order to prevent information overload in short-term memory. Users must be able to jump to related information without too much effort. The interface must allow the user to access the information with minimal effort and to move back to previous information with ease. For interaction sessions that are information-intense, the system must adjust the interface in order to prevent information overload. Some ways to prevent information overload include presenting less information on one screen or organizing the information in the form of graphical outlines to give the overall structure of the information and then presenting the details by linking to other screens with the details. The interface also must use good navigational strategies to allow users to move back and forth between information displays. Navigation also can be automatic, based on the intelligence gathered on the user's current position in the information and the information needs of the user.

Design for Minimum Input to Retrieve and Access Information

Because of the small size of the input device on mobile devices, information access must be designed to require minimum input from users. Input can use pointing or voice input to minimize typing and writing. Because mobile devices allow access of information from anywhere at anytime, the device must have input and output options in order to prevent distractions when using the mobile devices. For example, if someone is using a mobile device in a remote location, it may be difficult to type on a keyboard or to use a pointing device when accessing government information. The mobile technology must allow the user to input data using voice input or touch screen.

Target Government Information to the User

One of the variables that designers tend to ignore when they develop information for mobile devices is the user of the devices. Different users have different styles and characteristics, and some users may be more visual, while others may be verbal (Mayer & Massa, 2003). A graphic outline of the information can be presented before the details are presented in order to cater to users who prefer to get the big picture before they go to the details

of the information. Government information must be designed with the user in mind to facilitate efficient access and processing.

Government systems must be smart and should have built-in intelligence in order to customize and target the information for individual citizens. Information must be personalized by selecting and aggregating information according to the user profile (Huber, 2004). Intelligent software systems can be built to develop an initial profile of the user based on current and previous interaction with the government information database and then present materials that will benefit the specific user, based on the user profile. As the intelligent agent interacts with the user, it learns about the user and adapts the format of the information, interface, and navigation pattern according to the user's style and needs.

Use Visual Outline to Show the Structure of the Information

A visual outline can be used to show the main ideas in the information and the relationship between the ideas rather than to present information in a textual format. High-level visual outline can be used to represent information spatially so that users can see the main ideas and their relationships (Novak, Gowin, & Johanse, 1983). Tusack (2004) suggests the use of site maps as the starting point of interaction to which users can link back in order to continue with the information.

TRENDS IN USING MOBILE DEVICES FOR ACCESSING GOVERNMENT INFORMATION

The use of mobile devices with wireless technology allows access of government information from anywhere and at anytime and will dramatically alter the way that work is conducted (Gorlenko & Merrick, 2003). For example, mobile devices can make use of global positioning and satellite systems to send and receive government information digitally. There will be exponential growth in the use of mobile devices to access government information, since the cost of the devices will be lower than desktop computers and a user can access information from anywhere and at anytime. Also, the use of wireless mobile devices by businesses and organizations will be more economical, since it does not require the building of the infrastructure to wire buildings for employees and customers. The challenge for designers of government information for mobile devices is how to standardize the design for use by different types of mobile devices. Government information systems need to have agents to deliver the right information to the user. A profile agent can be used to learn about the user and then to interact with a presentation agent in order to customize and format the information to meet the user needs (O'Grady & O'Hare, 2004).

CONCLUSION

Government information was designed for delivery on paper medium. Governments need to rethink and redesign information for delivery on mobile devices. Future development of information for mobile devices should concentrate on the user to drive the development and delivery (Gorlenko & Merrick, 2003). Mobile devices can be used to deliver government information to users, but the materials must be designed properly to compensate for the small screen of the devices and the limited processing and storage capacity of users working memory. Design principles for government information on mobile devices are the same as design principles for other applications such as education and training. The only difference is that government information tends to be one way, and there is less interaction with the information, since the purpose of most gov-

ernment information is to inform citizens. More research should be conducted on how to improve security and privacy of government information on mobile devices. Also, the type of information presented on mobile devices must match the needs and the styles of the users. Government information systems must use the power of computer technology in order to develop intelligent agents to customize the information for users and to provide context-sensitive information. According to Rist and Brandmeier (2002), more research is needed on how to flexibly translate government information from one medium into another format and how to decide which media combinations are most appropriate, considering a mobile user's style, current task, and situation. Finally, governments need to shift from print and desktop delivery of information to delivery on mobile devices in order to make the transition to becoming mobile government (m-government).

KEY TERMS

Concept Map: A graphic outline that shows the main concepts in the information and the relationship between the concepts.

E-Government: The delivery of government information and services using electronic technologies.

Information Object: Digital information stored in chunks in a digital repository and tagged for retrieval to meet users' information needs.

Intelligent Agent: A computer application software that is proactive and capable of flexible autonomous action in order to meet its design objectives set out by the designer.

Interface: The components of the computer program that allow the user to interact with the information.

Mobile Device: A device that can be used to access information from anywhere and at anytime. The device consists of an input mechanism, processing capability, a storage medium, and a display mechanism.

Pervasive Computing: Use of computer devices to access information from interconnected networks using wireless technology.

Ubiquitous Computing: Computing technology that is invisible to the user because of wireless connectivity and transparent user interface.

User: An individual who interacts with a computer system to access information.

Wearable Computing Devices: Devices that are attached to the human body so that the hands are free to complete other tasks.

Section III
Tools and Technologies

This section presents extensive coverage of the technology that both derives from and informs mobile computing. These chapters provide an in-depth analysis of the use and development of innumerable devices and tools, while also providing insight into new and upcoming technologies, theories, and instruments that will soon be commonplace. Within these rigorously researched chapters, readers are presented with examples of the tools that facilitate and support mobile computing. In addition, the successful implementation and resulting impact of these various tools and technologies are discussed within this collection of chapters.

Chapter 3.1
Evaluation of Mobile Technologies in the Context of Their Applications, Limitations, and Transformation

Abbass Ghanbary
University of Western Sydney, Australia

ABSTRACT

Emerging mobile technologies have changed the way we conduct business. This is because communication, more than anything else, has become extremely significant in the context of today's business. Organizations are looking for communication technologies and corresponding strategies to reach and serve their customers. Mobile technologies provide ability to communicate independent of time and location. Therefore, understanding mobile technologies and the process of transitioning the organization to a mobile organization is crucial to the success of adopting mobility in business. Such a process provides a robust basis for the organization's desire to reach a wide customer base. This chapter discusses the assessment of a business in the context of mobile technology, describes the application and limitations of mobile technology, presents a brief history of mobile technology and outlines an initial approach for transitioning an organization to a mobile organization.

INTRODUCTION

This chapter evaluates the effects of mobile technologies on business and outlines an initial process of transitioning to mobile business. In 1874, when Alexander Graham Bell invented the telephone, he could not have imagined the significant impact it would have on number of aspects of human life. Similarly today, advancement in information and communication technology (ICT) has dramatically changed the way people live and conduct their businesses. One of the dramatic aspects of modern-day business activities is that these activities are conducted independent of location and time. For example, businesses are able to sell goods, facilitate customer enquiries, and coordinate their services through disparate

geographical and time boundaries primarily due to the wonders of communications technologies. Alter (1996) describes the ICT as tools for doing things, rather than just for monitoring performance of yesterday or last week. Thus it is quite logical to conclude that ICT has changed the very nature of the workplace.

The basis for the communications technologies in most modern business applications is the Internet. Increasingly, the required access and connection to the Internet has become very simple and ubiquitous in most developed nations. This Internet access has opened up opportunities for organizations to revolutionize their business processes. Undoubtedly, improvement of the communication technology has impacted not only our business domain, but also our socio-cultural domain. This, as per Unhelkar (2004), has resulted in the "next wave" of technologies called mobile technologies:

Mobile technologies are becoming the next technology wave as the increasing popularity and the functionality captures many hearts. Riding on the back of traditional Internet, mobile networks ensure that information is available to its users independent of a physical location.

This ubiquitous connectivity accorded by mobile networks referred to above impact has facilitated the increased communication between people. Furthermore, this mobile connectivity has also improved the ability of business processes to exchange data and conduct transactions.

This transformation of businesses has been evolutionary rather than revolutionary. For example, at the beginning of the Internet age, with the aid of its communications capabilities, businesses were transferred to e-business, and we even had the opportunity to do our daily business activities from home. Ghanbary (2003) has described the Internet as the most powerful tool that brings information to our homes through communication lines, like water and electricity that come by power lines and pipes. Powerful search engines and the capability of sharing information are the great advantages of the Internet.

With the aforementioned strengths of mobile connectivity, it is also essential to work out a process that would outline "how" an organization can transition to such an m-enabled organization. However, this potential process of transitioning an organization to a mobile organization needs to incorporate all the major advances of mobile technologies of the past decade.

This is so because the philosophy of ordinary communication has given way to more advanced and efficient communications based on mobile and wireless technologies that enable business processes to be executed independent of time and location, resulting in a better, faster, and satisfactory response to the needs of the customer.

This impact of mobility is an important element of the mobile transition process that is felt at both business and personal levels. However, as of today, this process framework remains a challenge that needs to be further researched to enable businesses to transition successfully. This need for further investigation is also ratified by Ranjbar (2002), who correctly mentions: "It is not always possible to foresee all the implications of a new technology until it is adopted by the mass of population and used for a relatively long time."

With the increase in the number of mobile organizations, the service providers realize that they need to identify their strengths as well as their weaknesses in terms of providing mobile services that provide solutions as well as rectify the shortcomings. The analyses of the weaknesses and strengths will give them an advantage to provide a convenient service and increase their customer loyalty.

BACKGROUND OF MOBILE TECHNOLOGY

The known mobile phones used today are the extension of American mobile radiotelephone. However, the distinction between such phones and two-way radios is not clearly known. The advancement on mobile technology and the relevant gadgets have been very moderate due to the limitation of this technology and the government regulations on radio transmission. The major concern of the American Communication Commission was to decide who would get what frequencies and which emergency service should have the priority on air for transmitting first.

The ordinary usage of mobile took place in the 1980s. The first generation of cellular mobile phones was used widely only by transmitting analogue signals. The large size and very high prices of mobile devices in addition to the cost of the calls are the well-known facts of this period.

In the 1990s, the second generation of mobile phones was available in the market using advanced digital technology. Very fast signals, cheaper calls and handsets, more reliable services, and the smaller handset devices are the characteristics of this period.

The uncontrollable growth of mobile technology has created new culture in the business world. The use of mobile and Internet technology has passed their boundaries to a business and social revolution. The new technology has capabilities of text, voice, and videoconferences using wireless devices as well as the ability to connect to the World Wide Web.

According to Conners and Conners (2004), the application and the use of mobile and Internet technologies are to organize people into various common interest groups. These groups can vary from harmless fun to serious military or political operations.

Information and communication technology has enlightened the business activities. The use of mobile devices is going to be another crucial factor to remain in the competitive market. Vaghijiani and Teoh (2005) explain this phenomenon of mobile technologies as an enormous opportunity for players up and down the value chain, from the device suppliers to carriers to the end users.

BACKGROUND TO A TRANSITION FRAMEWORK

New process frameworks need to build on existing work on process transitions. Electronic transitions have been studied and experimented by Ginige et al. (2002). In the electronic transitions, there has been ample focus on the effect of a dynamic environment and the rapidly evolving technology on organizations. Undoubtedly, these changes cause organizations to restructure and would introduce a new suite of business processes for them to enable them to remain in the market as well as grow by dealing with a greater number of customers.

The new business model and the use of technology in the development of these changes were the cause of the new term e-business. The term e-business might mean trade on the Internet for some managers, however it is looking at the facts in deeper methodology. The Australian e-business guide (Philipson, 2001) translates e-business as any business transaction or activity that uses the Internet. This includes not only the sale of goods and services directly over the Internet, but also the use of the Internet to promote and facilitate the sale of goods and services.

By using mobile phones or any other mobile devices, we are able to make our e-business model more accessible. The improvement and the efficiency will create more benefits, hence the productivity remains even when people are out of their offices.

The proper design of the e-business model is a necessary component for the success of the m-business model. M-business makes the practice of the e-business model easier, more effective,

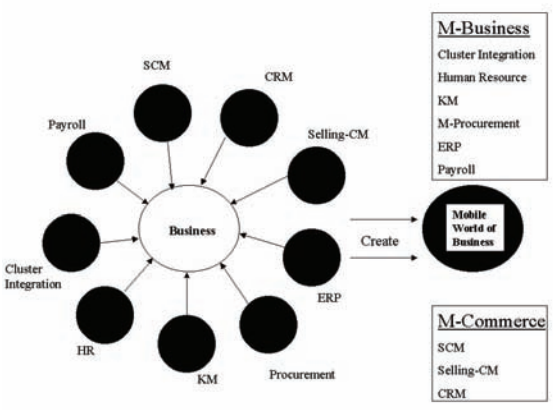
and more profitable since there is no restriction on approaching the required data. The share of internal data, providing better and more reliable customer service and better control over the organization in general, are other major benefits of mobile business.

Figure 1 shows the re-engineered and mobilized individual enterprise enabling the transformation of an ordinary business to a new and modern world of mobile business. The business and commerce sections are given in different boxes that provide a more comprehensive study of the transformation.

Figure 1 represents electronic mobile business activities in more detail.

- **Clusters Integration:** Our mobile business model must be able to integrate all the clusters of the organizations. This fact might look easy, however by careful analysis it is realised that to connect all the clusters of the organizations is a huge task. It needs more than technological advancement since some clusters might hesitate to share their information.
- **Customer Relationship Management:** The organizations must create close relationships with their customers. Customers want reliable and fast service. If the organizations provide them with what they want, they gain more business, and more business basically means more revenue. The CRM could be classified as a crucial factor of a mobile business, as it is in direct contact with people who are outside of the company. These people practically do not care how things are running as long as the great service is provided to them. A combination of technology, software, people, and re-engineered business processes are the fundamental of great customer relationship management.
- **Selling Change Management:** The right mobile business model should provide information about the available product directly to the customers. Direct interaction with the customers eliminates the retailer, and this will enable the business officials to provide detailed information about the product to the clients. As there are fewer hands involved in a purchase order, the prices offered to the customers will be dramatically low.
- **Enterprise Resource Planning:** The organizations have realised the importance of having the knowledge about back-office systems which could improve their customer order, integration of their clusters, and provide them with more sufficient information on how to run day-to-day activities by reducing the cost.
- **Supply Chain Management:** The technology is enabling the organizations to eliminate unnecessary processes to save time as well as money. The supply chain management of a business is the plan for materials to be directed to the customers as quickly as possible by cutting the inessential retailers. The information about the delivery, financial matters, as well as order transmissions are provided on any mobile gadgets. The mobile business has more power of monitoring and control over the order status.

Figure 1. Electronic mobile business model



- **Procurement:** As per Kalakota (1999), purchasing refers to the actual buying of materials and those activities associated with the buying process. Procurement on the other hand has a broader meaning and includes purchasing, transportation, warehousing, and inbound receiving.
  Organizations spend millions of dollars for procurement every year. Mobile procurement gives them the opportunity to have a better control on their inventory, better control over the purchase approval, and so on. They have better control over the cost as well as knowledge regarding their assets.
- **Human Resources:** The functionality of human resources in the mobile world could be classified as providing the title of available jobs on mobile devices and providing more sufficient information about the positions and required level of desired criteria on the Internet. Enterprise Bargaining Agreement online and other responsibilities of HR could be done while using the new technologies.
- **Payroll:** The available technology is giving the opportunity to advance the payroll that saves a great deal of time and human resources. This strategy is more beneficial to the organizations with odd clusters such as shift workers. If their roster is also automated, the payroll office could automatically generate a payroll list based on the automated roster, while only a human supervisor is required.
- **Knowledge Management:** In today's competitive business world, knowledge plays the crucial rule. The knowledge must be reliable and accessible through all clusters of the organization anywhere and anytime. Knowledge created by the supplier is about available services and products, and knowledge about the users is in the form of profiles. Imagine if a customer calls the engineering department of his electricity company to get the approval for the extension of his house. At the end the inquiry, he asks for the amount of his bill; the system should be able to provide the necessary information rather than transferring his call to another operator. The available information should support the day-to-day running of the business.

By the aid of the emerging mobile technology and re-engineering the individual departments of the organization, the new mobile organization is created. In general, the purposes of the value-added services are to impress customers and create more control over the business. By replacing business with m-business, we can reduce the cost and create more revenue by having more satisfied customers.

APPLYING MOBILE TECHNOLOGIES

By correct application of mobile technologies into the business processes, the business enterprises are likely to gain advantages such as increased profits, satisfied customers, and greater customer loyalty. These customer-related advantages will accrue only when the organization investigates its customer behaviour in the context of the mobile environment.

In general, the application of mobile technologies could be classified in two different categories, online and off-line services. The applications of online services are the executed applications when the mobile gadgets are connected to the mobile Internet.

The applications of the online wireless mobile Internet depends on situation (walking, driving), place (remote area, city metropolitan area), goal (aim of the connection), immediacy (instant action and reaction to demand), and load (how occupied the Internet provider is at the time of the connection). The congestion of the network clearly depends on the usage, which varies at different

times of the day. As expected during the business hours, the network load on the Internet service provider is heavy.

The major online mobile applications are:

- **Information:** General information about movies. Location of cinemas, hotels, hospitals, and universities. News, sports, travel, weather, and financial information.
- **E-Mail:** To send and receive mail while online using the mobile handheld.
- **Payment:** To buy the product and receive the service and pay by your mobile device and receive the payment on your mobile bill. There is trusted third party in mobile commerce regarding billing inquiries that increase the cost since another party is involved.
- **Mobile Internet Banking:** To complete the banking transaction using your mobile device while online. The participating banks decide what kind of transaction is allowed and how they provide the security for their clients.
- **Mobile Internet Shopping:** To shop online using the mobile gadgets. There are advantages and disadvantages in mobile shopping since the participants are not able to touch or smell the items they are buying unless it is first sale vs. the repeated sale.
- **Education:** Using mobile handset to download lectures, use library facilities (order book, search the library), and use laboratory.
- **Government Applications:** Election, government bulletin and broadcasting, disaster information system with the aid of location-based services, and automatically giving the priority to the broadcast.
- **Communication:** Videoconferencing, telephony, sending and receiving pictures, and international communication.
- **Leisure:** Download music, video, TV, and games, and for some particular people gambling could be classified as a leisure activity.
- **Telemetric:** Location-based services, global positioning services, and car navigation systems. Telemetric applications could be expanded to give the opportunity to your device to book a hotel room, purchase a ticket, gather your required information, and any related scenario just by a click of the button or voice order, assuming your personal mobile gadget is already holding all your personal and credit card details. These functions could be performed by connecting to your mobile Internet or just by connecting to your network provider.
- **Advertising:** Conjunction of mobile and Internet technology for advertising. Receiving an advertisement on the Internet (pop-up screens) is not something new; furthermore marketing organizations could use the same idea for mobile Internet.

The off-line applications are the services offered by related network providers and extra available features on the particular mobile devices. Networks must have infrastructure to support the fast transmission of the data, reliability of the data, the integrity of the data, and quality of service. The major off-line mobile applications are:

- **Communication:** Phone calls, SMS, messages, sending and receiving pictures.
- **Memory:** Phone book, music, different sounds, different effects (vibrate, volume), display, storing desired pictures and schedules and entertainment.
- **Expert System:** It would be possible for the organizations to use their mobile device as an expert system if their network provider has the capability to support it.
- **Remote Supervision:** To have control over the personnel while they are in an inaccessible area.

- **Traffic Information System:** Informing the drivers of traffic locations when they are driving close to the congested area.
- **M-Newspaper:** Subscribing to a newspaper if provided by the newspaper agency.
- **Advertising:** Based on the device's position, receiving the local advertisement.

Consumers' demands and corporate objectives could be different in the m-enabled world. While the application remains the same, expectation and usage are different. Usage in an m-enabled society is classified in three categories of interaction (voice, e-mail, chat, digital postcards, etc.), trading and business (banking, shopping, auctions, advertising, ticketing, etc.), and mobile-provided services (news, entertainment, driving direction, and much more).

It is very important to identify the sufficient information that is required to make the purchase decisions while the organizations are re-engineering their business processes. Ease of navigation and necessary links to other related Web sites are crucial factors for the software developers to consider while they are designing the new applications.

LIMITATION OF MOBILE TECHNOLOGY

Rising customer expectations have a direct connection to the advancement of technology. People's demand of the technology has not always been so realistic. The word "technology" has constantly fascinated human beings. Information and communication as the defining technology of the modern era have increased the expectations to an irrationally higher level. As Toffler (1980) predicted, people's dependence on technology has increased to a high level where technology has affected every aspect of human life. Mobile technology, which is an integration of communication and computer technology, has created such expectations in human behaviour that people cannot think of an era without such technology today.

It is clear that people rely on technology even when technology does not have the capability, or it is not robust enough, to support their task. There is no guarantee that I will not lose my work while writing this chapter on my computer, and the very same technology is used when human lives are involved. As an example, computers are used to take off and land airplanes.

However, mobile technology has its own characteristics and limitations which should be clearly identifiable to business enterprises. Of course these limitations will increase when mobile devices are connected to the mobile Internet.

Jamalipour (2003) explains that the access to the wireless mobile Internet is not just an extension of the Internet into the mobile environment giving users access to the Internet while on the move. However, it is about integrating the Internet and telecommunications technologies into a single system that covers all communication needs of people. He also believes that current network architectures used in either the wired Internet or the cellular networks would not be appropriate and efficient for future wireless mobile Internet, even if we assume that the cellular network will provide the major infrastructure of the mobile Internet. He concludes by saying that access to the mobile Internet is slow, expensive, and confusing.

Some limitations of mobile technology are as follows:

- **Cost:** The cost of restructuring the organization and personal devices.
- **Call Drops:** Disconnection while taking or downloading the data.
- **Connectivity:** Constant connectivity to a network is a big issue for mobile network providers. There are improvements in this area, but it should be taken into consideration when we are mobilizing the enterprise that

the network must support the expected assignment of the enterprise.

- **Lost Work:** Losing the performed work due to disconnection or dead battery.
- **Managing Technology:** Consistent maintenance of the software and the hardware.
- **Security:** Payment online, user behaviour, rules and hassles, mobile virus protection, file encryption, access control, and authentication are the most important security factors in the mobile environment, considering that mobile devices are very personal; in case of loss or theft, who is accessing the corporate or personal data?
- **Integrity:** The transmitted data is actually going to the expected individual. The message received is actually the message sent, and also the sender is the real owner of the mobile handset.
- **Privacy:** Who is accessing the corporate database and where personal details of the individuals are involved.
- **Regulations:** Government roles and regulations regarding the mobile matters.
- **Standardization:** Technical standards and compatibility of the users (business-to-business, business-to-customer).
- **Health Hazards:** By encouraging people to use mobile gadgets, are we jeopardizing their health?
- **Data Transmission Speed:** Slow transmission is very costly and ineffective.
- **Coverage:** The coverage of the network in a remote area is an identified and unresolved problem.
- **Adaptation:** Some people are resistant towards technology, and it would take time for them to adapt to the new technology.
- **Training:** The cost of training, managing mobile workforce, and controlling their activity.
- **Marketing Issues:** It would be a new era of marketing issues in mobile age such as sex, age, and so on.
- **Social Aspects:** Technology is creating a new pressure for ordinary people. People resistant to changes should be the major concern while planning the mobile transformation. Perpetual contact is another issue that is changing the face of our society. Mobile users are communicating with some other person while driving, walking on the street, and when they are in different public places. It is becoming commonly acceptable in our society to give priority to the mobile caller even when personal face-to-face conversation is getting disrupted.

Limited processing powers of handsets' microprocessors, memory size, battery life, small screen of handheld devices and their resolution, replacement costs, required ongoing support, network charges, as well as mobile Internet charges and enhancements are the other critical shortcomings of the mobile technology.

TRANSITIONING TO A MOBILE ORGANIZATION

The transformation of the organization by introducing the new and re-engineered processes is a very crucial matter. Should the enterprise revolutionize and transform as soon as possible or use the evolutionary process? Should the enterprise adapt to the new technology as soon as it is available or delay the process to see the outcome by using another organization's experience?

Considering there is no suitable answer for the above questions, there may be a need for a new approach to clarify this uncertainty. This new approach is supposed to be the combination of the revolution and evolution—revolution since the organization should not fall behind by remaining competitive in the market, and evolution to reduce the risk of not having a successful e-transformation. According to Murugeson and Deshpande

(2001), the development of an organization could be classified as the following:

The choice of a suitable development model, according to practitioners and researchers, is site (and applications), its document orientation, content and graphic design, budget and time constrains and the changing technology.

It could be quite risky if the organisations adapt to the new technology as soon as it is available in the market, as the system is definitely unknown and there might be hundreds of unresolved issues as well. Another factor at an early stage entry is the high cost involved in the introductory level of the new technology.

However, if they do not adapt during a specific period of time and their competitors do, there is a great chance of not being able to catch up with the advancements in the professional world. These are some issues that management is facing today. Their crucial decision making will determine the future of their companies. Serour (2005) clarifies that senior and middle management find it hard to proceed when there is (still) very little guidance available from real-world experience.

The organizations must allow internal and external parties involved to know that there are some changes that need to take place. In view of people's resistance to change, this will give them some time to prepare and adjust. The core of the training is for internal parties of the organization; however it is very important to provide sufficient information to external parties and advise them about the change.

The organizations must plan and manage change (cultural, technological, internal, and external) and understand the key areas associated to dangers related to their working environment that others have discovered and faced. The Australian e-business guide (Philipson, 2001) describes that implementations for e-business initiatives must be rapid and each project should be delivered in a maximum of three months. Build quickly and move to the learning stage, then build the next stage and fix the previous ones based on what you have learned.

Management must support the variation in business and market strategies, organizational restructure, and management strategies. The corporations must prepare all the existing clusters ready for change. Managing the transformation by having a reliable and calculated plan is the crucial factor for success. The transition must remain persistent alongside with detailed knowledge of the development of the individual clusters. According to Brans (2003), generally mobile transition takes place by distinguishing what kind of portable devices, networks, application gateways, and enterprise applications are required.

The benefits of mobilizing the organizations are: quick sale, closer communication within the internal departments, more strength and opportunities and less weaknesses and threats, professional façade for the organization, quick and reliable generation of customer data, and mobility at work.

CONCLUSION AND FUTURE DIRECTIONS

This chapter described some characteristics of m-business and offered a brief background of mobile phone technology.

When the Internet was introduced, nobody could imagine that this tool was going to make the next paradigm shift in all human interaction as well as business transactions. M-business is enabling organizations to increase global productivity. With the aid of mobile technology, the capability exists to operate in a very modern and extraordinary manner. The problems faced in the transformation of an organization to m-organization were identified and some solutions were recommended.

The domain of this chapter was to explain the particulars of a mobile business model, em-

phasising their significance, application, and the shortcomings of this technology in the world of business and trade. It is hoped that this chapter could convince the developers of the m-applications to spend more time in their design to fulfil the needs of the end users.

However, there are some critical issues that are unresolved in the world of mobile technology. These issues can be classified as security (integrity and privacy), national/international regulation, international standardization, security and integrity of databases on mobile devices, managing mobile workers and coordination of their activities, and the consistent maintenance of mobile hardware and software.

To create a robust and reliable mobile world, the developers could consider some other shortcomings of mobile technology. These issues are mobile payments, health hazards, the cost of restructuring the organization, damage to the handheld devices, legal liability of handheld devices (since the mobile gadgets are very personal and can keep confidential data related to the organization), and constant connectivity of mobile devices.

Chapter 3.2
Knowledge Representation in Semantic Mobile Applications

Panjak Kamthan
Concordia University, Canada

INTRODUCTION

Mobile applications today face the challenges of increasing information, diversity of users and user contexts, and ever-increasing variations in mobile computing platforms. They need to continue being a successful business model for service providers and useful to their user community in the light of these challenges.

An appropriate representation of information is crucial for the agility, sustainability, and maintainability of the information architecture of mobile applications. This article discusses the potential of the Semantic Web (Hendler, Lassila, & Berners-Lee, 2001) framework to that regard.

The organization of the article is as follows. We first outline the background necessary for the discussion that follows and state our position. This is followed by the introduction of a knowledge representation framework for integrating Semantic Web and mobile applications, and we deal with both social prospects and technical concerns. Next, challenges and directions for future research are outlined. Finally, concluding remarks are given.

BACKGROUND

In recent years, there has been a proliferation of affordable information devices such as a cellular phone, a personal digital assistant (PDA), or a pager that provide access to mobile applications. In a similar timeframe, the Semantic Web has recently emerged as an extension of the current Web that adds technological infrastructure for better knowledge representation, interpretation, and reasoning.

The goal of the mobile Web is to be able to mimic the desktop Web as closely as possible, and an appropriate representation of information is central to its realization. This requires a

transition from the traditional approach of merely presentation to *representation* of information. The Semantic Webprovides one avenue towards that.

Indeed, the integration of Semantic Webtechnologies in mobile applications is suggested in Alesso and Smith (2002) and Lassila (2005). There are also proof-of-concept semantic mobile applications such as MyCampus (Gandon & Sadeh, 2004) and mSpace Mobile (Wilson, Russell, Smith, Owens, & Schraefel, 2005) serving a specific community. However, these initiatives are limited by one or more of the following factors: the discussion of knowledge representation is one-sided and focuses on specific technology(ies) or is not systematic, or the treatment is restricted to specific use cases. One of the purposes of this article is to address this gap.

UNDERSTANDING KNOWLEDGE REPRESENTATION IN SEMANTIC MOBILE APPLICATIONS

In this section, our discussion of semantic mobile applications is based on the knowledge representation framework given in Table 1.

The first column addresses semiotic levels. Semiotics (Stamper, 1992) is concerned with the use of symbols to convey knowledge. From a semiotics perspective, a representation can be viewed on six interrelated levels: physical, empirical, syntactic, semantic, pragmatic, and social, each depending on the previous one in that order. The physical level is concerned with the representation of signs in hardware and is not directly relevant here.

The second column corresponds to the Semantic Web"tower" that consists of a stack of technologies that vary across the technical to social spectrum as we move from bottom to top, respectively. The definition of each layer in this technology stack depends upon the layers beneath it.

Table 1. Knowledge representation tiers in a semantic mobile application

Semiotic Level	Semantic Mobile Web Concern and Technology Tier	Decision Support
Social	Trust	Feasibility
Pragmatic	Inferences	
Semantic	Metadata, Ontology, Rules	
Syntactic	Markup	
Empirical	Characters, Addressing, Transport	
Physical	Not Directly Applicable	

Finally, in the third column, we acknowledge that there are time, effort, and budgetary constraints on producing a representation and include feasibility as an all-encompassing factor on the layers to make the framework practical. For example, an organization may choose not to adopt a technically superior technology as it cannot afford training or processing tools available that meet the organization's quality expectations. For that, analytical hierarchy process (AHP) and quality function deployment (QFD) are commonly used techniques. Further discussion of this aspect is beyond the scope of the article.

The architecture of a semantic mobile application extends that of a traditional mobile application on the server-side by: (a) expressing information in a manner that focuses on *description* rather than presentation or processing of information, and (b) associating with it a knowledge management system (KMS) consisting of one or more domain-specific ontologies and a reasoner.

We now turn our attention to each of the levels in our framework for knowledge representation in semantic mobile applications.

Empirical Level of a Semantic Mobile Application

This layer is responsible for the communication properties of signs. Among the given choices, the

Unicode Standard provides a suitable basis for the signs themselves and is character-by-character equivalent to the ISO/IEC 10646 Standard Universal Character Set (UCS). Unicode is based on a large set of characters that are needed for supporting internationalization and special symbols. This is necessary for the aim of universality of mobile applications.

The characters must be uniquely identifiable and locatable, and thus addressable. The uniform resource identifier (URI), or its successor international resource identifier (IRI), serves that purpose.

Finally, we need a transport protocol such as the hypertext transfer protocol (HTTP) or the simple object access protocol (SOAP) to transmit data across networks. We note that these are limited to the transport between the mobile service provider that acts as the intermediary between the mobile client and the server. They are also layered on top of and/or used in conjunction with other protocols, such as those belonging to the Institute of Electrical and Electronics Engineers (IEEE) 802 hierarchy.

Syntactic Level of a Semantic Mobile Application

This layer is responsible for the formal or structural relations between signs. The eXtensible Markup Language (XML) lends a suitable syntactical basis for expressing information in a mobile application.

The XML is supported by a number of ancillary technologies that strengthen its capabilities. Among those, there are domain-specific XML-based markup languages that can be used for expressing information in a mobile application (Kamthan, 2001).

The eXtensible HyperText Markup Language (XHTML) is a recast of the HyperText Markup Language (HTML) in XML. XHTML Basic is the successor of compact HTML (cHTML) that is an initiative of the NTT DoCoMo, and of the Wireless Markup Language (WML) that is part of the wireless application protocol (WAP) architecture and an initiative of the Open Mobile Alliance (OMA). It uses XML for its syntax and HTML for its semantics. XHTML Basic has native support for elementary constructs for structuring information like paragraphs, lists, and so on. It could also be used as a placeholder for information fragments based on other languages, a role that makes it rather powerful in spite of being a small language.

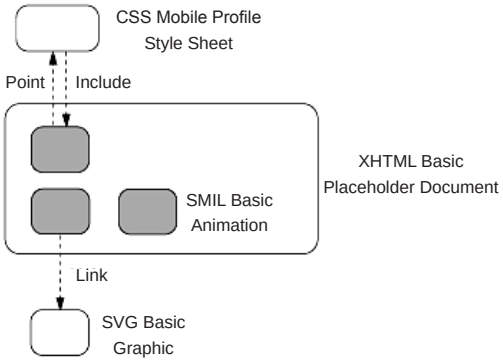
The Scalable Vector Graphics (SVG) is a language for two-dimensional vector graphics that works across platforms, across output resolutions, across color spaces, and across a range of available bandwidths; SVG Tiny and SVG Basic are profiles of SVG targeted towards cellular phones and PDAs, respectively.

The Synchronized Multimedia Integration Language (SMIL) is a language that allows description of temporal behavior of a multimedia presentation, associates hyperlinks with media objects, and describes the layout of the presentation on a screen. It includes reusable components that can allow integration of timing and synchronization into XHTML and into SVG. SMIL Basic is a profile that meets the needs of resource-constrained devices such as mobile phones and portable disc players.

Namespaces in XML is a mechanism for uniquely identifying XML elements and attributes of a markup language, thus making it possible to create heterogeneous (compound) documents (Figure 1) that unambiguously mix elements and attributes from multiple different XML document fragments.

Appropriate presentation on the user agent of information in a given modality is crucial. However, XML in itself (and by reference, the markup languages based on it) does not provide any special presentation semantics (such as fonts, horizontal and vertical layout, pagination, and so on) to the documents that make use of it. This is because the separation of the structure of a docu-

Figure 1. The architecture of a heterogeneous XML document for a mobile device



ment from its presentation is a design principle that supports maintainability of a mobile application. The cascading style sheets (CSS) provides the presentation semantics on the client, and CSS mobile profile is a subset of CSS tailored to the needs and constraints of mobile devices.

With the myriad of proliferating platforms, information created for one platform needs to be adapted for other platforms. The eXtensible Stylesheet Language Transformations (XSLT) is a style sheet language for transforming XML documents into other, including non-XML, documents. As an example, information represented in XML could be transformed on-demand using an XSLT style sheet into XHTML Basic or an SVG Tiny document, as appropriate, for presentation to users accessing a mobile portal via a mobile device.

Representing information in XML provides various advantages towards archival, retrieval, and processing. It is possible to down-transform and render a document on multiple devices via an XSLT transformation, without making substantial modifications to the original source document. However, XML is not suitable for completely representing the knowledge inherent in information resources. For example, XML by itself does not provide any specific mechanism for differentiating between homonyms or synonyms, does not have the capabilities to model complex relationships precisely, is not able to extract implicit knowledge (such as hidden dependencies), and can only provide limited reasoning and inference capabilities, if at all.

The combination of the layers until now forms the basis of the mobile Web. The next two layers extend that and are largely responsible for what could be termed as the semantic mobile Web.

Semantic Level of a Semantic Mobile Application

This layer is responsible for the relationship of signs to what they stand for. The resource description framework (RDF) is a language for metadata that provides a "bridge" between the syntactic and semantic layers. It, along with RDF Schema, provides elementary support for *classification* of information into classes, properties of classes, and means to model more complex relationships among classes than possible with XML only. In spite of their usefulness, RDF/RDF Schema suffer from limited representational capabilities and non-standard semantics. This motivates the need for additional expressivity of knowledge.

The declarative knowledge of a domain is often modeled using ontology, an explicit formal specification of a conceptualization that consists of a set of concepts in a domain and relations among

them (Gruber, 1993). By explicitly defining the relationships and constraints among the concepts in the universe of discourse, the *semantics* of a concept is constrained by restricting the number of possible interpretations of the concept.

In recent years, a number of initiatives for ontology specification languages for the semantic Web, with varying degrees of formality and target user communities, have been proposed, and the Web Ontology Language (OWL) has emerged as the successor. Specifically, we advocate that OWL DL, one of the sub-languages of OWL, is the most suitable among the currently available choices for representation of domain knowledge in mobile applications due to its compatibility with the architecture of the Web in general; and the Semantic Webin particular benefits from using XML/RDF/RDF Schema as its serialization syntax, its agreement with the Web standards for accessibility and internationalization, well-understood declarative semantics from its origins in description logics (DL) (Baader, McGuinness, Nardi, & Schneider, 2003), and provides the necessary balance between computational expressiveness and decidability.

Pragmatic Level of a Semantic Mobile Application

This layer is responsible for the relation of signs to interpreters. There are several advantages of an ontological representation. When information is expressed in a form that is oriented towards presentation, the traditional search engines usually return results based simply on a string match. This can be ameliorated in an ontological representation where the search is based on a *concept* match. An ontology also allows the logical means to distinguish between homonyms and synonyms, which could be exploited by a reasoner conforming to the language in which it is represented. For example, Java in the context of coffee is different from that in the context of an island, which in turn is different from the context of a programming language; therefore a search for one should not return results for other. Further, ontologies can be applied towards precise access of desirable information from mobile applications (Tsounis, Anagnostopoulos, & Hadjiefthymiades, 2004). Even though resources can be related to one another via a linking mechanism, such as the XML Linking Language (XLink), these links are merely structural constructs based on author discretion that do not carry any special semantics.

Explicit declaration of all knowledge is at times not cost effective as it increases the size of the knowledge base, which becomes rather challenging as the amount of information grows. However, an ontology with a suitable semantical basis can make implicit knowledge (such as hidden dependencies) *explicit.* A unique aspect of ontological representation based for instance on OWL DL is that it allows logical constraints that can be reasoned with and enables us to *derive* logical consequences—that is, facts not literally present in the ontology but *entailed* by the semantics.

We have a semantic mobile portal for tourist information. Let Mont Tremblant, Laurentides, and Québec be defined as regions, and the subRegionOf property between regions be declared as transitive in OWL (see Example 1.)

Then, an OWL reasoner should be able to derive that if Mont Tremblant is a sub-region of Laurentides, and Laurentides is a sub-region of Québec, then Mont Tremblant is also a sub-region of Québec. This would give a more complete set of search results to a semantic mobile application user.

In spite of its potential, ontological representation of information presents certain domain-specific and human-centric challenges (Kamthan & Pai, 2006). Query formulations to a reasoner for extracting information from an ontology can be rather lengthy input on a mobile device. It is currently also difficult both to provide a sound

Example 1. Ontological Inferences

```
<Region rdf:ID="MontTremblant">
 <subRegionOf rdf:resource="#Laurentides"/>
</Region>
<Region rdf:ID="Laurentides">
 <subRegionOf rdf:resource="#Qu&eacute;bec"/>
</Region>
<owl:TransitiveProperty rdf:ID="subRegionOf">
 <rdfs:domain rdf:resource="#Region"/>
 <rdfs:range rdf:resource="#Region"/>
</owl:TransitiveProperty>
```

Example 2. Device Profile

```
<rdf:RDF xmlns:rdf="http://www.w3.org/1999/02/22-rdf-syntax-ns#"
 xmlns:ccpp="http://www.w3.org/2002/11/08-ccpp-schema#"
 xmlns:prf="http://a.com/schema#">

</rdf:RDF>
```

logical basis to aesthetical, spatial/temporal, or uncertainty in knowledge, and represent that adequately in ontology.

Social Level of a Semantic Mobile Application

This layer is responsible for the manifestation of social interaction with respect to the representation. Specifically, ontological representations are a result of consensus, which in turn is built upon trust.

The client-side environment in a mobile context is constrained in many ways: devices often have restricted processing capability and limited user interface input/output facilities. The Composite Capabilities/Preference Profiles (CC/PP) Specification, layered on top of XML and RDF, allows

the expression of user (computing environment and personal) preferences, thereby informing the server side of the delivery context.

In Example 2, CC/PP markup for a device whose processor is of type ABC and the preferred default values of its display and memory as determined by its vendor are given. The namespace in XML is used to disambiguate elements/attributes that are native to CC/PP or RDF from those that are specific to the vendor vocabulary.

CC/PP can be used as a basis for introducing context-awareness in mobile applications (Sadeh, Chan, Van, Kwon, & Takizawa, 2003; Khushraj & Lassila, 2004).

One of the major challenges to the personalization based on profile mechanism is the user concern for privacy. The Platform for Privacy Preferences Project (P3P) allows the expression of privacy preferences of a user, which can be used by agents to decide if they have the permission to process certain content, and if so, how they should go about it. This ensures that users are informed about privacy policies of the mobile service providers before they release personal information. Thus, P3P provides a balance to the flexibility offered by the user profiles in CC/PP.

The Security Assertion Markup Language (SAML), XML Signature, and XML Encryption provide assurance of the sanctity of the message to processing agents. We note that an increasing number of languages to account for may place an unacceptable load, if it is to be processed exclusively, on the client side. We also acknowledge that these technologies alone will not solve the issue of trust, but when applied properly, could contribute towards it.

FUTURE TRENDS

The transition of the traditional mobile applications to semantic mobile applications is an important issue. The previous section has shown the amount of expertise and level of skills required for that. Although up-transformations are in general difficult, we anticipate that the move will be easier for the mobile applications that are well-structured in their current expression of information and in their conformance to the languages deployed.

The production of mobile applications, and by extension semantic mobile applications, is becoming increasingly complex and resource (time, effort) intensive. Therefore, a systematic and disciplined approach for their development, deployment, and maintenance, similar to that of Web engineering, is needed. Related to that, the issue of quality of represented and delivered information will continue to be important. The studies of specific attributes such as usability (Bertini, Catarci, Kimani, & Dix, 2005) and "best practices" for mobile applications from the World Wide Web Consortium (W3C) Mobile Web Initiative are efforts that could eventually be useful in an "engineering" approach for producing future semantic mobile applications.

The process of aggregation and inclusion of information in a mobile application is primarily manual, which can be both tedious and error prone. This process could be, at least partially, automated via the use of Web services where mobile applications could be made to automatically update themselves with (candidate) information. Therefore, manifestations of mobile applications through Semantic Webservices (Wagner & Paolucci, 2005; Wahlster, 2005) are part of a natural evolution.

CONCLUSION

For mobile applications to continue to provide a high quality-of-service (QoS) to their user community, their information architecture must be evolvable. The incorporation of Semantic Webtechnologies can be much more helpful in that regard. The adoption of these technologies does not have to be an "all or nothing" proposition: the evolution of a mobile application to a

semantic mobile application could be gradual, transcending from one layer to another in the aforementioned framework. In the long term, the benefits of transition outweigh the costs.

Ontologies form one of the most important layers in semantic mobile applications, and ontological representations have certain distinct advantages over other means of representing knowledge. However, engineering an ontology is a resource-intensive process, and an ontology is only as useful as the inferences (conclusions) that can be drawn from it.

To be successful, semantic mobile applications must align themselves to the Semantic Webvision of inclusiveness for all. For that, the semiotic quality of representations, particularly that of ontologies, must be systematically assured and evaluated.

KEY TERMS

Delivery Context: A set of attributes that characterizes the capabilities of the access mechanism, the preferences of the user, and other aspects of the context into which a resource is to be delivered.

Knowledge Representation: The study of how knowledge about the world can be represented and the kinds of reasoning can be carried out with that knowledge.

Ontology: An explicit formal specification of a conceptualization that consists of a set of terms in a domain and relations among them.

Personalization: A strategy that enables delivery that is customized to the user and user's environment.

Semantic Web: An extension of the current Web that adds technological infrastructure for better knowledge representation, interpretation, and reasoning.

Semiotics: The field of study of signs and their representations.

User Profile: An information container describing user needs, goals, and preferences.

Chapter 3.3
Mobile Portal Technologies and Business Models

David Parsons
Massey University, New Zealand

INTRODUCTION

Mobile portals have become a common entry point to the mobile Internet, and take a number of forms. They may be service provider portals, such as Vodafone's Live! portal (Vodafone, 2006), offering access to both in-house and brokered external services. Alternatively, they may be public pure play sites that provide some kind of managed access to resources using a yellow-pages approach. Good examples of this kind of mobile portal are WordDial (WordDial, 2006) and graBBit (Grabbit, 2006), though they have very different approaches to the way that they provide targeted access to resources, with WordDial using a keyword approach and graBBit modeled on more traditional search engines. As well as mobile and pure play operators, mobile portals are also provided by device manufacturers (e.g., Palm (Palm, 2006)), software companies (e.g., MSN (Microsoft, 2006)) existing Web portal providers (e.g., Yahoo (Yahoo, 2006)), mass media companies (e.g., AOL (AOL, 2006)) and transaction providers (m-commerce sites).

MOBILE PORTAL ADVANTAGES

The advantages that mobile portals have over standard Web portals are in ubiquity, convenience, localization, and personalization. Ubiquity means that the portal can be accessed anywhere, regardless of location. With ever widening coverage by mobile network providers, mobile portals have an increasingly ubiquitous presence. Availability at all times, via mobile devices, provides for convenience, with the ability for users to access portals at the point of need, for example to get up to date information on flight times or traffic conditions. Wireless connectivity is integrated into the mobile phone, whereas alternative ways of connecting to the Internet while traveling, such as accessing

wireless or fixed networks, or using publicly available computers, can be difficult and/or expensive to access in many locations. Localization is a specific strength of mobile portals, since they can use location awareness to provide services that are targeted to the user's current locality (e.g., local weather). Location awareness can be supported by a number of technologies, including triangulation from a mobile phone network or the satellite based global positioning system (GPS). Finally, personalization is a key component of mobile portals for two reasons. First, the difficulty of navigation and the small screen size of mobile devices means that it is important to target Web-based material as much as possible. Second, such targeting is easier for subscription type services that are common with mobile phone contracts, where the carrier is likely to be able to gather considerable information about users and construct accurate profiles of their activities and requirements. All of these characteristics are important features in the potential for mobile commerce, which relies on giving the best value-for-time service. Portals that are easily customizable, technically flexible, and contain relevant content are those that are most likely to be successful tools for mobile commerce (Clarke, Flaherty, & Madison, 2003).

MOBILE PORTAL TECHNOLOGIES

The technology of mobile portals is evolving as mobile devices become more sophisticated. Early portals were based on the wireless access protocol (WAP) version 1.0, using the Wireless Markup Language (WML) with very limited user interface features and severe limits on the type of content that could be accessed. In many cases, content was based on a transformation from HyperText Markup Language (HTML) pages, designed for standard Web browsers, into WML pages. These conversions, performed by WAP gateways that linked the mobile device network to the wider Internet, were slow and the content was not optimized for mobile users. Current WAP-based portals take advantage of the improvements in WAP technology that were introduced with version 2.0 (e.g., WAP push and end-to-end security) and more powerful handsets to provide richer interaction and media types. In addition, content is more likely to be tailored especially for mobile devices rather than being converted from HTML, developed either directly in WML or in XHTML-MP (eXtensible HyperText Markup Language – Mobile Profile) which is the evolutionary pathway from WML and is now the recommended markup language for mobile Internet domains (Cremin & Rabin, 2006).

Portals that were developed in the context of second generation (2G) mobile phone networks suffered from slow connection speeds, limiting the range of contents that could be provided. Portals running over third generation (3G) networks benefit from much faster data transfer speeds, so they can deliver rich multimedia content, such as TV and movie feeds and MP3 downloads. However, despite the market dominance of entertainment content, with the huge popularity of ring tones and screen savers, mobile portal services are not limited to entertainment alone. Some portals also host location based services, for example the provision of MapPoint access via the Vodafone portal in certain territories, and portal-hosted M-Payment services are increasingly popular.

DESIGN ASPECTS OF MOBILE PORTALS

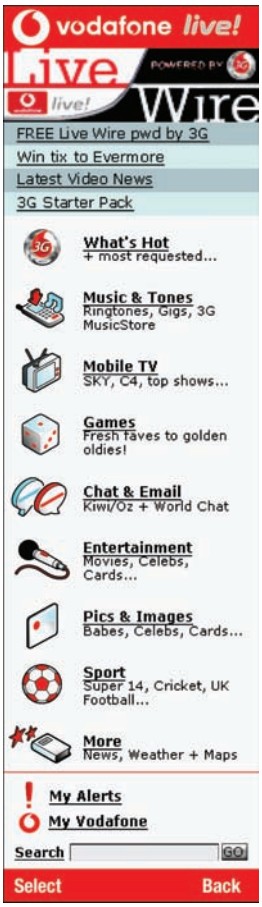
Mobile portals have had to be designed to provide the easiest access to services within the usual constraints of mobile devices, such as limited screen space, varying navigation button layouts on phones from different manufacturers, and lack of a consistent programming platform. Unlike portals designed for the desktop that are usually based around table-like structures containing separate portlets, mobile portals are structured

around nested menu lists, often with images, that provide quick scrolling access to services. The initial WAP portal pioneered by Vodafone Live! exemplified the typical style for mobile portals, with a brand header followed by a list of headlines that lead to other pages. Figure 1 shows a top level menu page from Vodafone Live! Although this type of mobile portal design has become a little more sophisticated over time with the move towards larger screens and XHTML-MP markup, the basic principles of using brief headline links and/or small images still apply.

Typical top-level mobile portal menus contain links to services such as news, weather, TV, downloads (games, ring tones, screen savers) and search engines. Mobile portals are not, however, only designed for one way services. One of the more unique features of a mobile portal is the ability to register for alerts, sent via SMS or using push technologies.

Because of the difficulties of configuring connections to the mobile Internet and managing page navigation with limited control keys, mobile carriers have worked with handset manufacturers to provide branded phones that include single key access to the carrier's mobile portal. This makes it easier to access the carrier's own portal but harder to access other portals.

Figure 1. The Vodafone Live! mobile portal (image courtesy of Vodafone New Zealand Ltd.)



BUSINESS MODELS FOR MOBILE PORTALS

There are three basic business models for mobile portals, which may be used in combination. Either they are based on subscription, payment for individual services or advertising. The role of the mobile network operator in the m-commerce value chain will vary between contexts, but at the most active level the operator will provide the network, the WAP gateway, the mobile portal and also act as an intermediary and trusted third party between the customer and other content and service providers (Tsalgatidou & Veijalainen, 2000).

The first generation of mobile portals, introduced in the late 1990s, had limited success due to factors including cost, limited browser capability and slow transmission speed. However in Japan, NTT DoCoMo's subscription-based I-mode portal showed that it was possible to achieve success in the mobile portal market by developing a large customer base built using youth targeted branding, low costs and suitable technology (CNET News, 2001). A key aspect of success in Japan, as opposed to early failure in Europe, was that DoCoMo successfully integrated the three value chains that comprise mobile telecommunications, the devices, the infrastructure, and the services (Sigurdson, 2001). More recent success outside Japan has been based on integrating these three components, via Web portals, that link devices to carriers by building portal access into their menus and brokering services from other providers.

Mobile portals have been an important revenue generator for mobile phone network providers because they have been the main driver for use of data services by personal, as opposed to corporate, users. For example, UK figures provided on a regular basis by the Mobile Data Association show that WAP page impressions (i.e., requests for one or more WML files that construct a single page) have increased hugely since 2002, when the first UK mobile portals were introduced, from about 200 million per month to nearly 2 billion by the end of 2005 (Mobile Data Association, 2006).

Portals provided by network providers sometimes use a walled garden approach to browsable content, which integrates third party content. In many cases, this content has to be paid for. Access to the portal is built into phones provided by the carrier, making access easy, but locking the user into one point of access to the mobile internet. From the user's perspective, the walled garden is useful in that the control of content means that all content will be appropriate to the mobile device. However, it limits the user's ability to browse the internet more widely. On many devices, although it is possible to do so it is much more difficult to set up than using the built in portal. As an alternative approach, some carriers simply provide direct access to the Web via a specific home page, such as T-Mobile's use of the Google home page (Mobile Pipeline, 2005).

FUTURE TRENDS IN MOBILE PORTALS

Beyond the current WAP generation, future mobile portals will take advantage of smart phone and Java Micro Edition devices to deliver more sophisticated content and interactivity, using dynamically loaded applications and leveraging XHTML-MP markup as the common evolution path from WAP, cHTML and XML. To enable two way interaction between users and portal providers, many portals include push elements, enabling alerts to be sent to users based on their user profiles, and increasingly, Podcasts will be integrated into mobile portals to enable more sophisticated push content (Lewin, 2005). As mobile devices evolve from WML based markup to XHTML-MP, and screen size and resolution increases, there will be less distinction between pages designed for the Web in general and those designed specifically for mobile devices. The

distinction between mobile and Web portals will blur, and eventually the distinction between them may well fade way almost altogether. In the interim, with the increasing number of portals available, and the increasing flexibility of devices, it is unlikely that providers will be able to sustain purely walled garden approaches. Rather, they will need to use their branded sites to provide unique content through their partners, and leverage the usability advantages of customized handsets, in order to retain users.

As devices and networks evolve, portal providers will have to adapt to changing technologies and markets. There will, however, still be significant differences in content provision between mobile portals and the rest of the Internet, because of the value added services that are possible through localization and personalization. Because of this, even when the mobile portal ceases to exist as a separate entity, Web portals will still include some elements that are unique to the mobile user.

CONCLUSION

Mobile portals have been an important component of the mobile Internet, providing mobile users with easier access to Web-based resources and enabling service providers to provide targeted content. Partnerships between network carriers and mobile device manufacturers are an important part of the business strategy of many mobile portals, enabling a walled garden approach that manages the user's Internet access. Early mobile portals had to be developed in the context of the limited form factor of WAP phones and restrictions on connection availability and speed. With the development of mobile phones with bigger, better screens (full color, high resolution, etc.) and high speed data connections, mobile portals have become both more sophisticated in the user interface and able to deliver a wider range of content.

KEY TERMS

Global Positioning System (GPS): A network of satellites that enables ground based devices to acquire their latitude, longitude and altitude. Since line of sight is required to four satellites for accurate positioning, availability and accuracy will vary depending on the device context. For example, GPS location finding cannot be used indoors.

Localization: The delivery of services to the user that are aware of the user's current location and therefore tailored to that context.

Mobile Portal: Access point to the mobile Internet that provides a gateway to mobile applications.

Personalization: Providing content to the user that is based on their user profile.

Ubiquity: The availability of a service in most, if not all, locations.

Vodafone Live!: The original WAP portal, launched by Vodafone in 2002.

WAP Gateway: Part of the infrastructure of the mobile internet, providing a gateway between the World Wide Web and mobile telephone infrastructure.

WAP Push: Technology that allows a server to push content to WAP phone without requiring the phone's browser to make a client request.

Wireless Access Protocol (WAP): A communications protocol developed specifically for mobile phones, which supports page markup using the Wireless Markup Language (WML).

Wireless Markup Language (WML): XML compliant markup syntax, developed by the WAP forum, for creating pages for display on mobile phones.

Chapter 3.4
Mobile Learning Technologies

Diane M. Gayeski
Ithaca College, USA

INTRODUCTION

While educational and corporate training environments have made large investments in getting wired to high-speed Internet connections, our work and social environments are rapidly becoming more mobile and flexible. The Internet and organizationally based intranets are powerful learning and performance tools, as long as users have a high-speed connection and up-to-date computing equipment. Online learning and information is not nearly as convenient or reliable when learners need to access sites from their homes, hotel rooms, client locations, or while on the road. In corporate settings, large numbers of critical employees such as factory engineers, health care professionals, builders, and maintenance workers often do not even have offices in which to use a computer.

Beyond the need for fast and flexible access to interactive learning, the field of online learning is being reshaped by several important economic and professional trends:

1. **Many corporate training departments are moving towards a more holistic professional model of "performance consulting" in which they provide solutions beyond instructional interventions; the trend is to provide short performance support tools and job aids that are meant to be used in the process of actually performing work.** Thus, the need for small and wireless media devices is even more pressing. Even the smallest laptop is a clumsy reference device when one is trying to troubleshoot a telephone system in a cramped equipment closet or when attempting to develop specs for a new manufacturing facility while walking around a construction site. Moreover, constantly updated information is often needed in tasks such as order-tak-

ing or quality control; therefore, some type of wireless connectivity, sometimes called "persistent computing," is needed.

2. **On the education front, many colleges and universities are attempting to broaden their student base and income by offering courses and noncredit educational experiences to adult learners who are already in the workplace.** Because of this, distance technologies often need to be able to be accessed in nontraditional locations, such as during commuting time. INSEAD, a large international business school based in France and Singapore, is already using applications that run on cell phones to allow their students to collaborate and check on course updates and grades. This is especially useful because many of their students are busy executives who can use their very limited time (such as while commuting or waiting to be served in a restaurant) to engage in coursework. These applications run in coordination with traditional classroom learning as well as WBT-based course materials.
3. **While interactive learning and Web browsing have become second nature even to very young children, it is expensive and cumbersome to equip elementary and high-school classrooms with traditional computers.** Thus, some other more mobile and less expensive devices that still offer the immediacy and interactivity of the Web are desirable. Many schools have purchased or received grants to equip every student with a small personal digital assistant.
4. **As education and business are becoming more global, there is a need to provide information and instruction to regions that are not well served by high-speed Internet connections or even good phone service.** In many developing countries, it is much easier and cheaper to use wireless connectivity than to attempt to install conventional wired access. The prevalence of cellular technologies in areas such as Japan, Singapore, and Scandinavia make it attractive to employ wireless systems because of the large installed base of users.
5. **Finally, millions of personal digital assistants and other handheld technologies such as MP3 audio players are now in the hands of users worldwide.** Many businesspeople already use palm-type computers as date books, and they would like to leverage their investments to use these devices for more applications. Digital audio players and other multifunction devices, including cell phones that connect to the Internet and share pictures, are becoming popular among young people; again, this rapidly growing installed base makes it inexpensive to offer instructional programs on them.

THE RAPID MOVE TOWARD WIRELESS COMPUTING

The communications landscape is becoming wireless even more quickly than it became wired. For example:

- By 2009, there will be more than 61 mobile workers in the United States alone.
- Almost 2 billion people now have cell phones worldwide.
- Of the 9 million handheld computer units purchased in the last few years, 80% are synchronized to some corporate user's computer at work.
- Laptops and personal digital assistants now outnumber conventional desktop computers.
- Over two-thirds of the telephone numbers issued worldwide are for cellular phones.

Today, it is common for office workers to have both cell phones and some type of mobile computing device. For less than the price of lunch for a corporate project team, one can buy wristwatch audio players, a credit card-sized organizer that will store thousands of phone contacts and appointments, or a digital camera that can directly send its pictures via wireless e-mail and browse the Web. New software systems can now turn a home or office PC into a mini-server which you can access from anywhere by using a variety of devices, so

you can be sitting in a traffic jam and download an MP3 audio file from your home PC and listen to it on your cell phone, or use your personal digital assistant to retrieve a user's manual from your office server while you are at a client site. College campuses are quickly adopting wireless networks to make instruction, collaboration, and scheduling available at a lower cost per delivery medium and networking than conventional desktop computers and wired campuses (Loh, 2001). Finally, there are literally thousands of "hot spots," which are wireless Internet connections in public locations such as hotels, libraries, airports, and parks (Wi-Fi Freespot Directory, 2004).

NEW PHILOSOPHIES OF LEARNING

Being tethered to an Internet line or being saddled with a laptop is not always effective or even possible, but this is not the biggest limitation of typical Web-based training. Beyond the technical constraints, there is a philosophical mismatch between what typically passes as good online training and what modern organizations need to improve performance. Most Web-based training is conceptualized and managed as courses which are designed, produced, and deployed by trainers, and which are in turn taken and passed by learners. These courses mimic college curricula more than workplace performance improvement efforts. This idea of both the course and the learner ever being "done" is a fundamental mismatch with the kind of continuous improvement systems in place in most organizations. For example, is a course on leadership or negotiation ever really complete and up-to-date—and is a learner ever completely through adding to his or her knowledge in this area?

Instead of courses, many training experts feel that we need "learning bytes": little packages of content and job aids that people can access at the peak moment of "teachability" and performance enhancement. Ideally, learning would occur when and where people need it most, and where it can most readily impact the success of their work. The information would be completely up-to-date, and would be interactive in its style and content.

In order for communication, documentation, and training professionals to align their efforts more closely with the emerging landscape of the modern workplace, they need to move:

- From producing courses to developing learning and performance systems that "grow themselves";
- From managing certification to encouraging continuous learning and collaboration;
- From developing curricula to building structures to capture and store knowledge bytes;
- From teaching and telling to aiding performance; and
- From creating schedules and managing facilities to adapting to the schedules and locations of the workers.

TYPES OF MOBILE DEVICES

Many types of mobile devices are potential platforms for information and collaboration that support learning and performance improvement in the workplace.

So, envision this: instructional designers now have a mobile delivery system for instruction, communication, collaboration, and performance aids that combines the following:

- Phone calls
- Music or audio playback
- Video and still-frame picture capture
- The ability to browse Web sites online
- E-mail send and receive
- Text and voice paging
- Global positioning and interactive map directions

Table 1.

PDAs	Personal digital assistants are handheld computers whose built-in software includes an address book, calendar, to-do list, and which also may include miniature versions of word processors, spreadsheets, and email clients. There are two major operating system platforms, Palm OS and Windows Mobile for Pocket PCs. Short training courses, documentation, and expert systems can easily be deployed on these.
MP3 players	These are the next generation Walkmans, but instead of playing cassettes or CDs, they play back digital audio files. The files are typically downloaded from the Web or "ripped" from your own CDs, using a conventional computer. Then they are downloaded into the MP3 player via a simple cable. You listen to files through a headset or adapter that lets you play it through your car radio. Beyond listening to music, trainers can record auditory instructional materials, and major website services provide audio versions of popular management books and magazines.
Digital text, audio, still picture, and video capture devices	A plethora of devices let you capture text, pictures, audio, and motion video. Besides the familiar digital cameras, small hand scanners, the size and shape of pens, are now available. Some of these are stand-alone devices while some (including audio capture devices and small digital still cameras) are built into PDAs. These allow you to create materials for training or documentation, and they also allow end-users to capture pictures or sounds on the job so that they can consult with colleagues or experts.
Tablet computers	These are basically laptops without the keyboard (or with a detachable keyboard) and they are very useful for performance support and data entry on the job. The user draws on the screen itself, or uses a stylus to tap on menu items. They can be strapped onto vehicles such as a truck dashboard or forklift truck, or carried around a construction site or storeroom.
Smart cell phones and pagers	"Smart" cell phones, widespread in Europe, are becoming more popular in other parts of the world; they allow you to wirelessly browse miniature versions of web sites, type short messages to other users, or receive automatic notifications of information such as flight delays or stock prices. Some universities are already employing these in graduate and continuing education courses.
GPS	Global positioning devices use a system of satellites to pinpoint your location—down to a couple of feet—using a small device that periodically sends out signals. These are used, naturally, for locating yourself on a map and creating routes to a destination. Companies with a mobile workforce use these to track performance and as security devices to locate employees who may need help.
Wearable devices	Remember Dick Tracy? Futurists say we'll soon be wearing wrist watches that are cell phones and web browsers, earrings that play music, and necklaces that carry our ID and medical information. They are being employed as performance aids especially within factory and equipment maintenance applications.

- Multimedia, hypertext training, and documentation
- Expert systems and smart job aids
- Programs that monitor performance or take measurements or perform calculations for workers

APPLICATIONS

Many corporations are already creating innovative and highly effective applications for mobile computing devices. For example, Cisco has created a small documentation and job aid program on one of its routers that can be downloaded from its Web site onto a PDA. Intel uses video clips on a Pocket PC to disseminate best practices to technicians in their chip factories. Maines Paper and Food service uses GPS systems and Palm computers to aid in the accuracy and efficiency of its delivery system to restaurants. Location scouts in the film industry use wirelessly connected video cameras to shoot and e-mail pictures of potential shooting sites to producers, saving days in their schedules. Cypress Semiconductor's Vice President of Marketing creates MP3 audio news programs that his staff can download on their computers or on portable MP3 players to listen to as they jog or commute. Telecommunications repair fleets for SBC Corporation are using ruggedized laptops that combine computer-based training, expert systems, and actual testing devices. And BOC Gases deploys wearable computers with interactive documentation that allows technicians in factories to quickly inspect and repair refrigeration systems.

In educational applications, Drexel University now uses a Web-based infrastructure that allows students to access their e-mail, pay bills, check on grades, and work with course materials either using conventional computers or wireless devices such as cell phones and personal digital assistants. One math teacher in Irvine, California has a class set of 40 (numbered) PDAs that she uses to give quizzes; the devices have become very popular with the students. The students are given the quiz ID of the assessment for that day, and they enter their student ID and quiz ID into the Classroom Wizard program. After answering the questions on the PDA, a student beams his or her answers to the teacher's computer, which scores it right away, and the student's score appears on his or her PDA. Medical residents in anesthesia in Great Britain use a program developed by their professors to access information about prescribing the right form and dosage of medications. And even elementary school students are using quizzes and games that run on handheld computers, thanks to simple and inexpensive authoring programs that any teacher can learn.

The challenge will not be in learning how to use and create programming for these devices: this is actually quite simple and versions of popular authoring tools are being introduced. Rather, this next revolution in technology will bring about discontinuities that will require a change in the fundamental approach to training, communication, collaboration, and performance support in the workplace. These devices are already being used widely in elementary schools, high schools, and colleges; the new workforce will not only accept this technology, but will demand it.

ABSTRACT

The mission of this chapter is to explore ways in which mobile computing via the employment of Tablet PCs can assist the human computer interaction in the design and project development process and thereby enhance learning. We follow the process of ethnographic action research and report on the learning, observations, and communications of students in a multimedia program who were given the use of a Tablet PC for their second year of their degree. We discuss the educational design and customized agent software developed for this project and draw conclusions for wireless networks, and benefits and issues involved in enabling mobile computing and encouraging group dynamics among students.

INTRODUCTION

It is interesting to consider how much people learn when mobile. When on the train traveling from home to university all manner of observations might influence the way a person thinks and reinforce some learning experience. It is also

often a good time to revise notes before an exam or interview. Similarly, when walking from one lecture to another or over to the cafeteria, students may exchange information that contributes greatly to their learning. In the study discussed in this book chapter, we observe and analyze the learning experiences of students who were each given a Tablet PC for a semester of their course.

Ethnographic action research is a methodology for investigating the impact of technology on a community. It was first devised in 2002 to explore the use of computers on communities in India (Tacchi, Slater, & Hearn, 2004). Its principles are that one change rarely impacts on only one individual, and changing one aspect may affect many other aspects of a student's life within his or her community.

BACKGROUND

In this chapter we report our research into mobile computing and the design process. This research has been supported by HP Mobile Technology for Teaching Grant Initiative—2004 Higher Education, and we have undertaken exploratory ethnographic action research to explore and analyze to what extent Tablet PCs enhance learning within the context of students learning the design development process.

Formal RMIT student surveys (the top 10 student concerns are available through RMIT University) indicate that students would like to engage more fully with the University and fellow students in a manner that meets both their social and academic needs. Observations and conclusions drawn from this research indicate that students:

- undertake more hours of paid employment to support their study costs, resulting in increased pressure to maximize time and resources in academic hours;
- want to interact with the University in ways that best suit their personal circumstances and preferred learning practices; and
- have limited amounts of quality contact time with fellow students on campus.

Tablet PCs have the potential to facilitate students' engagement with the University and fellow students in a manner that does meet their social and academic needs, and our research explores the extent to which this may occur through the use of mobile computing devices.

We chose students from a multimedia design degree (Bachelor of Design [Multimedia Systems]) for this study because they spend considerable time engaged in group projects. It is also a challenging use of mobile technology as students spend time generating, analyzing, and collaborating around images. The students are diverse, with academic interests ranging from creative media design to software development. The aim of this study trial is to explore new methods for applying mobile technologies within both formal and ad hoc study groups. Students from the multimedia design program are generally expected to work in their groups both in and outside of the classroom on design projects. Interaction between students is not moderated; rather it is supported by a learning program that emphasizes team skills. Students enrolled in this program are typically local school leavers and have completed Year 12 Mathematics and English. A very small proportion is international students, mainly drawn from China and India. The students are enrolled in two design courses that require teamwork and collaboration for one semester.

Applications used in multimedia design are typically central processing unit (cpu) intensive and require a large display screen with keyboard, mouse, and WACOM (registered brand name) Tablet as input devices. The Tablet PCs with digitized screen, and pen and ink technology present an opportunity to explore the extent to which

Tablet PCs may become an enabling technology for students learning design processes. A detailed description of Tablet PCs follows in Table 1.

The features we believe to be enabling are the digitized screen and ink technology, wireless capability, which means we can examine the use of enabling Web technologies such as blogs, and mobility, which means that students may capture inspiration as and when it occurs and store it locally on the hard drive or in a blog when in a wireless zone.

THE DESIGN PROCESS

The design process can be described as cyclical with iterative loops whereby an initial idea is developed into a concept. Feedback is sought and then the concept is expanded further into a proof of concept (in this case electronic) and finally manufactured into a product (in this case a Web site) that is ready for consumption with feedback sought and integrated at key junctures in the production process.

The participants in the study reported in this chapter were drawn from the students enrolled in a core second year design course of a Bachelor of Design (multimedia systems) degree program. In

Table 1. Work environment summary

Number and kind of Tablet PC's	16 Hewlett Packard TC1100 Tablet PCs
Hardware Configuration	• Tablet PC with builtin microphone • Detachable Keyboard • Pen/stylus • Earphones
Software Configuration (under University Licenses)	• Microsoft Windows XP Tablet Edition • Customised Agent Software • Microsoft Office (Word, Excel, Powerpoint, Frontpage); • Adobe Acrobat; • Macromedia products (Flash, Studio-MX2004); • Appropriate WiFi VPN network access software, including customised security and virus-checking software. This enables limited internet and university website access, but also allows wireless communication between Tablets; • Remote access to a personalised blog server for use in delayed project-related intercommunication and archiving. WordPress is installed on a server which is rendered visible to the WiFi network for student use.
Accessories for group use	3 docking stations, 2 digital cameras
Blog Server Hardware	Standard PC (Macintosh)
Blog software	WordPress
Number of students in whole class	80
Students involved in project	16 for individual work in semester 1, and team work for semester 2

this particular course students engage in a group project where they design and build a Web site for a client so as to gain direct experience of working for a client with specific team role responsibilities. The student learning is scaffolded through a design and production process modeled on a simulated student-centered work-based learning approach that is described in the following section.

Workplace-Based Learning

Industry practice is often explored and tested in an educational institution via simulated projects that seek to meet specific and relevant learning outcomes. However, a simulated project can be less than effective as it often may lack critical detail and commercial imperatives to solve specific problems and challenges.

Central to the strategy of situated learning in the workplace is the direct experience and subsequent knowledge gained in the process. However, guided learning in the workplace can be limited due to commercial constraints and lack of mentoring skills and processes. In the absence of a structured pathway of learning, students are required to integrate the formal theory gained in a university and practical knowledge gained in the workplace.

Leaving learners, particularly novices, to piece together a picture of the complex workplace environment without guidance is more likely to result in incorrect and fragmented understandings. (Cornford & Beven, 1999)

The issue then is how to integrate the hands-on learning that occurs in industry and then bring that back into a formal learning environment that will assist in contextualizing their experiences and skills gained.

Guided learning can augment many of the strengths of learning through everyday activity, and also be able to address some of its weaknesses. (Billet, 2001)

As Billet proposes, a combination of strategies is required to achieve a meaningful outcome for students. An integration of the strengths of the workplace-based model, coupled with the benefits of a face-to-face learning environment (such as a tutorial seminar program) and underpinned by a lecture program would provide an effective structure in which to enhance learning outcomes.

In the absence of situated learning where students are located in the workplace, the structure of the curriculum focuses on the development of commercial projects over the duration of the semester within the educational institution. Students form small working groups within their tutorial classes and are provided with a commercial project and a client.

The design of this problem-based learning environment supports constructivist teaching and learning practices. Students are guided through a process that encourages, through the design process, a construction of knowledge and understanding based on direct experience. Savoie and Hughes (1994), outline several actions to put this into effect:

- Identify a problem suitable for the students;
- Connect the problem with the context of the students' world so that it presents authentic opportunities;
- Organize the subject matter around the problem, not the discipline;
- Give students responsibility for defining their learning experience and planning to solve the problem;
- Encourage collaboration by creating learning teams;
- Expect all students to demonstrate the results of their learning through a product or performance.

The forming strategies presented to the students are drawn from the Savoie and Hughes (1994) outline of actions. Students form work teams comprising of three to five individuals based on friendship groups.

MOBILE COMPUTING AND THE DESIGN PROCESS

Like those in the design industry, students often work together in concentrated patches, and then continue development largely on their own. They frequently juggle multiple projects and other concerns. Communication can be patchy and often is not centralized. Retrieval of communication items and files can also be unreliable. The result may take up valuable resources and development time and manifest in poor outcomes, frustration, and lack of momentum.

Development of a communication strategy and document retrieval process has been implemented to facilitate the design and development process. This is made possible by the use of mobile computing in the form of streamlining processes. The group members are asked to maintain a personal blog (Weblog) that is intended to provide a record of their research into their specific area of concern, and at the same time, also make this research transparent to the rest of the group. A Rich Site Summary (RSS) aggregate has been put in place to alert other team members that the new posts are up on the blog and can be viewed at their convenience. RSS is described in wikipedia as:

RSS is a family of Web feed formats, specified in eXtensible Markup Language (XML) and used for Web syndication. RSS is used by (among other things) news Web sites, Weblogs, and podcasting. The abbreviation is variously used to refer to the following standards:

- Rich Site Summary (RSS 0.91)
- Resource Description Framework (RDF) Site Summary (RSS 0.9 and 1.0)
- Really Simple Syndication (RSS 2.0)

Web feeds provide Web content or summaries of Web content together with links to the full versions of the content and other metadata. RSS in particular delivers this information as an XML file called an RSS feed, Web feed, RSS stream, or RSS channel. In addition to facilitating syndication, Web feeds allow a Web site's frequent readers to track updates on the site using an aggregator. (http://en.wikipedia.org/wiki/RSS_%28file_format%29)

RSS feeds allow people to remain up to date with changes that have been made to a blog or Web site that they visit regularly. An aggregator is a way of getting a customized and consolidated view of all the sites one regularly visits.

A group blog has also been set up to facilitate group communication. The groups use these in different ways:

- introduction of a new item of interest to the group overall;
- meeting minutes and actions to be taken;
- posting up documents, drafts, or approved designs;
- general considerations or concerns to the group;
- miscellaneous items such as notification of next meetings, introduction of new group members, and communication with tutor/exec producer.

Additionally, a client blog (now largely standard industry practice) has been put into place, with clients being given read and write access to monitor development and design of their project. This has been particularly useful in confirming outcomes and minimizing unnecessary client contact (usually in place to prevent clients from being uniformed).

Customized agent software has also been developed to facilitate document retrieval and assist in the process of design and programming.

The agent is required to locate files on the server via a server agent and report back to the Tablet holder using a Tablet agent to notify updates to files and filing systems.

The overall intentions of these items are to:

- maintain communication across the groups and their clients;
- provide a map of next steps and actions;
- maintain momentum and focus throughout the design process;
- help members locate themselves within the framework of the group (particularly useful when they are involved in other projects or other commitments);
- aid group dynamics as lack of communication can contribute heavily to unsuccessful outcomes;
- enable contact maintenance with the client.

Tablet Personal Computers and the Wireless Network

Sixteen Hewlett Packard TC1100 Tablet PCs are given to the students, as well as three docking stations and two digital cameras for shared use. This creates an excellent opportunity to test two different aspects of mobility: wireless networking and the differences between the Tablet PCs and desktop computers.

The first aspect of mobility is the wireless ad-hoc networking made possible by the hardware. This enables two different kinds of interactions: person-to-person (via WiFi or Bluetooth—a short-range networking protocol chiefly used for wireless peripheral control or file transfer) and person-to-blog/server via WiFi—a longer-range networking protocol that is principally used for wireless network access.

As shown in the student comments later in this chapter, significant use is made of the wireless components, due partly to the communicative nature of the projects, and partly to the particular team assignment work.

One problem we encounter in implementing the system is the use of a specialized network protocol for the communication between agent and server (the agent system is described in more detail in the next section). A previously unallocated TCP/IP port (or channel number) is used as the communication port by default. Although the software allows any port to be chosen, it needs to be the same port for all tablets, as they must all use the same channel. In addition, the network needs to know that this port has been allocated for specific use, and all appropriate permissions need to be obtained. This effectively means that although the project can exist on a wireless network, that network has to be preconfigured to accept it.

While wireless networks exist that will accept any port (and thus need no such pre-configuration), they are generally insecure because of this blanket acceptance policy. The alternative is to allow the network packets of information to be encrypted on the Tablet PC and at the server end. This is effectively a virtual private network (VPN). The use within our University of a VPN as the wireless medium initially causes some concern because of the necessity to customize the VPN settings for using this port. In addition, our security policies do not directly allow access to the Internet (via port 80—the HTTP "channel") and prevent direct access to the internal wired network.

Students are required to access their blogs, which are installed on a server on the wired intranet. For this project, special provision and permissions are required to enable access to this server from the wireless network. This exposes the server to the wireless network, exchanging its internal security status for the wireless security arrangements. So the safety of a private intranet needs to be exchanged for that for a VPN. Because of the differing security models for these two configurations, we recommend that it would be preferable in future to have a wirelessly ac-

cessed server dedicated to this task alone, and any unrelated server activity be moved to a different separate internally wired server.

The second aspect of mobility that the students are exposed to is the user interface differences to a desktop computer. As seen in Table 1, the Tablet PCs have a keyboard, a screen that can be separated from the keyboard, a pen or stylus, and appropriate software to accept pen gestures, commands, and handwriting storage and recognition. For this Tablet PC, the keyboard is normally intended to be used only for extended text entry, and the pen used for normal Tablet functionality.

The tasks the students undertake often involve drawing and sketching (see the included software in Table 1), so it is encouraging to see some students using the pen in all activities, while others are content to use it only when appropriate.

The principal difference between a pen and a mouse depends on the dialog mode—input or selection mode. Neither pen nor mouse works in isolation as a positional input device. In both cases, these move a cursor, which is the positional input coordinate identifier. Herein lies the difference. A mouse moves the cursor using relative coordinates, which implies that the cursor's initial position is known to the user. So to press a button on the screen, the user must home in the cursor to the button, and then press the mouse button to select/activate. Moving the cursor is a necessarily interactive process, and any person who has experienced slow mouse response lag can appreciate the crucial dependence on interactivity that the mouse requires. Contrast this with a pen, where the user identifies the target button and using his/her hand positions the pen to the target. No intermediate interactivity is required to enable accurate positioning.

In input mode, the difference between pen and mouse is smaller, and more subject to personal taste. The benefit of the mouse is consistent hand positioning, support for the wrist and elbow, and having the hands away from the desktop so that it is always visible (note that these are all desktop-based advantages). While pen has direct positioning and given fast interaction can easily be used for drawing, the arm is usually not in a comfortable position for long duration detailed work. However, quick sketches in a mobile context are easily facilitated. Lastly, the direct positioning of the cursor facilitates handwriting as easily as with a real pen, allowing text to be entered via handwriting recognition, a tool that some students have mentioned using in our study.

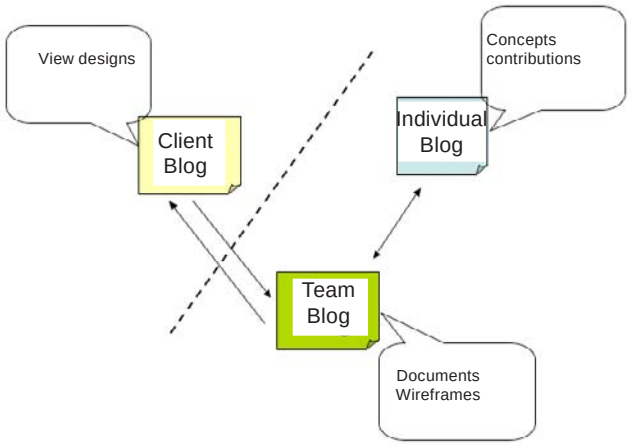
Customized Agent Software

Customized agent software has been developed, primarily for content synchronization between Tablets within each project group, and between Tablets and blog, or server-based data storage. Major check-points in content developments are stored on a communal server and could be accessed by participants and also the project coordinator(s) for progress verification and eventual project assessment.

We include an overview of the software model or architecture employed and the role each component plays in it. As will be explained in the next section, actual student usage of the software did not precisely follow the usage patterns envisaged by the previous design. However, this provides insight into the students' view of the environment, and how they adapt it for their own use.

Part of the process of designing a supportive environment includes the specification of the agent-based software. It must be able to provide automated support for a range of tasks such as proactive notification to students if the group files have been updated, to ensure that they check and access any relevant changes. This removes the tedium of repetitive manual checking. Intelligent agents are a popular technology for open environments such as the Internet (Singh & Huhns, 2005). Small autonomous pieces of software (agents) can reside on different machines, and communicate with each other to achieve tasks. In this project we have an agent on each Tablet, which communicates

Figure 1. Team communication using three blogs

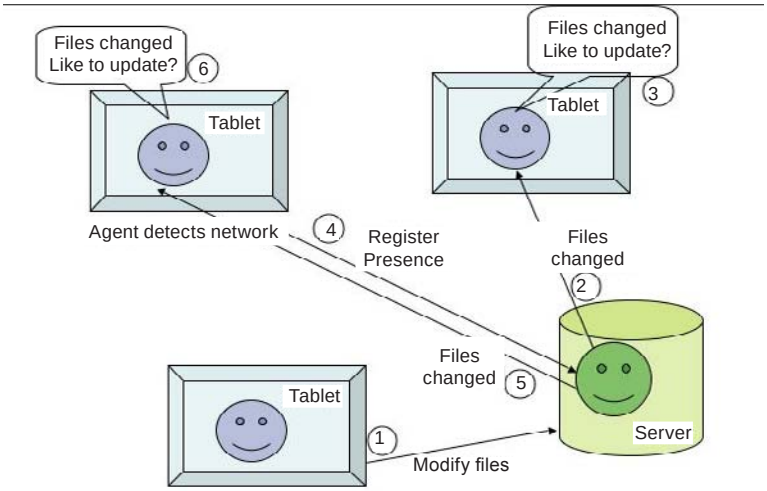


with an agent on the central file server where files are located. Figure 1 shows the interaction between the agents that results in the user being notified if there are any updates.

While this initial task is quite straightforward, it is envisaged that there will be potentially a range of automated tasks that can be performed by the agent software on behalf of, or in support of the user. The intention is to interact with students to develop the particular support they will find useful. Observation of student behavior during the trial period indicates that the availability of the wireless network to the Tablets led to far less use of the central server and the file structure contained there than had been the case previously. Consequently we consider that it would be advantageous to adapt the agent software to better support the communication mechanisms the students actually use. For example they e-mail versions of their files to each other frequently. While this appears to have worked for this small project, this mechanism does not offer the same level of backup and support as does storing files on the central file server. We could, for example, adapt the agent functionality to better support the way the participants end up doing things, by having the Tablet agent recognize when new files are sent to other team members, and automatically store these into the central server.

The agent approach used is what is referred to as *belief desire intention* (BDI) agents. This approach develops agents in terms of these mental concepts, as developed in philosophy, to explain how focused practical reasoning happens in humans (Bratman, 1987). Beliefs are the information that the agent has (or believes it has, as it may not always be accurate) about the world, other agents, or even itself. Desires are the goals the agent wishes to accomplish—which may arise based on information from the environment: for example, if a file is updated in the central repository, an agent managing that repository may then have a goal to ensure that all group members are notified of the change as soon as possible, potentially using various communication means such as e-mail or even sms, if the user is not accessible via the network. Intentions are the plans the agents has regarding how it *intends* to accomplish its goals. If, during execution of the plan, there is some problem, the agent will adapt its intentions (or plans) to attempt to still achieve the goal. One advantage of this approach is the ease with which it can be adapted and evolved to manage an extremely large number of complex

Figure 2. Specification of the customized agent-based software



interactions regarding which decisions should be made. This enables the kind of support to be easily tailored to both very specific situations, and also to individual groups and/or users. For example the agent residing on a particular user's machine can build up beliefs regarding the way that user likes to work. Agent technology also facilitates pro-active behavior on the part of the system (to achieve *desires*, or goals). The agent software can persist in trying to achieve a particular goal (of which user notification of change is a simple example) using alternative approaches if attempts are unsuccessful. This makes it possible to build flexible and robust systems in dynamic environments.

Research Questions

In this research, we consider the question of how Tablet PCs help human computer interaction in the design and project development process. Our focus is on:

- The immediate circle of students in terms of how they are organized, how they carry out their work, and how the Tablet PC fits into their lives as students of multimedia design;
- The everyday lives of the participants, their ways of doing things, and the impact mobile technology in the form of wireless Tablet PCs has on this (if any);
- The construction of knowledge and meaning through the use of blogs and the impact mobile technology in the form of wireless Tablet PCs has on this (if any);
- The wider social context in terms of access to a wireless intranet, access to mobile computing, access to a personal blog.

Discourse analysis and ethnography provide the base for qualitative research into the contents of the blogs, structured interviews, and focus groups. Ethnography, in its literal sense, means "to write or represent a culture" (Tacchi et al., 2004). Ethnography is an approach that may encompass several methods rather than a specific methodology. The methods are integrated to provide a holistic account of a culture, in this case, students enrolled in the Bachelor of Design

(multimedia systems) and their use of Tablet PCs in their everyday design studies. The structured interviews, informal feedback conversations with participants recorded as field notes by the researchers, questionnaires, blogs, and focus group conversations will be integrated so that the knowledge and experience gained through one method informs the other methods. This is in keeping with ethnographic and action research principles. This is in contrast to other studies where students used Tablet PCs only during their classroom learning, such as Tutty (2005; Tutty, White, & Pascoe, 2005, 2006). Our focus is on mapping the experience of the student participants in detail and to enable the use of the Tablet PC to become part of everyday life as ubiquitous computing. Therefore we did not use a comparison group of students who were not given Tablet PCs for their learning and personal use.

Our intervention is the introduction of the Tablet PCs, the wireless network, and the use of blogs. Students are provided with Tablet PCs for the whole semester and are able to carry them around with themselves wherever they go and to take them home. This allows the Tablet PCs to become a part of the students' normal daily living and learning routines.

WHAT THE STUDENTS SAID

In his discussion of the computer for the 21st century, Mark Weiser introduces his concept by suggesting that:

The most profound technologies are those that disappear. They weave themselves into the fabric of everyday life until they are indistinguishable from it. (Weiser, 1991)

In this study, we are interested in how the students have woven the use of the mobility afforded by the Tablet PC into their lives. To this end, we administer an initial survey to measure their initial use and experience of computers generally. We find that the majority of students consider them-

Table 2. Baseline survey of students' skill levels

Responses – Skill Level Questions	5 Expert	4 inter	3 novice	2 none	1 unsure
Drawing with a mouse	14%	43%	43%	0%	0%
Drawing with a pen on a WACOM tablet	10%	19%	43%	24%	5%
Writing with a pen on a WACOM	5%	33%	38%	14%	5%
Using wireless networking	19%	43%	38%	0%	0%
Using the Internet	81%	19%	0%	0%	0%
Using a computer	71%	29%	0%	0%	0%
Installing software	57%	38%	5%	0%	0%
Downloading software from the Internet	62%	29%	0%	5%	0%
Using handwriting recognition software	10%	33%	33%	24%	0%
Using a PDA	10%	19%	29%	43%	0%
Using blogs	0%	10%	43%	43%	5%
Putting together my own blog	5%	10%	29%	43%	14%
Developing my own website	14%	38%	33%	5%	10%
Using chat software such as ICQ	52%	19%	24%	5%	0%
Using agent software	5%	10%	19%	43%	19%
Finding information I need using the Internet	62%	33%	5%	0%	0%

selves as novices and have no experience using pens with their computers. However, all indicate they believe they have average or expert Internet skills. All have computers at home, and all save one has Internet at home—most have broadband. The details of this questionnaire and the student responses have been published in Berry and Hamilton (2006). These results bear out our initial assumptions about the communicative ecology of the students. Our initial assumptions were that students would not have had extensive experience using pens and digitized screens.

The second part of the survey is designed to collect baseline information about the participants perceived skill levels in human computer interaction. The survey items fall into several categories: drawing skills, ability to use pens and Tablets or digitized screens, ability to use wireless networks, experience with handwriting recognition software, ability to use and maintain blogs, general use of the Internet to locate information, download and/or install software, ability to use mobile devices (specifically PDAs), and Web design and development skills. The snapshot that emerges from the survey response data indicates that a significant number felt themselves to be either novices or average users across most items except those dealing with use of the Internet to locate information, and downloading and installing software.

Students were asked to read each statement and circle the number that best suits their thoughts about their skill level at this time:

1 I am unsure of my skill level
2 I have no knowledge about this
3 I am a beginner/novice at this stage with a basic introductory skill level
4 I have intermediate skills
5 I am an expert user with highly proficient skills

Next, we conduct focus group meetings so we can meet the students face to face and discuss how they initially use the Tablet PCs, what they intend to do, and any issues they currently have. The questions for these focus groups may be viewed at http://raws.adc.rmit.edu.au/~e01913/blog, and a discussion of the results is also in our earlier paper (Berry & Hamilton, 2006), as well as selected segments posted on a University Web site, http://www.lts.rmit.edu.au/mobcommec/index.htm.

For the first semester, the students mostly work individually; however, for the second semester, they are required to work in groups on an industry-based project as discussed previously. They are placed in groups regardless of whether they have a Tablet PC or not, as the majority of students in the class do not have a Tablet PC. Originally we had wanted all participants in a particular group to have a Tablet PC; however, in practice, this was not possible, as groups are composed of friendships, which are formed irrespective of how the Tablet PCs have been allocated. Each group of students has four or five members, and all have Tablets in the majority of groups; however, there are two groups where only one student has a Tablet PC and one group where all except one member has a Tablet PC.

We analyzed the focus group tapes using discourse analysis and have selected the comments that best reflect the general trends. Discourse analysis is a technique that has its origins in linguistics and is also used in ethnography, which examines lived experience as its subject. We allow the students, our research collaborators, to speak for themselves. They become the experts in the uses and usefulness of the Tablet PCs. We adopted and maintained a nonjudgmental position and treated everything as valid. Sharp, Woodman, and Robson (2000) also used discourse analysis as part of their methodology to study software engineering practices. They follow the principle that "all views should be attended to, and given equal weight." We also adhere to this principle in our presentation of the student views. Ethnography is not empirical in its approach to phenomena.

In this section we present the student responses

reflecting their lived experience and the impact possession of a Tablet PC has had on their learning and group work practices. We asked a very open-ended question that led to conversations about how the Tablet PCs fit into their work practices in their work groups. We chose to allow their voices to speak instead of overlaying their responses with an empirical set of categories. This is in keeping with postmodern anthropology and ethnography. Clifford (1986) foregrounds the dilemma of writing about lived experience and suggests possible ways of structuring and articulating the text:

Whatever else an ethnography does, it translates experience into text. There are various ways of effecting this translation, ways that have significant ethical and political consequences. One can "write up" the results of an individual experience of research. This may generate a realistic account of the unwritten experience of another group or person. One can present this textualization as the outcome of observation, of interpretation, of dialogue. One can construct an ethnography composed of dialogues. One can feature multiple voices, or a single voice. One can portray the other as a stable, essential whole, or one can show it to be the product of a narrative of discovery, in specific historical circumstances. (Clifford, 1986, p. 115)

Tyler (1986) discusses the multivocal or polyphonic nature of post-modern writing that aims to set down lived experience:

A post-modern ethnography is a cooperatively evolved text consisting of fragments of discourse intended to evoke in the minds of both reader and writer an emergent fantasy of a possible world of commonsense reality, and thus to provoke an aesthetic integration that will have a therapeutic effect. (Tyler, 1986, p. 125)

We asked the students the following question:

How are you Using the Tablets so far This Semester?

Their responses range from:

I have found the Tablet extremely useful in this scenario [work group]. I have used it in a way, so as a group, we can have lunch in the cafeteria and also discuss/browse relevant Internet sites—this makes it convenient and efficient instead of having lunch first then going over to the labs to discuss Web sites (since we are very busy students). Sometimes, when our lab is too packed, or fellow students use two computers at once to render images, and so forth, I take out my Tablet and use it instead. As a group, we did our proposal presentation to the client today; we had to use the Tablet to set up with the classroom projector to run our PowerPoints and Flash files. Without this, we would have had to do it in our client's office, which would have not been a terribly good experience.

And:

I have used the Tablet to create the Flash, and showing other team members and students the work. I have also used the Tablet to do other course homework.

From students who have the only Tablet PC in their group, to:

…really good, been using it to do the wireframes, site maps, and some other stuff. Also working on my blog banner with it, which I will be animating in Flash.

And:

I have been using the Tablet for all of my project work this semester. Some examples are using Flash to do some test animations, using Dreamweaver to put together some html docs, and we have all been taking notes using Windows Journal. We

have been attempting to create a wireless network between our Tablets for easy transfer of files; I'm still working on that...

Both of these comments are from students who all had Tablet PCs in their group. Hence it would appear that while the majority of students are adopting the use of the Tablet in their immediate circle of friends, if their friends do not have one, they are becoming the note-taker, keeper of resources, and demonstrator of group work for the client.

Other responses include:

The Tablets are a great resource. When developing our proposal for our client, we took in mind that using a multimedia enriched presentation, especially for a children's writer, allows for the group to typically show where they are heading with the project. There is nothing easier than images and animation to describe the design flow of the group. The Tablets have allowed us to work with this content and to have it displayed on big projectors easily, knowing that it will work the way we want it to. We have been able to do designs on the spot for our client as well as take notes and even voice record our whole meeting so we know exactly what the client likes and dislikes about the project.

I am using my Tablet in every design class and also out of class for this project. It is very useful as when we have meetings we can view items on this Tablet and the work we have produced on this Tablet.

The use of Tablet PCs is becoming part of the everyday lives of the participants and their ways of doing things:

This semester I used my Tablet PC mainly for updating the blog and maintaining design research in a folder stored on my laptop that can be easily taken from home to school.

The students are adopting it not just for their coursework, but also for their own construction of knowledge:

I have also been using the Microsoft Journal program to consolidate design ideas and do rough sketches (as I find Firework's FreeHand far too awkward because of its vectors), so essentially I just use it as good old 'butchers paper' in terms of sketching and making notes as design ideas come to me.

I use the Tablet to do a lot of writing as I'm a writer; I write on the train a lot thanks to the Tablet, and this writing often includes rationale for my designs to post on my blog. I use the laptop to connect to the RMIT wireless to send e-mails in the caf [student union cafeteria], and our group often meets in the caf so we can access the Internet and do any kind of research, e-mailing, or other Internet related tasks together whilst discussing our design project.

People have been using them for virtually every aspect of their studies, from note taking to sketching out designs.

This semester I have decided to use the Tablet PC for everything. This means any notes taken, and design ideas, Web page development, assignments, and so forth I am doing with the Tablet. Thus far it has been pretty good. We have tried to establish a wireless link between the Tablets, but have been so far unsuccessful.

Unfortunately access to the wireless network has been patchy:

I was having a great run with the wireless access, and was looking past the constant connectivity

failures. Unfortunately what this meant was that I am now getting the message that I have logged on too many times. Other than that, the Tablet has been a success and is most definitely a very good tool in the learning environment. In regards to using the imaging and graphics software on it, the small screen has been my major issue, as well as the processor not being able to handle images with a large file size.

And there have been issues with screen size. Some students have found the processing power slower, especially when they are using a large package like Photoshop:

I have decided to use the Tablet PC for everything: all note taking, all assignments, and most of my Internet research via the wireless network. This has been relatively successful, although I have had many complications with wireless connectivity and now with me getting the message saying that I have exceeded the maximum amount of logins. I have used the Tablet for a lot of the design development, and have basically transferred all of the usual things I would do on paper onto the Tablet. All of my note taking and assignment thoughts are now done on the journal software. More recently the PC has been running exceptionally slow. I am not sure, but I think it may be a virus. I have noticed a file labeled MediaGateway.exe, which should not have been there. I must have accessed it to view something on the Web. And it has rendered the Tablet almost unusable at the moment. I can still operate the PC in safe mode and have uninstalled that file following the Windows instructions. Anyway, I have backup plans in the interim, and will push on regardless. Other than this, the Tablet has been running exceptionally well and has been a brilliant asset to my development this year, and much more so this semester.

The majority of students have found using the Tablet PC enhanced their social context in terms of their access to the wireless intranet from the cafeteria, to their interactions with their clients:

So far this semester I have been using the Tablet PC in a number of ways. I used to the Tablet to construct the Home Hardware Web site proposal presentation. It was useful because I was able to carry it around anywhere, and my group members and I were all able to work on the presentation outside of class (e.g., the Cafe).

- I also used it to and from uni in the train to construct mock-ups for the Web site.
- The Tablet PC was also used after our client meetings to type up any notes, which were then uploaded onto my blog.
- I have also been using it to 'sketch' in ideas using the journal.

Some students are experimenting with the construction of knowledge beyond their immediate classrooms, to experimenting with various different new aspects provided by the mobility and wireless access to the Internet:

…sketching and listening to music. I bring it to meetings and use my handwriting to jot down notes. We haven't managed to set up MSN Meeting or use the agent, so it is like a laptop, to type up documentation.

I'm actually utilizing my Tablet quite a lot this semester. I'm currently using it for taking notes in lectures and classes, brainstorming, doing work on public transport, in the city, and at RMIT. I'm mainly using the programs Word, Photoshop, Illustrator, Journal, and Notepad on the Tablet.

Some light Flash work and using it as more of a tool to take down notes in class/lectures. More handy then a normal book that we write in, as we don't have to search through annoying papers, and so forth. Also use it sometimes in the cafeteria to

research for our projects whenever other classes are taken. Very handy.

Other students are aware of these different options, but are busy enough adapting the technologies to their everyday needs as students:

So far we are using our Tablets like normal laptops, bringing them to class and working on them with Flash, Photoshop, and Illustrator. We haven't actually made use of the Tablet function in any way, as our project design is quite basic and comprised without the Tablet. It is good for us all to have one to bring and log on to wireless.

The Tablet goes everywhere; it's my test environment at home and at Uni. I keep the most up to date information on my Tablet, and I access it over a network to modify files stored on its Web server. I don't think I've rebooted it for about two weeks; it's great to turn on and off very quickly. I'm amused on the train with it, and wherever I go I can get work done. It's the Tablet's portability that's most valuable to me. It's very flexible in how I can use it (standing up/sitting down), and it's powerful enough to do my HTML/PHP/CSS work for the project.

During client meetings I am using the Tablet to take notes and track the meeting. I am also using it to check my e-mails at Uni and to transfer data from home to Uni.

Tablets this semester are really helpful! They have been great when working on my ideas for design and being able to show the other members in my group my work by simply turning on my computer. It almost works as a folio for me, in that I can transfer my work onto the Tablets (or even the work I have produced on the Tablets), bring it to Uni, and connect it up to the net to do simple things like update the blog and share my ideas with my teammates. I have been using the wireless connect a lot more this semester—once again really helpful, whereas now we can have meetings in the caf and not have to rely on computer rooms to be able to connect to the Internet to discuss our work and ideas during the meetings.

Of the 16 allocated to students in this design course, only one student found he was not using his Tablet PC, and his issues were:

To be totally honest, I haven't been using the Tablet at all this semester. I'm finding that the Tablets are extremely slow loading and laggy. Every time when you open up a browser, e-mail, or any application at all the system just hangs and you cannot do anything else until the application has opened. On top of that, because my role consists of using the keyboard a lot, the small keyboard makes things difficult to work with; therefore, I haven't used the Tablet at all.

We have the distinct impression that the Tablet PCs with their digitized screens and capacity for wireless networking have largely disappeared in to the fabric of the students' everyday life (Weiser, 1991). To check this impression we administer the final survey that contains items identical to the baseline survey. The results indicate that while their general abilities with the use of the Internet remained unchanged, the responses in the other categories at the beginning of this section are all now at the average and expert skill level, thus indicating that the participants feel their skills have definitely improved over the study period, especially with regard to using digitized Tablets with a pen and wireless networking.

Students were again asked to read each statement and circle the number that best suits their thoughts about their skill level at this time:

1 I am unsure of my skill level
2 I have no knowledge about this
3 I am a beginner/novice at this stage with a basic introductory skill level

Table 3. Exit survey of students' skill levels

Responses – Skill Level Questions	5 Expert	4 inter	3 novice	2 none	1 unsure
Drawing with a mouse	18%	55%	18%	9%	0%
Drawing with a pen on a WACOM tablet	27%	45%	18%	9%	0%
Writing with a pen on a WACOM	36%	45%	9%	9%	0%
Using wireless networking	18%	55%	18%	0%	0%
Using the Internet	73%	18%	9%	0%	0%
Using a computer	64%	36%	0%	0%	0%
Installing software	45%	45%	9%	0%	0%
Downloading software from the Internet	36%	45%	9%	9%	0%
Using handwriting recognition software	9%	73%	9%	9%	0%
Using a PDA	0%	18%	55%	27%	0%
Using blogs	27%	55%	18%	0%	0%
Putting together my own blog	18%	64%	18%	0%	0%

Finding information I need using the Internet	91%	0%	9%	0%	0%

4 I have intermediate skills
5 I am an expert user with highly proficient skills

CONCLUSION

Implementation of mobile computing effectively facilitates the establishment of a learning community among the students. Many of the structures initially set up seem to have broader application than originally anticipated. Mobile computing assists project groups by extending their communication beyond traditional methods.

Students are able to communicate with other groups effectively and solve a wide range of problems. Instant messaging and e-mail are a key component of contact over this semester and appear to be more prominent than previously observed. Additionally, alternate forms of record management such as document posting on secure sites to be retrieved seem to also be utilized. Weblogs are a key component in record keeping and are often linked to other student Weblogs recording a series of interesting or relevant information.

Many of the strategies set up to facilitate the mobile computing in fact benefit all projects. Teaching staff are able to monitor project development with ease and often recognize issues that come up early in the piece, as the process is far more effectively documented. This has enabled early intervention and in many circumstances provided the group with clear direction to move forward and work through the challenges faced in each project.

The students are able to monitor their own work in relationship to their team members. Problems encountered in previous semesters do not appear to be the status quo with the presence of the mobile computing. There are often typical issues in the

teaching and learning process such as:

- students being unprepared for meetings;
- leaving items at home and not available for discussion;
- technical difficulties of transporting files and data across platforms and via e-mail;
- lack of opportunity for meetings with each other out of class times due to work or study constraints;
- difficulties of interpretation or communication between group members and the client;
- progress slowed by weekly meetings.

The capability of the Tablet PCs and mobile computing allows students to communicate, review, and update their information and development strategies with fewer delays.

FUTURE TRENDS

So far our findings have been encouraging. However, our investigations have opened up further avenues to explore and have posed future research questions relating to allowing all students access to Tablet PCs for all their courses.

We note that the Tablet PCs provide a platform for the development of ideas and enable the centralizing of notes, sketches, various media, and drafts. This means that projects can move along faster, as more information and record keeping can be provided at meetings, more groundwork is covered in a more sophisticated way, and the progression of ideas can be seen more easily. It also results in less information being misplaced or lost, as might be the case with scraps of paper. However, memory storage can become an issue, and many students purchased memory sticks, both for the memory storage and faster transfer of files.

Tablet PCs can help students by providing a communication strategy to expand and support development processes and provide an immediacy to what students are doing, bypassing some pen and paper steps (as an aside: we noticed 40% of students in the cafeteria in Building 8, on Thursday July 28, at 10:30am were using notebook computers). In providing the means to show clients the current status of work, they also enable a clearer understanding of where the project is currently positioned. One student's final comments were:

The tablet has been very convenient for the year. It has assisted me with my design client work and everyday tasks. Thanks!

Chapter 3.6
Mobile Technology and its Applications in Instructional Conversation

Jason Caudill
Independent Consultant, USA

INTRODUCTION

Mobile learning (m-learning) is the most recently developed category of electronic learning (e-learning), both of which are valuable tools in instructional conversation. What makes m-learning unique, and thus deserving of its study as an independent concept, is mobility; learners have the opportunity to go not just beyond the classroom, but beyond the limits of desktop and even laptop computers to engage in instructional environments. As an independent concept, m-learning has its own hardware and network technology, as well as a relationship with and difference from e-learning. As a component of instructional conversation, m-learning provides learners with opportunities to engage in discussion from almost any location at any time, making the conversations much more natural and beneficial to the group.

M-learning technology is, to support the uniqueness of the discipline, mobile. Devices that people carry on a regular basis and can access at almost any location are what drive m-learning practice. Working in concert with these devices is mobile networking technology, which provides the mobile learner with access to instructional material from a wide variety of locations and frees them from being tied to a cabled network connection at a static location.

Given that m-learning is using modern technology to achieve its goals, it is reasonable to associate m-learning with e-learning, and this is entirely correct. M-learning can in many ways be viewed either as an extension of e-learning or as a specific component of e-learning. While a discussion of detailed definitions will come later, it is important to recognize that entering into m-learning is not a departure from e-learning; the practitioner is simply adding new tools to their box.

There are four main objectives of this chapter, all of which relate to preparing instructional conversation practitioners to integrate m-learning

into their teaching. The first of these objectives is to gain knowledge of m-learning hardware. As with any technical application, learning the available tools is a critical first step in applying them. Second, readers should gain knowledge of m-learning networking. As will be explored, hardware mobility is of little use without a mobility of information, and information mobility is enabled by mobile networking. Third, readers will gain an understanding of the relationship of m-learning to e-learning which will provide them with a base from which to launch their own m-learning applications. Fourth, readers will review current applications of m-learning technology in the field of instructional conversation to provide examples of how to apply their new knowledge of m-learning to their own instructional conversation environments.

BACKGROUND

To begin an exploration of m-learning, it is first necessary to build a vocabulary of terms for the field and how those terms will be used here.

Defining m-learning is somewhat complicated, in part because m-learning has not been in use for long enough to firmly establish what it is and what it is not. Some of the definitions currently in the literature include: Kambourakis, Kontoni, and Sapounas (2004) define m-learning as being, "The point at which mobile computing and e-learning intersect to produce an anytime, anywhere learning experience." Colazzo, Ronchetti, Trifonova, and Molinari (2003) state that, "A mobile learning educational process can be considered as any learning and teaching activity that is possible through mobile tools or in settings where mobile equipment is available."

With this definition in mind, it is important to define exactly what is meant by the term mobile device. By most definitions personal digital assistants (PDAs), mobile phones, and MP3 players can be considered mobile devices (Mellow, 2005; Andronico, Carbonaro, Casadei, Colazzo, Molinari, & Ronchetti, 2003). Outside of these definitions, however, there is a certain amount of disagreement over exactly what constitutes mobile technology. The biggest question is whether or not laptop computers are mobile devices. In one sense they are; laptops can operate on battery power and access wireless networks for communication. In another sense, however, laptops are not truly mobile because they are not handheld devices, they require a user to be seated or standing beside a table or shelf to use, and they also need to be carried either independently or in a large case. For the purposes of the chapter, mobile devices will be defined as those devices that are small enough to fit in a shirt or jacket pocket and can be used in a variety of different environments, so laptops are not included. That said, it is important to remember that laptop and even desktop computers have the capability to access m-learning media, they are just not m-learning devices.

Now that the hardware being used in m-learning has been defined, the actual media formats of m-learning will be explored. As will become obvious, some media formats are platform-specific, while others will work across a wide variety of different mobile devices.

Probably the most basic and also the most proprietary media being used in m-learning is the short message service (SMS) via mobile phone. SMS is, in essence, a small format mobile e-mail application. Users can send short messages, usually around 150-200 characters, over mobile networks where they are received by users' mobile phone handsets. What defines this technology as basic in the field of m-learning is that instead of being user-requested the messages are sent to users at the discretion of the provider. Because SMS applications lack the on-demand features seen with other m-learning technology, it is classified here as a lower-level application. This is not in any way to say that SMS is not important or useful, quite the contrary, and later sections will highlight just how useful SMS ap-

plications can be to certain environments. The second factor that somewhat limits SMS is the proprietary platform required to support it. For now, SMS only works with mobile phones, which necessitates anybody in a system using SMS to have a handset and service. Many, if not most, students already have access to this technology, but there is no guarantee of universal access and, additionally, service contracts vary as to the cost, if any, of each text message received, which can add to the expense of the student.

Personal digital assistants (PDAs) are the next category of mobile learning technology to define. These handheld devices have changed dramatically from their early days of being just address books and calendars with a calculator. The best of these devices today are much closer to being palmtop computers than anything else, integrating wireless networking technology, e-mail, and even Internet access along with the traditional date book functions. Also, the most fully featured models today have the option of storing and playing media files of multiple formats and utilizing removable storage media to provide the storage capacity for those files. What this utility means for the m-learning environment designer is that any number of m-learning media formats can be accessed by the learner with just one device. This accessibility lends considerable flexibility to the instructional designer, and also to the learner, who has the option of using their choice of media at any given time with their PDA.

Probably the fastest growing and most universally accepted m-learning media format is the podcast. Podcast, at their most basic level are simply digital audio files, most often formatted as MP3 files. While the term Podcast was derived from the Apple Computer company's MP3 player, the iPod, it is not necessary to have an iPod to listen to podcasts. Any electronic device capable of playing MP3 files can play a podcast. As MP3 technology spreads, these devices include not only computers and dedicated MP3 players, but also PDAs, mobile phones, and even such unexpected items as sunglasses and wristwatches. All podcasts contain audio information that can be listened to on a mobile device, but they are not limited to just audio information. Podcasts can include still images that change in time with the audio playback, giving the user the opportunity to view slides or other visual aides during the presentation, much like watching an instructor's PowerPoint presentation during a live lecture. The next step beyond the inclusion of still images actually steps beyond being a podcast and turns into something different.

Video podcasts, sometimes referred to as vodcasts, are self-contained audio and video files that are compiled in one of a variety of digital video file formats. Vodcasts can be distributed as instructional video or can be a full video file of a lecture, as opposed to the audio only or audio plus still images that are possible with a regular podcast. While vodcasts can obviously convey larger amounts of information, they are not as accessible to users as the audio podcast. To play a vodcast, a device must have a screen and video playback capability, requirements that eliminate many MP3 players and other devices. Also, vodcasts require the viewer to watch the presentation, as opposed to just listening to information, which eliminates vodcasts as an option for use while driving or doing other activities that are compatible with listening to audio but not viewing video.

There are two sides to mobile technology, the first being hardware and the second being networking. Currently, there are two main wireless networking standards being used for two primary purposes.

The IEEE 802.11 communication protocol, commonly referred to as Wi-Fi, is the most prevalent wireless networking technology currently in use. Wi-Fi is commonly available in two speeds, B, which communicates at a speed of 11 kilobits per second (kps) and G, which communicates at a speed of 54 kps. There are other standards in existence, but B and G are what most networks operate on and both B and G wireless network

devices can operate on both B and G wireless networks. What Wi-Fi technology provides to the mobile computing user is the opportunity to access networked resources while away from wired connections, and also to quickly and easily collaborate with other mobile technology equipped teammates. Details of exactly how the technology is employed will be explored following the other primary wireless technology in use, Bluetooth.

The IEEE 802.15.1 wireless communication standard is what is commonly referred to as Bluetooth. While Wi-Fi is traditionally a wireless network connection to the Internet, Bluetooth functions much more frequently as a device-to-device data transfer mechanism. Using Bluetooth, it is possible, without cables or external storage media, to transfer data between two Bluetooth-equipped hardware devices quickly and easily. This technology gives mobile technology users the capability of sharing important information between, for example, their laptop, PDA, and mobile phone, all without having to carry cables or physically connect the devices to each other. The advantage to this technology is that it provides the mobile learner with an easy way to utilize information on multiple devices, thereby freeing them from having to rely on any single piece of hardware for their mobile computing.

With these two widespread wireless protocols defined, how are they used? There are two different applications of Wi-Fi technology that will be defined here, hotspots and ad-hoc networks.

Hotspots are simply areas where Internet access is available via Wi-Fi technology. Originally seen in coffee shops and similar urban locations as a draw for customers to be able to stay connected to e-mail and Internet resources while spending time in the business, the hotspot phenomenon has expanded rapidly. Currently, there are many businesses and hotels that offer free Wi-Fi access as a service to their customers, and in some cities entire downtown districts have been equipped with broad coverage Wi-Fi so that anywhere in the area, people can access the Internet from their wireless devices. Wi-Fi compliments a wide variety of different m-learning applications. Podcasts can be downloaded over a wireless network, course management systems can be accessed, and e-mail can be used as a direct communication between learners or between learners and instructors.

The other capability of Wi-Fi is to create what are called ad-hoc networks between devices. This process does not require a router or other hardware, only compatible devices that include Wi-Fi functionality. What this ad-hoc networking capability allows users to do is to gather at any location and quickly, easily, without cables, transfer files and information between hardware devices while working collaboratively.

The ad-hoc networking capabilities of Wi-Fi are somewhat similar to what Bluetooth technology gives to users. While it is technically possible to offer Internet access via a Bluetooth network, it is very rarely used as such. Bluetooth's primary use is as a device-to-device networking service. File transfers, data backups, and even the dialing of mobile phones can be accomplished through Bluetooth communication between the correct types of devices. In the context of mobile learning, this connectivity between devices enables users to easily share information between different pieces of mobile hardware so that they can access that information on whatever type of device is most convenient.

To finish the discussion of mobile networking technology, the newest and potentially most useful addition to the field will be examined. Third-generation technology, marketed as 3G, is broadband wireless networking via cellular phone networks. The speed of 3G is 384 kilobits per second. The key advantage to 3G technology is that unlike Wi-Fi and Bluetooth, both of which are local area networks (LANs), 3G is a wide area network (WAN). WAN technology covers a much broader area and has the capability of providing wireless Internet services to 3G-equipped hardware anywhere in a city or even beyond city limits; the scope of coverage depends only on

the presence of compatible transmission towers. What this means to users of 3G technology is that they have the ability to connect in a much wider variety of locations than the users of Wi-Fi technology, thus giving them even more opportunities to participate in a learning activity on their own time at the location of their own choosing. The one serious drawback to this technology is that at the moment it is still relatively expensive, around $60 a month, versus the usually free access to hotspots afforded by Wi-Fi technologies.

Discussions of the Topic

Having defined the technology that is involved in m-learning, how does m-learning contribute to instructional conversation? To answer this question it is first necessary to determine just what instructional conversation is and how it is being used in today's classrooms.

Putnam and Borko (2000) define instructional conversation as, "…a mode of instruction that emphasizes active student involvement in goal and meaning-oriented discussions." Instructional conversation as a teaching tool has been found to be effective in working with students who are at risk educationally (Watson, 2000). Doherty, Hilberg, Epaloose, and Tharp (2002) make the point that "fully inclusive, small-group ICs are stressed because they increase the participation of all students, including the more passive learners." Indeed, the increased accessibility to learners who may not be likely to join a live conversation but are comfortable conversing via discussion board or other computer-mediated format where they have the time to collect their thoughts, draft, and edit their responses, has long been a benefit of online education, and this advantage carries through to the mobile applications of instructional conversation.

From a technical standpoint, "the increasing availability of computer-based tools and resources and the growing emphasis on using these in subject teaching and learning has a potentially significant impact upon established patterns of classroom interaction" (Hennessy, Deaney, and Ruthven, 2005). In relation to multimedia, Mayer (2003) discusses the personalization effect, defined as the fact that, "…students learn more deeply from a multimedia explanation when the words are presented in conversational style rather than formal style."

What is it about m-learning that makes it a valuable component in instructional conversation? There are considerable similarities between instructional conversation and contextual life-long learning, whose features are that:

- "learning is not confined to pre-specified times or places, but happens whenever there is a break in the flow of routine daily performance and a person reflects on the current situation, resolves to address a problem, to share an idea, or to gain an understanding
- formal education can not provide people with all the knowledge and skills they need to prosper throughout a lifetime. Therefore, people will need to continually enhance their abilities, in order to address immediate problems and to participate in a process of continuing vocational and professional development."

Sharples (2000) discusses the connection of m-learning technology to lifetime learning and outlines the attributes of technology devices that facilitate this goal:

- **Highly portable:** So they can be available wherever the user needs to learn
- **Individual:** Adapting to the learner's abilities, knowledge, and learning styles and designed to support personal learning, rather than general office work
- **Unobtrusive:** So that the learner can capture situations and retrieve knowledge without the technology obtruding on the situation
- **Available anywhere:** To enable communi-

cation with teachers, experts and peers
- **Adaptable:** To the learner's evolving skills and knowledge
- **Persistent:** To manage learning throughout their lifetime, so that the learner's personal accumulation of resources and knowledge will be immediately accessible despite changes in technology
- **Useful:** Suited to everyday needs for communication, reference, work, and learning
- **Intuitive:**To use by people with no previous experience with technology"

It is apparent from Sharples' technology attributes that accessibility and usability are keys to the success of learning technology, particularly m-learning technology whose purpose is to be a part of a learner's daily life. Combined with the purpose of instructional conversation, that being to engage learners in educational discussions of a topic, m-learning technology can serve to greatly enhance the learning experience. Having precisely defined the components, how this contribution is made by the technology can be explored.

MAIN THRUST OF CHAPTER

Issues

M-learning as a technology has some very important issues in its application and use. User access is a major consideration when considering the implementation of a m-learning program, as is the choice of what kind of technology, which directly affects pedagogy options, will be utilized. Also important are questions of instructional design and training for both instructors and learners.

The number one consideration when embarking on an m-learning program is that of learner access to the technology. In practice, the best design, the best content, and the best intentions for a program are all useless if the target population does not possess the technological resources to access the material. It is absolutely critical to any m-learning application that there is market saturation of the technology in the targeted group of learners (Viteli, 2000). The challenge presented by this issue varies by situation, with some environments being much easier to manage than others. A professional graduate-level program, for instance, can easily place a technology requirement on all incoming students, specifying hardware, software, network, and operating system requirements as a prerequisite for participating in the program. Other situations, however, do not have a population with the resources to buy into new technology. Most K-12 public schools, for instance, have neither their own resources nor the universal student resources to levy technology requirements on learners. What this means for the instructional designer, for the practitioner of instructional conversation, is that the resources of the learner have to be considered and accounted for before employing a new technology. To work, m-learning requires population access to the technology.

Assuming user accessibility, the choice of what kind of m-learning technology to use is critical to the design of an m-learning system. While some technologies are directly involved in instructional conversation, others are facilitators of conversations, serving to make the conversations that do occur more effective, or even just making them accessible, and therefore possible. Because of this, multiple technologies may be chosen in any given instructional design. Some of the questions that can be asked before making this decision are: does communication need to be one-way or two-way? Can the information be conveyed with text only, audio only, with the inclusion of pictures, or is video required? Can messages be sent out at the discretion of the instructor or do learners need to be able to access information at will? Do messages need to be confidential or shared among all participants? All of these things factor into making decisions about the components of an m-learning system. Table 1 provides a list of

Table 1. M-learning technologies and their applications in instructional conversation

M-learning Technology	Application in Instructional Conversation
e-mail	distribution tool for information or media, conversation tool via listserv or direct learner/instructor discussion
SMS	quick, reliable distribution of notes and information to learners
PDA	mobile network access for e-mail, discussion boards, mobile computing applications to prepare for assigned conversation topics
Podcasts	deliver media to learners in advance of discussions, archive discussions for later reference
Vodcasts	deliver video examples of activities, distribute instructional video files of the topic for discussion
Wi-Fi	mobile network access on a variety of mobile devices providing access to online learning materials
Bluetooth	ad-hoc networking for group discussions and local file transfer of learning materials

m-learning technologies and their related application in instructional conversation.

Controvercies

The biggest controversy facing m-learning technology, and especially podcasting and vodcasting is one of intellectual property rights. Not only is there the very real concern of violating an existing copyright by distributing material that an instructor does not have the rights to, but the rights to material created by an instructor are a matter of serious debate as well. It will be largely left to the legal system to define who owns specific content in specific situations, but considerable litigation can be expected in the future to determine exactly how intellectual property rights will be determined for instructors and professors using digital media to record and distribute their course content.

Problems

Currently the question of how to provide technology access to learners is a serious problem when considering a move to m-learning technology. In a corporate training environment, this problem is simply one of whether or not the company has the resources, or the desire, to invest in the technology for employees to use. While a definite problem, this is not something insurmountable. For public universities and preparatory schools, however, the issue is much more serious.

As technology continues to play a more and more important role in education there are serious effects being seen from what is called the digital divide. Basically, the digital divide is the performance gap between students from families that do have computers and other technology in the home and those who do not. A full discussion of all the related issues is beyond the scope of this chapter, but the fact that the digital divide exists does have real implications on m-learning integration in public schools at all levels.

Where private schools have the luxury, more often than not, of mandating the purchase of specific hardware and/or software as a school supply, public schools do not. This puts public schools in the uncomfortable position of having to either provide students with technology or not pursue m-learning. Given the funding difficulties being faced by most public schools, preparatory and university alike, the purchase of multiple PDAs,

much less mobile phones with service, is highly unlikely. This being the case, many, if not most m-learning applications remain beyond the reach of public institutions of learning.

What these problems all have in common is that they are problems of access. How does an organization provide its learners with access to m-learning materials? The access is key, the best instructional design and the fastest servers are unable to improve the learning environment if learners do not have the means to access the instructional resources on that server.

Solutions

Unfortunately for practitioners, solutions to the access problems are not yet here. It can be predicted that in the near future there will be hardware solutions inexpensive enough to provide wide access to mobile technology but when that time is, can not be known.

The most encouraging current work involves the MIT Laptop Project, which has designed a Wi-Fi capable, hand-crank-powered laptop running open source software that will be available when in production for $100 per unit. The goal of this project is to bridge the digital divide for developing countries and communities. While by most definitions laptops are not considered to be mobile technology, it is encouraging that efforts are being made to provide affordable, wirelessly networked hardware and software to those people who are least able to afford it. It is impossible to project when this type of work will extend to truly mobile devices, but as with everything in technology, it is reasonable to forecast drastic drops in the price of mobile devices compared to the performance that they offer.

For solutions to come, m-learning likely needs to mature as a discipline and be well established enough to demand the attention of development efforts. Currently, the technology and the pedagogy of mobile learning are so new that very little outside the field of instructional technology is being done.

Recommendations

The best recommendation for current or future practitioners of m-learning is to establish a good knowledge base of not only technical expertise, but of e-learning pedagogy. While hardware, software, and networking technologies change, the basic purpose of m-learning, to convey information to learners, does not. If a practitioner has a clear picture of what they are trying to convey and how they want learners to interact with the system, then virtually any technology can be adapted to serve that purpose.

M-learning in Instructional Conversation Practice

M-learning technology, as an emerging field of study, is still new to the practice of instructional conversation but there are already some excellent examples of its usefulness. Mobile technology as a conversational tool needs to meet several criteria:

…the minimum equipment needed to hold conversations that promote effective learning consists of the following: a shared language in which to express commands, questions, instructions, agreements and disagreements; minds capable of giving rise to conversation about some shared phenomenon; and an external representation of the phenomenon that can provide a common framework for exploring differences of conception. Relating this to the design of learning technologies, we require more than transparent channels of communication and a means for transmitting knowledge, we also need a shared language (among learners, and between learners and computer systems), a means to capture and share phenomena, and a method of expressing

and conversing about abstract representations of the phenomena (Sharples, 2002).

To facilitate these conversations, mobile technology is being used to enable impromptu collaboration, facilitate discussion in language learning classes, and provide practical learning experiences for groups of students.

Mobile devices using Wi-Fi or Bluetooth networking technology are very well-suited to participate in quickly assembled, wireless networks between multiple devices that are being used close to each other. The general term for this type of connection between machines is an ad-hoc network, a network that comes together as the users of the devices come together and then ceases to exist when the users leave the area. Using these ad-hoc networks, it is possible for users to collaborate and exchange information via mobile devices at virtually any location quickly and easily. The attributes of ad-hoc mobile networking that support its use in instructional conversation are that it is opportunistic, spontaneous, proximity-based, and transient (Kortuem, Schneider, Preuitt, Thompson, Fickas, & Segall, 2001). By capitalizing on these attributes, mobile learners have the freedom to effectively engage in collaborative activities in many more locations and at many more times than they would with more traditional file storage and transfer technologies.

Related to ad-hoc networking applications is the use of mobile technology in language learning environments. Liang, Liu, Wang, and Chan (2005) discusses the use of modified pocket electronic dictionaries in foreign language courses, citing one characteristic exhibited as being, "…interactive-based, connecting it with the student's ELMD to perform individualized, group-based, or whole-class learning activities expanding the degree of student participation." By utilizing the technical capabilities of the mobile device, in this case a pocket electronic dictionary, discussion among students and instructors can be facilitated. This application is very similar to what can be accomplished with student PDA devices, enabling participants to share files and other information via mobile device to enhance the learning experience of everyone involved in the conversation.

The value of these experiences, as delivered by mobile technology, is explained by Lowand O'Connell (2002):

The data connectivity and communication aspects of many mobile devices support social interaction, collaboration and construction of learning—for example:

- *The ability of mobile phones to exchange media via MMS, e-mail, and SMS*
- *The ability of PDAs to connect to the Internet and interface with both synchronous and asynchronous communication tools*
- *The exchange of compatible memory cards between learners to copy reviewed and recommended audio or video resources across media players, PDAs or mobile phones.*

What these communication abilities address in the m-learning arena is the need for the learner to relate, one of the four R's of mobile learning, the other three being record, recall, and reinterpret (Low and O'Connell, 2002). The practical application of mobile technology to relating to others in a learning environment involves:

- *The learner may use a portable device to communicate with other people (for example, with other learners), or with a teacher (that is, in a learning relationship).*
- *The learner can use the device to communicate directly and synchronously (for example, mobile phone conversation), or access asynchronous communication services (for example, Web discussion board or Web log).*

- *They can also recommend and share resources, for example, linking mobile devices (usually wirelessly) and sending a file from one to the other.*
- *Communicative and collaborative: underpinned by a social constructivist or connectivist theory of learning (Low and O'Connell, 2002).*

Mobile applications of instructional conversation as a whole are growing rapidly, as is the field m-learning. Patten, Sanchez, and Tangney (2006) describes several new applications that have the goal of facilitating learner interaction. Four of the applications are described here:

- **TxtIT:** An SMS messaging application "to support interactivity in the classroom"
- **Mapping Challenge:** A treasure hunt game using mobile phones
- **SortIT:** A collaborative problem-solving application for handheld devices

The final m-learning collaboration tool to be highlighted here is an automated tutoring system called Alykko. Silander and Rytkonen (2005) introduce Alykko with the explanation that, "Communication, collaborative knowledge building, observations, and finding new innovations describe the student's learning activity in the authentic learning. When using mobile devices, students are able to construct useful knowledge in a real situation." The Alykko system works with students to construct an instructional conversation by providing "…focusing and deepening questions to a student based on the student's progress and activity" (Silander and Rytkonen, 2005). As such, the system actually gives learners the opportunity to engage in an environment of instructional conversation while working independently; the electronic device prompts the learner to think and analyze the material in question, much the same as a conversation with peers would do.

It is clear from these examples that a wide range of things can be accomplished in the realm of instructional conversation using mobile technology. As was said earlier, m-learning, and the technology behind it, are still new innovations and their full use in instructional conversation has yet to be determined. By starting now, and building a solid understanding of the basic components, it will be possible to find new applications of the technology as capacities and capabilities change.

FUTURE TRENDS

Emerging Trends

One of the most important emerging trends in m-learning is the shifting undergraduate student population. With more and more students being what are classified as "nontraditional," that is, older students with full-time jobs and possibly families, demands for distance and mobile learning opportunities will likely increase.

To best serve these nontraditional students, it is often important to engage them in conversation and encourage them to share their professional experiences from the workplace. Given the breadth of experiences that the average nontraditional student has versus the traditional undergraduate, instructional conversation becomes even more important. Combining the need for instructional conversation with the demanding schedules of this new category of learners lends itself very well to the incorporation of m-learning technologies to facilitate the conversations.

Future Research Opportunities

Because m-learning is such a new discipline, the field is open to a wide variety of future research projects. In relation to the use of m-learning technologies with nontraditional learners, it would be particularly interesting to do a study on the use of

m-learning with traditional versus nontraditional students to see if there is any performance gap based on familiarity with the technology.

For any group of students, it would be useful to study the actual impact of m-learning technology on instructional conversation, perhaps by running a study where one section of a course uses the technology and another does not. As with many educational studies, the design of the assessment instrument would be very important, but the results could help to better design instructional conversation via m-learning in the future.

CONCLUSION

Overall Coverage

There is a broad and expanding selection of mobile learning technologies available. Just during the writing of this chapter, the competition for video-capable MP3 players has exploded, with multiple large firms competing with the iPod. What matters far more than the technology, however, is the application of the technology and its relationship to instructional conversation. Regardless of the medium, discussions among learners and instructors are the key component to instructional conversation and an important contribution to any learning environment. In order to capitalize on these advantages the practitioner must have a good understanding of both pedagogy and technology.

Concluding Remarks

Technical advancements have given instructors a wide variety of tools to use in their goal of conveying information to learners. As practitioners, it is important to stay current in technical trends, but also to remain grounded in good design and good practice. Think of the learner first, and tailor any new innovation to serve them. Not every new idea will be successful, but if they are student-focused every new idea will be worth pursuing.

FUTURE RESEARCH DIRECTIONS

Because m-learning is so new and the research into the field is at such an early stage, there are many possibilities for mobile technology and instructional conversation research. Perhaps the most important is practical research in the effects of mobile technology when applied to instructional conversation environments. Closely linked to this study of effectiveness would be a study of the different effectiveness of different mobile technologies.

Before studies could be conducted it is necessary to construct an assessment instrument to determine the volume and quality of activity in the instructional conversation. This instrument would need to define specific points that researchers could use to analyze conversation participation. These points might classify types of posts to a conversation, what constitutes a significant contribution, and how contributions can be categorized in regard to their level of significance to the conversation. Before research studies could be conducted it would be necessary to validate this instrument.

The application of the instrument would be to implement mobile technology as a component of instructional conversation into a course design that already uses instructional conversation with some other technology. Ideally, this experimentation would occur in two different sections of a single course taught during the same semester by the same instructor to minimize differences between instructional environments so that observed differences in student activities in the instructional conversations can best be attributed to the difference in technology. By analyzing the results of these two courses with the assessment instrument, it should be possible to establish the differences

in student activity with or without the inclusion of mobile technology. Ideally, this study would be run repeatedly, comparing each of the different mobile technologies with an environment not using mobile technology to discover which mobile technologies are effective and which are not.

As a second step of this process, subsequent studies of the same design could be run to determine the effectiveness of different types of mobile technology. By using two different types of mobile technology in a study instead of one class using mobile technology and one not, it should be possible to identify the most effective mobile technologies in instructional conversation. It is highly likely that a long-term, intensive study of this type would result in pairing different mobile technologies to different instructional conversation environments and thus some technologies would be useful for some environments but not necessarily for others.

For instructional designers and other technology researchers, there is much work to be done in testing the use of mobile technology in instructional conversation applications. As the technology continues to change research opportunities will expand.

INTRODUCTION

A significant rise in the use of mobile computing technologies has been witnessed in recent years. Various interpretations of the mobile computing paradigm, for example, ubiquitous and pervasive computing (Weiser, 1991) and more recently, ambient intelligence (Aarts & Marzano, 2003)—have been the subject of much research. The vision of mobile computing is often held as one of "smart" devices operating seamlessly and dynamically, forming ad-hoc networks with other related devices, and presenting the user with a truly ubiquitous intelligent environment. This vision offers many similarities with the concept of distributed artificial intelligence where autonomous entities, known as agents, interact with one another forming ad-hoc alliances, and working both reactively and proactively to achieve individual and common objectives.

This article will focus on the current state of the art in the deployment of multi-agent systems on mobile devices and smart phones. A number of platforms will be described, along with some practical issues concerning the deployment of agents in mobile applications.

BACKGROUND

In the most general terms, an agent is one entity that acts, or has the authority to act, on behalf of another. In terms of information technology, an agent is a computational entity that acts on behalf of a human user, software entity, or another agent. Agents have a number of attributes that distinguish them from other software (Bradshaw, 1997; Etzioni & Weld, 1995; Franklin & Graesser, 1996; Wooldridge & Jennings, 1995):

- **Autonomy:** The ability to operate without the direct intervention from any entity, and possess control over their own actions and internal state.
- **Reactivity:** The ability to perceive their environment and react to changes in an appropriate fashion.
- **Proactivity:** The ability to exhibit goal-directed behavior by taking the initiative.
- **Inferential Capability:** The ability to make decisions based on current knowledge of self, environment, and general goals.
- **Social Ability:** The ability to collaborate and communicate with other entities.
- **Temporal Persistence:** The ability to have attributes like identity and internal state to continue over time.
- **Personality:** The ability to demonstrate the attributes of a believable character.
- **Mobility:** The ability to migrate self, either proactively or reactively, from one host device to another.
- **Adaptivity:** The ability to change based on experience.

An agent requires some space where it can exist and function, and this is provided for by an agent platform (AP). An AP comprises "the machine(s), operating system, agent support software,…agent management components…and agents" (FIPA, 2000, p. 6). The AP allows for agent creation, execution, and communication.

The majority of computer systems currently in operation use algorithms that are based on the concept of perfect information. The problem is that in the real world, businesses often require software functionality that is much more complex than this (Georgeff, Pell, Pollack, Tambe, & Wooldridge, 1999). Typically, computational entities within these systems should have an innate ability to deal with partial information and uncertainty within their environment. These types of systems are highly complex and are intractable using traditional approaches to software development. The rate at which business systems must change, due to market pressures and new information coming to light, requires software architectures and languages that more efficiently manage the complexity that results from alterations being made to the code and the specifications.

Agent architectures, and in particular belief-desire-intention (BDI) (Rao & Geogeff, 1995) agent architectures, are specifically designed to deal with these types of issues and thus contain mechanisms for dealing with uncertainty and change. A problem with traditional systems is that they assume that they exist within a static or constant world that contains perfect information. The types of mobile systems that we are concerned with are dynamic and perhaps even chaotic, embedded with agents that have a partial view of the world and which are resource bounded.

Agents rarely exist in isolation, but usually form a coalition of agents in what is termed a multi-agent system (MAS). Though endowed with particular responsibilities, each individual agent collaborates with other agents to fulfill the objectives of the MAS. Fundamental to this collaboration is the existence of an Agent Communications Language (ACL), which is shared and understood by all agents. The necessity to support inter-agent communication has led to the development of an international ACL standard, which has been ratified by the Foundation for Intelligent Physical Agents (FIPA).

JAVA 2 MICRO EDITION (J2ME)

Most agent platforms developed for mobile devices have been written in the Java programming language—on mobile devices that usually means Java 2 Micro Edition (J2ME). This edition of Java contains a cut down API, a reduced footprint Java Virtual Machine, and a slightly different syntax (e.g., parameterized classes in Java 5). Java applications that contain dependencies on the idiosyncrasies of the different editions cannot be ported to a different range of devices without making alterations to the code. Their performance, however, is improved because the code is no longer developed to the lowest common denominator. Different algorithms and coding styles are now used for desktop machines and embedded devices rather than adopting comprised or overarching approaches that do not maximize the performance or maintainability of either.

A NUMBER OF AGENT PLATFORMS EXISTS FOR MOBILE DEVICES

3APL-M

3APL-M (Koch, 2005) is a platform that enables the fabrication of agents using the Artificial Autonomous Agents Programming Language (3APL) (Dastani, Riemsdijk, Dignum, & Meye, 2003) for internal knowledge representation. Its binary version is distributed in J2ME and J2SE compilations. 3APL provides programming constructs for implementing agents' beliefs, goals, basic capabilities, and a set of practical reasoning rules. The framework comprises an API that allows a Java application to call 3APL logic and deliberation structures.

Agent Factory Micro Edition

Agent Factory Micro Edition (AFME) (Muldoon, O'Hare, Collier, & O'Grady, 2006) is an agent platform developed for the construction of lightweight intelligent agents for cellular digital mobile phones and other compatible mobile devices. AFME is broadly based on Agent Factory (Collier, 2001), a pre-existing J2SE framework for the fabrication and deployment of agents. AFME differs from the original version of the system in that it has been designed to operate on top of the Constrained Limited Device Configuration (CLDC) Java platform augmented with the Mobile Information Device Profile (MIDP). CLDC and MIDP form a subset of the J2ME platform specifications. Though sharing the same broad objectives of the other projects mentioned in this section, AFME differs in a number of ways. With a jar size of 85k, it is probably the smallest footprint FIPA-compliant deliberative agent platform in the world. The platform supports the development of a type of software agent that is: autonomous, situated, socially able, intentional, rational, and mobile. An agent-oriented programming language and interpreter facilitate the expression of an agent's behavior through the formal notions of belief and commitment. This approach is consistent with a BDI agent model.

LEAP

Probably the most widely known agent platform for resource-constrained devices is the Light Extensible Agent Platform (LEAP) (Berger, Rusitschka, Toropov, Watzke, & Schichte, 2002). LEAP is a FIPA-compliant agent platform developed to be capable of operating on both fixed and mobile devices with various operating systems in wired or wireless networks. Since version 3.0, LEAP extends the Java Agent DEvelopment Framework (JADE) (Bellifemine, Caire, Poggi,

& Rimassa, 2003) by using a set of profiles that allow it to be configured for various Java Virtual Machines (JVMs). The architecture of the platform is modular and contains components for managing the lifecycle of the agents and controlling the array of communication protocols. The platform is split into several agent containers, one for every device used. These containers are responsible for passing messages between agents and choosing the appropriate communication protocol. One of these containers, known as the main container, includes agents that fulfill the white and yellow pages services as necessitated by the FIPA specification.

MAE

The MAE (mobile agent environment) (Mihailescu, Binder, & Kendall, 2002) agent platform has been designed to be independent of device and language implementations. To accomplish this, the platform is divided into a reference API specification, reference implementation, and non-standard implementation additions. The reference API specification is not dependent on programming language or hardware, and it contains the core platform components. The Reference Implementation contains all the device-dependent code required by the reference API specification. The third part, non-standard implementation additions, is used for application-specific components.

While this approach gives a high degree of platform independence, unless it is being deployed in an environment of homogeneous devices, it means a lot of work as each platform may require its own implementation.

MicroFIPA-OS

MicroFIPA-OS is an agent toolkit based on the standard FIPA-OS but optimized for resource-constrained mobile devices (Tarkoma & Laukkanen, 2002). It targets the personal Java platform and thus operates on personal data assistants. The system can run in minimal mode whereby agents do not use task and conversation managers. Yellow and white page services are provided in compliance with the FIPA specification. The platform is entirely embedded, however it is recommended that only one agent operate on low-specification devices.

NON-EMBEDDED AGENTS FOR MOBILE SERVICES

There are other types of agent platforms suitable for mobile services that do not embed the agents in the mobile device:

- platforms that use the mobile device as just an interface while the agents are executed on more capable hosts, for example MobiAgent; and
- platforms that do part of the execution on the mobile device, while simultaneously executing the remainder the task on other hosts such as KSACI (Hübner, 2000a, 2000b).

MobiAgent

A MobiAgent (Mahmoud, 2001) platform comprises a handheld mobile wireless device and an agent gateway, which are networked and communicate through hypertext transfer protocol (HTTP). The agent gateway executes the agent and its associated apparatus. The user interacts with the agent through an interface on the mobile device, which connects to the agent gateway and configures the agent. After the agent carries out a task, it reports back through the interface. This approach requires the minimum amount of processing and memory resources on the mobile device, but it makes the connectivity essential.

KSACI

Simple agent communication infrastructure (SACI) is a framework for creating agents that communicate using the Knowledge, Query, and Manipulation Language (KQML) (Finin, 1997). Each SACI agent has a mailbox to communicate with other agents. Infrastructure support is provided for white and yellow pages, but the platform is not FIPA compliant. KSACI is a smaller version of SACI suitable for running on the kVM (Albuquerque, Hübner, de Paula, Sichman, & Ramalho, 2001). The platform is not entirely situated on the constrained device and only supports the running of a single agent, which communicates via HTTP with a proxy running on a desktop machine.

DISCUSSION

A mobile computing environment is typified by resource constraints. Issues like processing power, memory, battery life, connectivity, and input/ouput (I/O) all require careful consideration.

It is often reported that intelligent agent platforms are unsuited for mobile applications because of their excessive computational overhead. This problem is usually due to particular agent platform implementations rather than an innate problem with the agent paradigm itself. Improving the efficiency of the reasoning algorithms within these systems can often lead to significant gains in efficiency. Additionally, the programming style adopted by the developer can have a considerable impact on performance. Developing in a style that conforms to the Law of Demeter (Lieberherr, Holland, & Riel, 1988) can reduce the footprint of the software by minimizing duplicated code while also improving maintainability in that internal implementation details of the object model are hidden. Further performance gains may be obtained through the use of autonomic procedures. An example of such a procedure, termed Collaborative Agent Tuning, may be found in Muldoon, O'Hare, and O'Grady (2005). Tuning enables agents collectively to alter their response times and computational overhead so as to maximize system performance.

The communication infrastructure is another fundamental resource that must be managed astutely when developing multi-agent systems. It is particularly important when working with lightweight devices that have limited battery power since sending messages consumes significantly more battery resources than normal processing. Mobile devices often have limited bandwidth and must make intelligent decisions as to what information to download and when to download it.

Additionally there is the issue of human-agent communication. Consideration must be made for the I/O capabilities of the devices. Most would have some form of keyboard input in the form of a touch screen or keypad. How the agent would convey information would be a bigger modality issue—is there a screen, does it allow for graphics or just text, how big is the screen, and how much of it is available to the agent?

FUTURE TRENDS

In the future, agents will emerge that are endowed with autonomy, mobility, and human-computer interaction facilities (Bradley, Duffy, O'Hare, Martin, & Schön, 2004). Such agents will opportunistically migrate, based on their tasks at hand, to different platforms (each offering varying capabilities and prospects), which would usually be for the benefit of an associated user. The presence of the agent moving through cyberspace as the user moves through physical space allows the associated user to be contactable at anytime through the agent.

A clear application of such nomadic agents is that of an autonomous "intelligent" digital assistant that is independent of any one physical device. These entities will effectively give any

user his or her own personal assistant that will help with the information overload in daily life, assisting with personal communications and offer a generic interface to any number of devices. These devices will have the ability to react to the current needs of their user, and beyond this, grow and learn to anticipate future needs and requirements. Perhaps our vision can be best summed up by Luc Steels' metaphor for what the robots of the future will be like:

[It] is related to the age-old mythological concept of angels. Almost every culture has imagined persistent beings which help humans through their life. These beings are ascribed cognitive powers, often beyond those of humans, and are supposed to be able to perceive and act in the real world by materialising themselves in a bodily form at will. (Steels, 1999)

He goes on to detail how angels may "project the idea of someone protecting you, preventing you from making bad decisions or actions, empowering you, and defending you in places of influence."

CONCLUSION

Agents encapsulate a number of features that make them an attractive and viable option for realizing mobile services. At a basic level, their autonomous nature, ability to react to external events, as well as an inherent capability to be proactive in fulfilling their objectives make them particularly suitable for operating in complex and dynamic environments. Should an agent be endowed with a mobility capability, its ability to adapt and respond to unexpected events is further enhanced. However, there are a few negative aspects to using agents. These systems can be more complex and require more device resources than the equivalent application-specific programs. Having no native support, agents require their own agent platforms for creation, execution, and communication. These problems will be reduced with advancements in mobile computing technologies, however in order to optimize system performance, agents will still have to manage their resources in a prudent and intelligent manner.

KEY TERMS

Agent: A computational entity that acts or has the authority to act on behalf of a human user, software entity, or another agent.

Agent Communication Language: A formal language used for communication between agents.

Agent Platform: Provides the necessary infrastructure on which an agent operates.

Ambient Intelligence: Computing and networking technology that is unobtrusively embedded in the environment.

Embedded Agent: An agent that is contained wholly, along with its platform, on a particular device.

Mobile Service: One of several services provided through devices in a mobile computing environment (i.e., mobile phones, personal data assistants, wearable computers, etc.).

Multi-Agent System: A system comprising several agents—on the same platform or across multiple platforms—with a common goal.

Pervasive Computing: Computing involving computers, usually mobile devices, in all aspects of daily life.

Ubiquitous Computing: Computing in which the computers are embedded in everyday objects and all computing is done in the background.

Chapter 3.8
A Database Service Discovery Model for Mobile Agents

INTRODUCTION

The number of services that will become available in distributed networks (in particular, on the Internet) is expected to grow enormously. Besides classical services such as those offered by printers, scanners, fax machines, and so on, more and more services will be available nowadays. Examples are information access via the Internet, music on demand, Web services, and services that use computational infrastructure that has been deployed within the network. Moreover, the concept of service in mobile agent systems, which will be described in this article, has come into prominence recently.

The mobile agent model is a new distributed software development paradigm as compared to the traditional client-server model. Instead of calling operations on servers with some form of synchronization, the user passes on his or her goal to an agent that can migrate within the computational environment and knows how to handle it without being controlled. In brief, mobile agents are active, autonomous, intelligent objects that are able to move between locations in a so-called agent system. Mobile agents must interact with their hosts in order to use their services or to negotiate services with other agents (Song & Li, 2004). Discovering services for mobile agents comes from two considerations. First, the agents possess local knowledge of the network and have a limited functionality, since only agents of limited size and complexity can migrate efficiently in a network and have little overhead. Hence, specific services are required that aim at deploying mobile agents efficiently in the system and the network.

Second, mobile agents are subject to strong security restrictions, which are enforced by the security manager. Thus, mobile agents should find services that help to complete security-critical tasks other than execute code that might jeopardize remote servers. Following this trend, it becomes increasingly important to give agents the ability to find and make use of services that are available in a network (Bettstetter & Renner, 2000).

Some of the mobile agent systems developed in the last few years are Aglets (Lange & Ishima, 1998), Voyager (Recursion Software Inc, 2005), Grasshopper (Baumer et al., 1999), Concordia (Mitsubishi Electric, 1998), and D'Agents (Gray et al., 2000). Research in the area of mobile agents looked at languages that are suitable for mobile agent programming, and languages for agent communication. Much effort was put into security issues, control issues, and design issues. Some state-of-the-art mobile agent systems focus on different aspects of the above issues (e.g., Aglets on security, D'Agents on multi-language support, Grosshopper on the implementation of the FIPA [FIPA, 2002], and MASIF [Milojicic et al., 1998] standard). However, few research groups have paid attention to offering an environment to combine the concept of service discovery and mobile agent paradigm. Most existing mobile agent systems require their programmers to specify agent migration itinerary explicitly. This makes mobile agents weak in their ability to sense their execution environment and to react autonomously to dynamic distributed systems.

In this article, we propose a new service discovery model DSSEM (discovery service via search engine model) for mobile agents. DSSEM is based on a search engine, a global Web search tool with centralized index and fuzzy retrieval. This model especially aims at solving the database service location problem and is integrated with our IMAGO (intelligent mobile agent gliding online) system. The IMAGO system is an infrastructure for mobile agent applications. It includes code for the IMAGO server—a multi-threading logic virtual machine, the IMAGO-Prolog—a Prolog-like programming language extended with a rich API for implementing mobile agent applications, and the IMAGO IDE, a Java-GUI-based program from which users can perform editing, compiling, and invoking an agent application. In our system, mobile agents are used to support applications, and service agents are used to wrap database services. Service providers manually register their services in a service discovery server. A mobile agent locates a specific service by submitting requests to the service discovery server with the description of required services. Web pages are used to advertise services. The design goal of DSSEM is to provide a flexible and efficient service discovery protocol in a mobile agent environment.

The rest of the article is organized as follows. The next section presents a brief background related to this article and discusses the problem of service discovery in mobile agent systems. The section Disvoery Services Via Search Engine Model (DSSEM) introduces DSSEM and compares it with several service discovery protocols (SDPs) currently under development. The comparison criteria include functionality, dependency on operating systems, and platforms. The section titled Service Discovery in the IMAGO system gives an overview of the design of service discovery module and integration with the IMAGO system. Finally, the last section provides some discussion and concluding remarks as well as future work.

BACKGROUND AND MOTIVATION

The general idea of distributed services is that an application may be separated from the resources needed to fulfill a task. These resources are modeled as services, which are independent of the application. Services do not denote software services alone but any entity that can be used by a person, a program, or even another service (Hashman & Knudsen, 2001). Service discov-

ery is a new research area that focuses not just on offering plug-and-play solutions but aims to simplify the use of mobile devices in a network, allowing them to discover services and also to be discovered (Ravi, 2001).

In general, the service usage model is role-based. An entity providing a service that can be utilized by other requesting entities acts as a provider. Conversely, the entity requesting the provision of a service is called a requester. To provide its service, a provider, in turn, can act as a requester, making use of other services. To form a distributed system, requesters and providers live on physically separate hosting devices. Providers from time to time should advertise services by broadcasting to requesters or by registering themselves on third-party servers. From requests' point of view, it must do the following:

- Search and browse for services
- Choose the right service
- Utilize the service

Before a service can be discovered, it should make itself public. This process is called *service advertisement.* The work can be done when services are initialized or every time they change their states via broadcasting to anyone who is listening. A service advertisement should consist of the service identifier plus a simple string saying what the service is or a set of strings for specifications and attributes. An example is given in Table 1.

There are several ways that a client looks up services that it requires. If the client knows the direct address of services, it can make direct requests, or it can listen to broadcasting advertisements and select those that it needs. The common method, however, is that the client forms a description of the desired service and asks a known discovery server if there is any service matching the request.

Table 1. A typical advertisement of service

Identifier: office-printer-4
Type: printer/postscript/HP20
Speed: 24ppm
Color: yes

A variety of service discovery protocols (SDPs) are currently under development by some companies and research groups. The most well-known schemes are Sun's Java-based Jini™ (Sun, 1999), Salutation (Salutation Consortium, 1998), Microsoft's UPP (Universal Plug and Play, 2000), IETF's draft Service Location Protocol (SLP) (Guttman et al., 1999), and OASIS UDDI (OASIS, 2005). Some of these SDPs are extended and applied by several mobile agent systems to solve the service discovery problem. For example, GTA/Agent (Rubinstein & Carlos, 1998) addresses the service location issue by extending SLP, a simple, lightweight protocol for automatic maintenance and advertisement of intranet services. Though SLP provides a flexible and scalable framework for enabling users to access service information about existence, location, and configuration, it only possesses a local function for service discovery and is not scalable up to global Internet domain, because it uses DHCP and multicast instead of a central lookup mechanism. AETHER (Chen, 2000) makes an improvement to Jini by building a dynamic distributed intelligent agent framework. Jini provides a flexible and robust infrastructure for distributed components to find each other on the Internet. However, it relies on the use of standard Java-based interfaces implemented by both clients and servers in their work. This requires existing systems to be modified for use with Jini; however, a significant amount of the production software currently available around the world is unlikely to be modified. After a study of different SDPs and mobile agent systems that are adopting

these methods, we found that several problems cannot be solved easily by the existing protocols due to their limitations.

First of all, most existing works support an attribute-based discovery as well as a simple name lookup to locate a service. Usually, there is only a set of primitive attribute types in the service description, such as string and integer, to characterize a service. Thus, the service discovery process is achieved primarily by type matching, string comparison, or integer comparison. Here, we define a service description as a sequence of flags or codes that can be multicast to service requesters or registered on a third-party server for advertisement purposes. Generally speaking, a service description is composed of two parts: property and access. The property of a service description describes the type, characteristics, constraints, and so forth of a service, which will be published in the service discovery server for advertising purposes. The access of a service is more complicated. It may contain multiple access method tags, as there could be multiple ways to invoke a service (e.g., using the interface of services, downloading the client-proxy code, locating a database, RPC, RMI, or URL location).

For example, Table 2 shows a service description in SLP, where the value of type tag (i.e., service:printer) indicates the property of the service. It also contains some other property tags to describe this resource in detail, such as paper per minute or color support. In the searching phase, much of the power of SLP derives from its ability to allow exact selection of an appropriate service from among many other advertised services with the same tags. This is done by requesting only the service or services that match the required keywords and attribute values specified by requesters. These keywords and attribute values can be combined into boolean expressions via "AND" and "OR" or common comparison operators "<=", ">" or substring matching. Considering the previous example again, the search request from a requester could be "< service:printer, bmw, ((name = lj4050) (page per min.>8)) >".

Table 2. Example of SLP service description

type = service: printer
scope = administrator, bmw
name = lj4050
paper per min. = 9
Color-support = yes
usage = //li4050.com: 1020/queue1

A further step in SDP's development is using eXtensible Markup Language (XML) to describe services. In fact, Web service discovery protocol UDDI, its description language WSDL, as well as the communication protocol SOAP are all based on XML. In addition, an XML description can be converted to a Java document object model (DOM) so that it can be merged into a service registry system. The example in Table 2 can be described in XML as follows:

<description ID="0198">
<type> service: printer </type>
<scope> administration, bmw </scope>
<name> lj4050 </name> .....
<usage> //li4050.com: 1020/queue1 </usage>
</description>

No matter what kind of description format is applied, the lack of rich representation for services has not been changed. The problem arising directly in our project is that these protocols are not adequate to advertise some special services such as database services. A database system already has a well-defined interface, and all a mobile agent requires is a way of finding the location of specific databases and deciding where to move. In this situation, the only way we can accomplish this is by registering the database's name and attributes for future discovery. However, for a database service, people care more about the content of the database than its name or structure. Considering an example of a bookstore, before placing an order

to the bookstore, customers would like to know if the books they require are available in the store by checking the summary of all books with some keywords or a fuzzy search criterion. From this point of view, a simple string identifier or XML identifier cannot meet the requirement.

The second problem is ranking. After requesters have searched all services that may be required, they still need to select the right one for utilization. Just imagine that over the entire Internet, tens of thousands of providers could publish their services by their own will. We should be able to know which ones provide the most realistic and highest quality services that users want. Obviously, moving to the hosts one by one to find out the required information is not a wise choice. Therefore, generating a service rank is essential. However, none of the existing SDPs offers such a mechanism for ranking discovered services. They are satisfied only with finding a service without considering whether the service would be able to serve the requester.

The most significant contribution of our research is that we enrich the service description by using Web page's URL (later the search engine will index the content referenced by this URL) to replace the traditional string-set service description in mobile agent systems. Because of their specific characteristics, such as containing rich media information (text, sound, image, etc.), working with the standard HTTP protocol, and being able to reference each other, Web pages may play a key role as the template of the service description. On the other hand, since the search engine is a mature technology and offers an automated indexing tool that can provide a highly efficient ranking mechanism for the collected information, it is also useful for acting as the directory server in our model. Of course, DSSEM also benefits from previous service discovery research in selected areas but is endowed with a new concept by combining some special features of mobile agents as well as integrating service discovery tools with agent servers.

DISCOVERY SERVICES VIA SEARCH ENGINE MODEL (DSSEM)

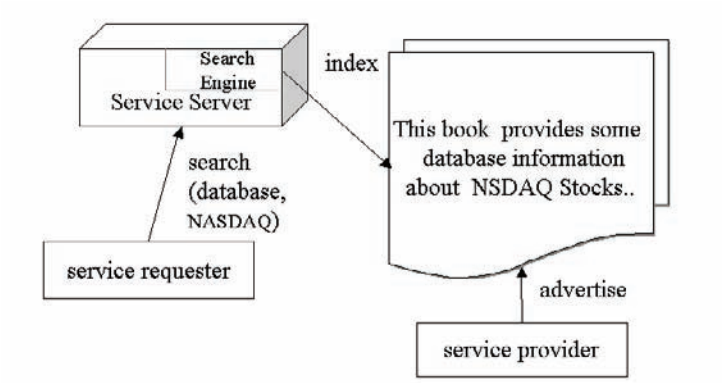
As the most important media type on the Internet today, hypertext Web pages are posted to advertise the information by industries and individuals. Though millions of them are published on the Internet, these Web pages still increase rapidly every day for a variety of reasons. They are spidered and indexed by commercial search engines such as Google, Yahoo!, AltaVista, and so forth. Users easily can find Web pages' locations by submitting the search request to those search engines.

In principle, if we install a lightweight search engine on the service discovery server that can retrieve Web pages posted by service providers and design a Web search interface for the incoming mobile agents, then the problems described previously could be solved in an easy way. In this situation, service providers don't need to register the service description on the service discovery server. Instead, they register the URLs of their Web sites that advertise all the information concerning services. As a middleware on the service discovery server, the search engine periodically will retrieve the document indicated in the URLs and all their referencing documents, parse all the tags and words in the documents, and set up the relationship between the keywords and the host address of these service providers.

On the other hand, mobile agents can utilize the system interface by accessing the search engine's database and obtain a destination itinerary that includes a list of ranked host addresses of the service providers. Based on the previous discussion, Figure 1 shows the service discovery process of DSSEM.

The current version of DSSEM concentrates on the database service discovery. The database service advertisement information can be converted easily to Web page representation. The specific characteristic of a Web page is that it contains rich media information and flexible layout and can reference each other. As an example in Figure 2,

Figure 1. Service discovery process of DSSEM



we find that a two-dimensional database table can be converted into a one-dimensional Web page. Moreover, some binary data stored in the database, such as image, can be extracted from higher-dimensional space to a lower-dimensional space as the text representation in the Web page.

To use Web pages as a medium to advertise services for service providers, we should modify the template in the service description of SLP. The remarkable change is that some properties once represented by strings or XML language now are represented as a Web site's home URL. Table 3 illustrates a service description template of a bookstore example.

The proposed model is similar to SLP and Jini with respect to the service discovery process; however, it extends those protocols by setting up a centralized, seamless, scalable framework on the Internet. Unlike some multicasting services protocols, the centralized service discovery server makes DSSEM service discovery available on the Internet worldwide. The process of registration is similar to UDDI, and the process of discovery is similar to the lookup service in Jini. Besides that, features of mobile agents bring DSSEM other incomparable advantages. First, code mobility is almost impossible in most distributed systems. Therefore, a client must download the resource

Figure 2. Web representation of database

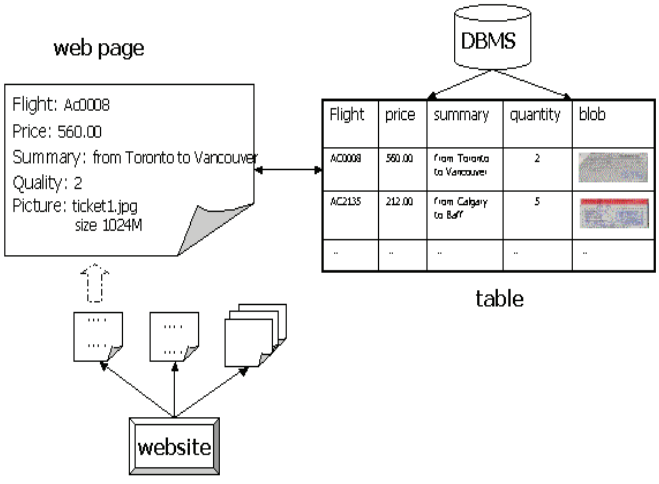


Table 3. An example of service description

type = service: database
name = bookstore
URL = //www.cis.uoguelph.ca/
location(URL)= www.uoguelph.ca
interface = dp_get_set(Handler, 'SQL statement', Result_handler)

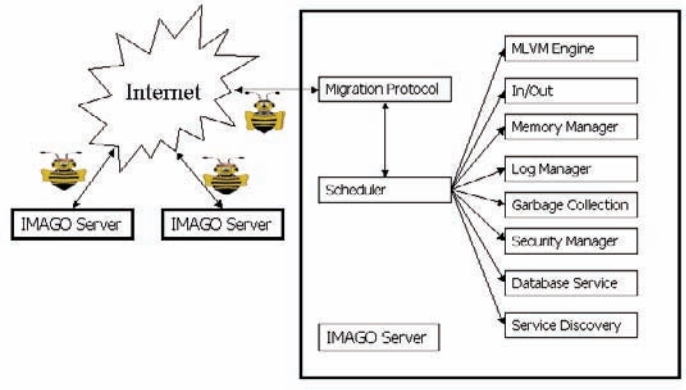
drivers to invoke services. Although RPC or RMI mechanism can help to call services remotely, it might consume tremendous network bandwidth when dealing with services involving a huge amount of data, such as database services. DSSEM goes one step further. It makes agents migrate to the destination hosts and utilize services locally. Second, the security issue is seldom considered in current service discovery protocols. However, a mobile agent server requires a strict security concern for authorization and authentication when it accepts the incoming agents and provides them services for utilization.

SERVICE DISCOVERY IN THE IMAGO SYSTEM

IMAGO is a mobile agent system in which agents are programs written in IMAGO Prolog that can move from one host on the Internet to another. Briefly speaking, an agent is characterized as an entity that is mature (autonomous and self-contained), mobile, and bears the mental model of the programmer (intelligent) (Li, 2001). From an application point of view, the IMAGO system consists of two kinds of agent servers: stationary server and remote server. The stationary server of an application is the home server where the application is invoked. On the other hand, agents of an application are able to migrate to remote servers. Like a Web server, a remote server must have either a well-known name or a name searchable through the service discovery mechanism. Remote servers should provide services for network computing, resource sharing, or interfaces to other Internet servers, such as Web servers, database servers, and so forth.

In fact, an IMAGO server, no matter if it is stationary or remote, is a multithreading logical virtual machine to host agents and provides a protected agent execution environment. The IMAGO system is portable in the sense that its servers run on virtually all Linux boxes with Gnu C compiler and Posix package. Tasks of an IMAGO server include accepting agents, creating a secure run time environment, and supervising agent execution. It also must organize agent migration from or to other hosts, manage communications among agents, authenticate and control access for agent operations, recover agents and the information

Figure 3. The infrastructure of IMAGO system



carried by them in case of network and computer failures, and provide some basic services for the agents, such as database service and discovery service.

The architecture of the IMAGO server is shown in Figure 3. In this architecture, the system modules are configured to deal with different tasks. The core module of the IMAGO server is the scheduler. It maintains an agent list, where each entry on the list matches different stages of the life cycle of an agent, such as creation, execution, memory-related processing (i.e., expansion, contraction, or garbage collection), termination, and migration. The agent list is sorted with respect to system-defined priorities. For example, the highest priority is given to agent migration, followed by agent creation and execution, memory manipulation, and, finally, database service and service discovery.

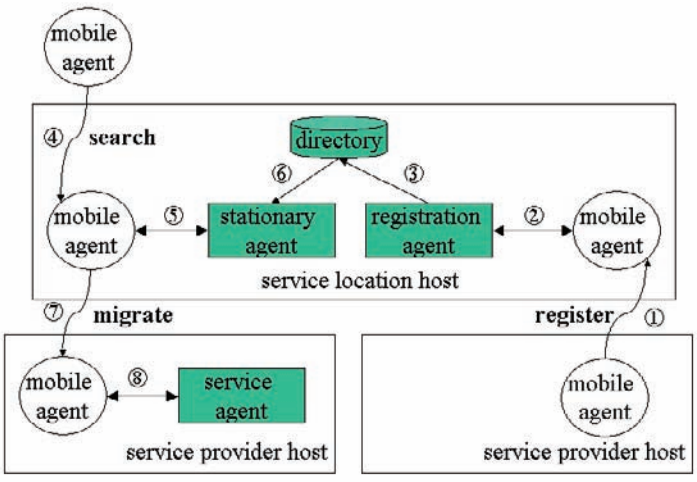
In the early phase of system design, database operation becomes the major service to applications in the IMAGO system. Thus, the problem of service discovery focuses on how to find such services effectively. Once a database server has been found, agents may migrate to that remote server and invoke database access locally through built-in primitives. As an example, the following code shows a typical database access issued by an IMAGO agent:

```
dp_connect(URL, DatabaseName, UserName,
     Password, AccessMode), //connection
dp_get_set(Handler, 'select …..', ResultHandler),
          //data access
dp_disconnect(Handler).        //disconnection
```

Before a database service is advertised, the service provider should fill out a registration form and submit the form to an IMAGO service discovery server. The contents of the form include service type, database name, URL of the service provider host, access mode, HTTP URL of the service Web site, interface function, and the verification information. We chose URL as the host address, since it is compatible with most commonly used Web browsers and independent of address families (i.e., IP, IPv6, and IPX).

To illustrate how DSSEM works, Figure 4 shows the steps involved in the service registration and discovery process in our IMAGO system. A service discovery server is called the service location host. In order to gather useful information, the search engine, IMAGOSearch, should be installed

Figure 4. The processes of Web search module



independently on the service location host. This search engine maintains a special database system designed to index Internet addresses (i.e., URLs, Usenet, Ftp, image locations, etc.). Like traditional search engines, IMAGOSearch consists of three main components: spider, indexer and searcher. They are grouped into two modules, where one module includes spider and indexer, running in the background of a service location host, and the other module is the searcher, running in the foreground to provide discovery services. First, the spider gets the URLs from a URL list that contains initial Web site URLs registered by service providers. The spider then traverses along these URLs in the breadth-first manner and loads the referred hypertext documents into the service discovery server. The salient words of these documents are extracted by the indexer. Some related information such as text also is saved into the database for user retrieval. In addition, the indexer looks for URL anchors that reference other documents and adds them to the URL list. Besides considering the weight of each word in the documents (e.g., a word occurrence in the title should be assigned a higher weight than that which occurs in the body), IMAGOSearch also pays attention to positions of each word and its relative distance during ranking. The ranking algorithm we use is called the shortest-substring ranking (Charles et al., 2000), which offers a simple way to weight each Web page based on a search criteria and total them up to form Web site ranking. The searcher behaves as a bridge between the IMAGO server and the search engine. It is responsible for accepting the search requests from mobile agents, querying the database, ranking search results, and, finally, returning a destination itinerary.

The application programming interface for mobile agents is a built-in predicate; namely, Web_*search(query, number, Result)*, where *query* is a compound term, such as *locate("tsx", "stock transaction", "imago server"), number* is an integer indicating the maximum number of results expected, and *Result* is a variable to hold the returned values. When an agent issues a Web_search(…) predicate, the agent is blocked, and control is transferred to the service discovery module of the hosting IMAGO server. This module will communicate with the searcher, wait for search results, and resume the execution of the blocked agent. Search results will be delivered to the agent in the form of a list, where list entries are ranked in terms of priorities from high to low.

Table 4. Comparison of different SDPs

Feature	SLP	Jini	Salutation	UPnP	DSSEM
Network transport	TCP/IP	Independent	Independent	TCP/IP	SITP
Programming language	Independent	Java	Independent	Independent	Independent
OS and platform	Dependent	Independent	Dependent	Dependent	Dependant
Code mobility	No	On demand	No	No	Yes
Srv attributes searchable	Yes	Yes	Yes	No	Yes
Leasing concept	Yes	Yes	No	Yes	Yes
Event notification	No	Remote event	Periodic and automatic	Publish events	No
Security	No	Java-based	Authentication	No	Strict
Service Description and Scope	Service type and attribute matching	Interface type and attribute matching	Functional units and attributes within it	Description in XML	Web page description and fuzzy matching

DISCUSSION AND CONCLUSION

In this article, we have discussed the design of a service discovery protocol—DSSEM—and its implementation in the IMAGO system. Table 4 summarizes the main features of selected protocols compared with DSSEM. From an implementation point of view, the most critical issue about the performance of a search engine is the quality of search results. However, we cannot make a comparison with other major commercial search engines, since they are operating at different levels. Thus, user evaluation is beyond the scope of this article. In order to show that our search engine does return useful information, Table 5 gives the experimental results for a query using the keywords *imago lab*. The results show that all server URLs have come from reasonably high-quality Web sites, and, at last check, none were broken links. An R_w value is calculated according to word occurrence, weight, and a factor value measuring the distance of keywords by a ranking algorithm (Charles et al., 2000). We define the result that has the highest R_w value as the highest priority and assign it a 100% rate; therefore, the percentage of other results are rated relatively. Of course, a true test of the quality of a search engine would involve extensive experiments, analysis, and user evaluation, which is part of our future work.

Aside from the search quality, IMAGOSearch is designed to scale up cost effectively, as the sizes of Web pages grow. Because IMAGOSearch only indexes Web servers registered by IMAGO Server users, we do not need to worry about indexed pages exceeding the maximum size of the database. One endeavor that we are undertaking is to reduce the table redundancy and to use the storage efficiently. Our experiment shows that indexing 22,000 different documents consumes only 140Mb disk space. The search time is dominated mostly by the performance of CPU, disk I/O, and the underlying database system.

When a mobile agent wants to locate certain services, it first must move to the service discovery server and then make a local query and migrate to the destination hosts after obtaining the itinerary. This brings us to the problem that, as a central unit, the service discovery server might become a bottleneck, especially when it is handling thousands of Web pages every day and simultaneously hosting as many incoming mobile agents as possible. A possible solution is to duplicate service discovery servers. Replicas not only make the service discovery mechanism very efficient but also increase the ability of fault tolerance.

The results of our work are encouraging, and further studies in this field are being planned. First, the current implementation of search engine deals with only the AND logical relationship between search strings; it could be enhanced to parse some complex search criteria that combine keywords with boolean expressions (AND, OR) and conditional expressions (<=, >=, substring match, etc.). Second, since a database contains multidimensional information, how to reflect dimensional relationship by a flat Web page is a big challenge. A possible way to address this issue is to use XML metadata to describe the database dimension.

Table 5. Search results for imago lab keyword

draco.cis.uoguelph.ca	R_w= 13.8 100%
www.cis.uoguelph.ca	R_w = 10.65 77%
www.uoguelph.ca	R_w= 4.6 33%
www.cas.mcmaster.ca	R_w= 4.23 30.6%

ACKNOWLEDGMENT

We would like to express our appreciation to the Natural Science and Engineering Council of Canada for supporting this research.

INTRODUCTION

Owing to the rapid development of mobile technology over the past few decades, there have been many different kinds of mobile devices emerging in the market, and most of them work with databases seamlessly. Mobile phone gaming, downloading of ringtones, and e-calendaring are some of the prominent examples of mobile applications that require the close integration of mobile devices with databases. Mobile devices take various forms and configurations. The packaging, form factors, hardware platforms, operating system support, and functional capabilities vary across these devices. There are, however, many common attributes shared by the devices, such as notebook computers, pen-based computers, handheld computers, and the like, all of which are used in mobile computing. These devices can be categorized into the following categories according to their functionalities and features, as detailed in Dhawan (1997). They are:

- notebook computers
- personal digital assistants
- tablet computers
- hybrid mobile devices
- mobile phones

In this article, we focus on personal digital assistants (PDA) and mobile phones as they are the most popular and commonly used mobile devices in the industry.

Mobile Computing Applications

Mobile applications include basic applications like datebook, address book, to-do list, and memos and also horizontal and vertical industry applications that mainly fall into the following three categories (Dhawan, 1997):

- Shrink-wrapped horizontal industry mobile computing applications that can be used in broad segments of various industries, e.g., electronic mail, electronic messaging via paging, and sales force automation.
- Generic horizontal industry applications requiring extensive customization, and these include database access from an information server, computer-aided dispatch (CAD), and intrasite and intersite mobility applications among others.
- Vertical industry applications include the applications that are specific to industries like insurance, banking, airlines, government, utilities, and transportation, e.g., finance industry insurance and financial planning, and stock trading.

The diverse variety of the types of mobile applications demonstrates the reach of mobile computing into almost every facet of personal and business life. One of the applications that is gaining popularity is mobile e-commerce. Mobile e-commerce refers to commercial activities performed electronically. An example of this is an online shopping mall (via the mobile devices to the Internet). Mobile commerce is one of the most popular applications these days in addition to obtaining stock quotes, directions, weather forecasts, and airline flight schedules from mobile devices (Munusamy & Hiew, 2004).

Comparison Between Mobile Devices and Desktop Computers

Compared to desktop computers, mobile devices have small memory, low computing capabilities, limited interaction facilities, and limited display and network processing capabilities. With recent technological advancements, hybrid devices combining the functionality of mobile phones together with PDAs have been developed. The differences are mainly attributed to their hardware design and system configurations. Table 1 compares desktop computers, PDAs, and mobile phones with respect to their processing power, memory, storage capacity, connection speed, and display. The data presented is current as of June 22, 2004. Data related to specifications for the desktop, PDA, and mobile phone have been downloaded from the Web sites of Dell Inc. and Nokia Inc. and relate to the Dell Dimension 8400 Desktop, the Dell Axim X3 Pocket PC 400 MHz WiFi, and the Nokia 7610, respectively.

From Table 1, it can be observed that mobile devices have smaller memory size and storage capacity as well as display size than desktop computers. So, the amount of data that can be transferred and displayed at a time is less than that of desktop computers. Furthermore, the processing power of mobile devices is usually limited when compared with desktop computers. The amount of data that can be processed at a given time is also small. Also, mobile devices have lower connection speeds and less stable network connections. They must have ways to overcome these deficiencies in order to ensure good performance in retrieving data from remote databases.

Challenges for Mobile Devices

Some of the challenges faced by mobile devices when connecting to remote databases include challenges in network connectivity, data transmission, security, and data consistency.

Table 1. Comparison between a desktop computer and mobile devices

	Desktop	PDA	Mobile Phone
Processing Power	2.8–3.4 GHz	400 MHz	Unknown
Memory	512 MB–2 MB	64–1024 MB	8 MB (internal)
Storage Capacity	80–400 GB	N/A	N/A
Connection Speed	56 Kbps–100 Mbps	56 Kbps–11 Mbps	Up to 40.3 Kbps
Display	15–19 inch	3.5 inch	1.3 inch

- **Network connectivity:** Mobile devices usually work in an unstable network environment. The network stability is affected by many factors, such as weak signal and strong interference. Without physical network connections, mobile devices often lose connection with the network.
- **Data transmission:** Wireless networks have limited bandwidth compared to traditional cable networks. The slow transmission speed imposes problems in uploading and downloading data. Large network latency constraints also result in long response time.
- **Security:** Any message between the database system and mobile devices is sent over the air, and it is possible for hackers to sniff the message and perform eavesdropping. Advanced encryption and user authentication technology is needed to prevent any such types of hacking activities.
- **Data consistency:** Database applications apply extensive caching and replication to boost performance, which can lead to possible data inconsistency. Mobile devices with little memory storage and slow connection speed cannot obtain all the information from the central database system instantly. The narrow bandwidth of the devices also affects immediate updates from the mobile devices to the database server. It is thus quite difficult to keep data consistent between mobile devices and the database server.

The objective of this article is to give a brief overview on the design of databases for mobile applications and to describe how the database design is currently being done for a successful mobile application called mBroker that is operational in Hong Kong. The article provides a description of the functionalities of the mBroker system and highlights the database design being used by the mBroker solution at the present time.

BACKGROUND

The database design for mobile applications is different from normal database applications running on personal computers. Due to the limited hardware configurations and network settings of mobile devices, database vendors usually provide special database systems and APIs (application programming interfaces) tailored for mobile devices.

Database manufacturers like Oracle, IBM, and Sybase usually follow a similar architecture to build mobile database applications. The main components include a micro database engine, synchronization middleware, and wireless networking. The difference is often the naming of different components. Figure 1 depicts the typical database architecture for mobile applications.

Micro Database Engine

Mobile devices have limited hardware in terms of processing power, memory size, and battery life. A normal database engine requires a minimum 20 MB memory to operate, which is unavailable for mobile devices. Therefore, database vendors develop robust micro database engines for most mobile devices.

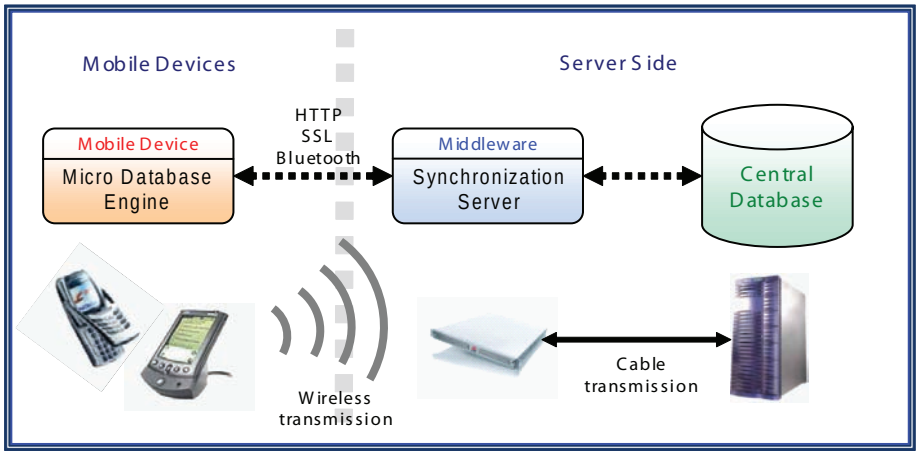
Micro database engines only focus on the most frequently used functionalities which are relevant to mobile applications. These include basic SQL statements, Join, Group By, Order By, scrollable cursors, and simple primary key and foreign key operations. For high-end mobile devices, advanced indexing features are sometimes included to improve performance. Database operations which are rare and less useful are removed from the micro engine. For example, view creation, subqueries, stored procedures, triggers, and user-defined functions are not provided in micro database engines. The DB2 Everyplace and Oracle Lite (Viellard, 2001) are examples of micro database engines.

Synchronization Middleware

The network capabilities of mobile devices are limited. Real-time online database access requires a large and stable network bandwidth, which is expensive and not always required for mobile applications. Thus, database vendors employ extensive caching and synchronization techniques in mobile database applications. Caching is to preload data to the devices for offline browsing. Users can then browse data seamlessly even if the wireless network is unstable or even unavailable. If instant update to the central server is not necessary, data modification operations are further optimized. Updates are made to the data on the devices first, and the modifications are not reflected on the server database immediately. Data are updated to the remote central database later by synchronization.

Synchronization is done by middleware which is sometimes called a synchronization server or mobile server. Advanced synchronization methods keep data in both mobile devices and the cen-

Figure 1. A typical database architecture for mobile applications



tral database consistent. The middleware acts as a middleman between the mobile devices and the central database. It collects changes in the mobile devices and executes appropriate SQL statements to update the central database. At the same time, the middleware also propagates updates in the central database to the mobile devices.

Wireless Networking

Different types of mobile devices communicate using different network protocols. Database vendors usually include a number of network protocol supports in their products, for example, GSM, IEEE 802.11, and Bluetooth.

Security

To overcome the security problems of mobile database applications such as eavesdropping, the mobile database architecture needs to support both username/password authentication and encrypted communication based on the Secure Sockets Layer (SSL) protocol and other popular encryption algorithms.

In spite of the well designed architectural model, there still exist a number of limitations in the integration of the databases with mobile devices.

Literature Review

Previous research related to database design for mobile applications has involved various mechanisms for avoiding compromise in the performance of the database due to the use of the wireless network. Some of the techniques used involve reducing the number of data exchanged over the wireless network and providing a data cache on the mobile host (Chan, Si, & Leong, 1998). To address the challenges related to maintenance of data consistency for mobile data access, several techniques have been suggested in the literature. These have ranged from transaction management (Mazumdar & Chrysanthis, 1999) and concurrency control for mobile databases (Prabhu, Ray, & Yang, 2004) to replication of mobile databases which are allocated on the fixed network (Budiarto, Harumoto, Tsukamoto, Nishio, & Takine, 1998). It is argued in Budiarto, Nishio, and Tsukamoto (2002) that without replication, mobile databases have a very low availability, and it is shown using simulation that the performance of replication strategies depends on various factors such as network size, mobility, access ratio, and access concentration. Another important issue for mobile databases is how to provide consistent results for location-specific continuous queries, the likes of which may be encountered when navigating road maps using mobile devices. In Gok and Ulusoy (2000), several approaches are compared in terms of relative performance for providing answers to location-dependent queries from mobile users. An analytical model based on the idle replacement policy is described by Hung, Lin, Peng, and Yang (2001) to solve the problem of overflows of visitor location registers for mobile databases. For a detailed discussion on the various issues related to database design for mobile databases with respect to factors such as mobile location data management, transaction processing and broadcast, cache management and replication, query processing, and mobile Web services, the interested reader may refer to Barbara (1999), Madria, Mohania, Bhowmick, and Bhargava (2002), and Yang, Bouguettaya, Medjahed, Long, and He (2003).

MAIN THRUST

Sixteen Hong Kong brokerage firms are currently improving their productivity and customer satisfaction levels by using the "mBroker" solution offered jointly by Heracle Technologies Limited and Hutchison Telecom, built on the Palm OS platform for Palm handhelds (Lai, Tam, & Lemaitre, 2004). The mBroker solution provides a

secure trading platform to remotely access stock information in real time and to conduct stock trading activities.

Problem Description

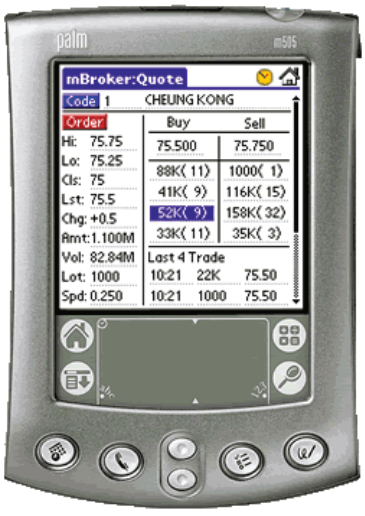
It is time-consuming and labor-intensive for investors to rely on desktop computers or consult brokerage agents to obtain the latest stock quotes or the trading history of any particular stock index, as well as to place an order. Mistakes such as overlooked orders, data entry errors, or delays due to congested telephone lines often occur when dealing with an agent.

It is critical to guarantee high speed and accuracy for this type of situation. Speeding up the order processing and accessing real-time information without compromising accuracy are goals that all brokers strive for to retain their competitive edge.

The mBroker Solution

mBroker—an innovative, secure, and cost-effective wireless stock trading system with specific design for PDA stock trading—allows PDA users to get stock quotes and trade stocks at any time in any place in the world. More importantly, it is totally secure as it uses the "Hongkong Post Mobile e-Cert" and also Oracle8i. With mBroker, investors can place an order remotely via an intuitive touch screen interface of Palm handhelds, without the need to contact the agent.

Figure 2. Application interface of mBroker on a PDA device



Functionalities of mBroker

There are a diverse range of services related to stock trading activities provided by mBroker on Palm. These include:

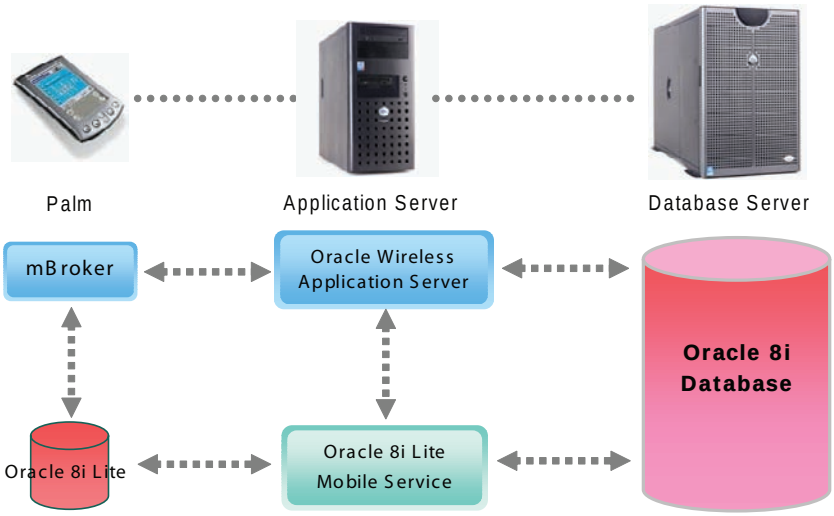
- Place, modify, and cancel orders.
- Access real-time stock quotes.
- Keep track of the Hang Seng Index.
- View order status and transaction history.

The mBroker application can be run on Palm OS 3.5 or above and only occupies approximately 190 Kb of memory space. What makes this solution attractive is the minimal deployment cost. Since there is no special software or hardware requirements for participating brokerage firms, their customers can enjoy the service simply by subscribing to the mBroker service. The user interface is very user-friendly since it has a similar look and feel to any other Palm application. Both English and Chinese versions of this software are available to the users.

Architecture of mBroker

Figure 3 shows a simplified view of the mBroker application and the database system architecture. The Oracle database stores stock information and statistics. The stock data includes stock codes, stock names, and stock prices. In order to help the investors in making investment decisions, the database also stores information such as past selling prices of the stock, the high/low price information, and transaction volume statistics.

Figure 3. A simplified view of the architecture of mBroker



A subset of this information is loaded onto the Palm for fast offline browsing.

Transaction details are also required for order tracking and enquiry. Therefore, all the transaction details are logged in the Palm and the central database. These include the broker ID, status, stock type, price, quantity, transaction timestamp, etc.

The mBroker application follows an architecture that is similar to that discussed earlier. The stock and transaction information is originally stored in a central Oracle 8i database server. When a mobile device with mBroker wants to retrieve stock quotes from the central database server, it will send requests to a middleware named Oracle Lite Mobile Service in order to subscribe to the information (Viellard, 2001). This middleware is installed in a server machine and acts as a middleman between different mobile devices and the central database server. It obtains the required information from the database server and sends it back to the mobile devices. The middleware is responsible for synchronization, keeping the mobile devices informed of any changes on the database server. When the user buys or sells stock via mBroker, requests are sent from the mobile devices to the middleware. The middleware then updates the central database accordingly. The middleware is capable of receiving thousands of requests at the same time and decides the sequence of processing the transaction requests following predefined business rules written in PL/SQL.

Choice of Database

Heracle Technologies Limited chose to use Oracle8i as the central component because of mobile service provided by Oracle8i Lite. Oracle8i Lite is accessed by users through the application server and provides the necessary workspace for end users to request context switching between online and offline modes. It also automatically initiates the necessary two-way replication of data and applications between server and client, depending on changes of mode. When it comes to stock order transactions, it is imperative to ensure a maximum level of security. Not all proprietary databases, e.g., DB2, can support a public key infrastructure (PKI; Browder, 2002); Oracle8i supports PKI and therefore this was the obvious choice for mBroker.

Security of mBroker

To ensure the security of the stock order information (OI), the OI is encrypted using the PIN input and sent to Hongkong Post's Certification Authority server for authentication. All transaction details are secured by Hongkong Post Mobile e-Cert, secured by PKI technology. The Mobile e-Cert can be obtained from Hutchison Telecom, the world's first certified Registration Authority for the issuance of Mobile e-Cert. A high security solution ECC163 cryptography is adopted. Upon verification, the order is allowed to pass through the Order Routing System gateway of Hong Kong Exchanges and Clearing Limited (HKEx) to the designated brokerage firm's system for subsequent processing. Once the transaction is completed, a confirmation note with a transaction reference number is sent back to the user's mBroker interface.

Disaster Recovery in mBroker

Oracle8i database has a component called Data Guard, which offers the most complete and robust disaster recovery solution and high availability through the use of a transactionally consistent standby database. The Data Guard automates the complex tasks of disaster recovery and provides monitoring, alerting, and control mechanisms to maintain a standby operation. Moreover, Data Guard reduces planned downtime by utilizing the standby server for maintenance and routine operations in addition to reporting.

Current Performance of mBroker

mBroker takes less than six seconds on average to complete an order via a handheld, whereas the user takes approximately one minute to complete the same using a phone call. The issue of wireless security is addressed by the introduction of user/server authentication and digital signatures. As a result, an automated, speedy order placement in a highly secured wireless environment is ensured.

FUTURE TRENDS

In view of the issues discussed so far it is obvious that there are many areas which need to be improved. In the future, the goal is to provide the following functionalities for mBroker (Huntsman, 2003):

- Providing intelligent roaming capabilities to enable users to work without interruption, even when network connections are disrupted.
- Exploiting multiple network interfaces in a single device or being able to select the fastest or least costly connection.
- Successfully synchronizing databases by caching contents to local devices through asynchronous connections.
- Allowing portability to a range of devices.
- Conserving power at the operating system level and maximizing performance.

CONCLUSION

In this article we have provided a brief background on the use of databases for mobile applications. This is a growing area and is facing a number of challenges at this time. The database design for mobile applications is also discussed in this article . We have also discussed a successful mobile application called mBroker which is currently in use in Hong Kong. Another similar example is the new mobile workforce effectiveness solution called SMARTselling, developed by Eleven Technology and powered by SQL Anywhere Studio from iAnywhere Solutions. This technology is currently being used by Pepsi Bottling Group and by Proctor and Gamble. This software helps in automated order entry and runs on a small

handheld device that communicates wirelessly with back-office systems. With the help of this application, tedious, error-prone, and costly paper-based processes can be eliminated, and the time spent on checking inventories and shelf displays can be significantly reduced. It is hoped that in the future more mobile applications like mBroker and SMARTselling will be developed, which will affect the various facets of everyday life for people around the globe.

KEY TERMS

Bluetooth: A wireless technology developed by Ericsson, Intel, Nokia, and Toshiba that specifies how mobile phones, computers, and PDAs interconnect with each other, with computers, and with office or home phones. The technology enables data connections between electronic devices in the 2.4 GHz range. Bluetooth can replace cable or infrared connections for such devices.

Caching: The technique of copying data from a server machine (the central storage place) to a client machine's local disk or memory; users then access the copy locally. Caching reduces network load because the data does not have to be fetched across the network more than once (unless the central copy changes).

Database Synchronization: When a database is being synchronized, no new update transactions are allowed, and all open update transactions are finished. After that, all updated blocks are written to disk.

Horizontal Industry Applications: A horizontal industry is one that aims to produce a wide range of goods and services. Horizontal industry applications are utilized across many different industries. While the core part of the application does not require changes, an organization needs customization at the front end or at the back end. Database access and service representative dispatch are typical examples of these applications.

IEEE 802.11: 802.11 refers to a family of specifications developed by the IEEE for wireless LAN technology. 802.11 specifies an over-the-air interface between a wireless client and a base station or between two wireless clients. The IEEE accepted the specification in 1997.

Load Balancing: It is the method of distributing system load evenly across server machines by placing identical copies of frequently accessed information among available server machines.

Middleware: This software manages the communication between a client program and a database. For example, a Web server connected to a database can be considered middleware as the Web server sits between the client program (a Web browser) and a database. The middleware allows the database to be changed without necessarily affecting the client and vice versa.

Mobile Application: A mobile application is any application that can be used on the move. It may or may not be wireless. It must be tailored to the characteristics of the device that it runs on. Limited resources, low network bandwidth, and intermittent connectivity are all important factors that affect the design of these applications.

Mobile Device: A mobile device is anything that can be used on the move, ranging from laptops to mobile phones. As long as the location is not fixed, it is considered mobile. Areas that are not included in the definition of mobile include remote offices, home offices, or home appliances.

Public Key Infrastructure (PKI): A system that enables users of a public network to exchange data securely and privately through the use of a public and private cryptographic key pair, which is obtained and shared through a trusted authority. It provides for a digital certificate that can identify an individual or an organization and director services that can store and, when necessary, revoke the certificates. The comprehensive architecture includes key management,

the registration authority, certificate authority, and various administrative tool sets.

Replication: The process of creating read-only copies of any data. Replication is supported by the security, directory, and file services in a distributed computing environment. Replication can improve availability and load balancing.

Secure Sockets Layer (SSL): SSL is a transaction security standard developed by Netscape Communications to enable commercial transactions to take place over the Internet. It's one of a few competing security standards.

Vertical Industry Applications: A vertical industry is one that is focused on a relatively narrow range of goods and services. Vertical industry applications are specific to certain industries. Usually there are some characteristics of the business processes unique to a particular industry that make certain applications very specific for that particular industry. As a result, some vendors develop turnkey software solutions for their own use.

Chapter 3.10
A Virtual Community for Mobile Agents

Sheng-Uei Guan

Fangming Zhu
National University of Singapore, Singapore

INTRODUCTION

Electronic commerce (e-commerce) is booming with the increasing accessibility of the Internet. E-commerce is revolutionizing the concept of carrying out business functions. By using a Web browser, buyers are able to access numerous e-commerce Web sites, where they can make purchases within a reasonable price range. Suppliers realize that e-commerce is essential to the success and competitiveness of their businesses. The benefits of conducting business online include reduction of the cost for many transactions and streamlining of operations.

However, there are also some obstacles to the success of e-commerce. Firstly, buyers may be lost in the ocean of the items available. Secondly, it is a tedious task to search for a specific product through the Internet and it is difficult to bargain within the current infrastructure. Thirdly, some transactions are so complicated that they are too difficult to be dealt with. For instance, merchants often negotiate transactions with multiple issues of concern such as price, quantity, and method of delivery. Many strategies are adopted to accomplish these tasks, and both the negotiating counterparts and the environment can affect the choice of the strategies. However, in many existing auction Web sites, price is the main focus for both bidders and sellers. Bidders and sellers are seldom given a chance to negotiate the other issues, and many commercial opportunities are neglected.

This chapter discusses SAFER for e-commerce (secure agent fabrication, evolution & roaming for e-commerce), which uses secure agents to alleviate problems in e-commerce

BACKGROUND

Software agents have demonstrated potential in conducting transactional tasks in e-commerce through the Internet. It acts on behalf of an entity to carry out a delegated task. One of the earliest agents in e-commerce is the shopping agent, which carries out automatic comparative price shopping on the Web. A client can assign one or many shopping agents to carry out the shopping task. Agents can gather price information and present it to the client for a decision. Certainly, the task of a software agent involves more than online data gathering and filtering. For example, software agents are also used in negotiation (Guttman & Maes, 1998; Krishna & Ramesh, 1998). Negotiation agents are instructed with expected prices, quantities, delivery modes, and/or negotiation strategies (Oliver, 1996; Kang, 1998). Besides, software agents can also undertake other tasks, such as payment (Guan & Hua, 2003; Guan et al., 2004), mediation, distribution, interaction and sales promotion in e-commerce.

Software agents (Bradshaw, 1997; Poh & Guan, 2000; Wang et al., 2002; Guan & Zhu, 2002; 2004; Guan et al., 2004) can be endowed with attributes such as mobility, intelligence and autonomy. To alleviate concerns such as authorization, traceability, integrity, and security in e-commerce and the Internet, constructing appropriate architecture for agent systems in e-commerce is a fundamental consideration in facilitating agent-based transactions (Lee, 1997; Guan & Yang, 2004). As software agents become more common, there is a need for skilled programmers and even ordinary e-commerce clients to manipulate them. A practical way is to provide sites with methods to fabricate various agents according to the requirements of the clients. Agents should have an evolutional ability to enhance its intelligence and survivability. Roaming is one of the basic capabilities for agents so that they can fully utilize the power of network computing. They can achieve timesaving and cost cutting in completing its task without compromising security by roaming from one host to another (Yang & Guan, 2000; Guan & Yang, 2002).

THE SAFER ARCHITECTURE

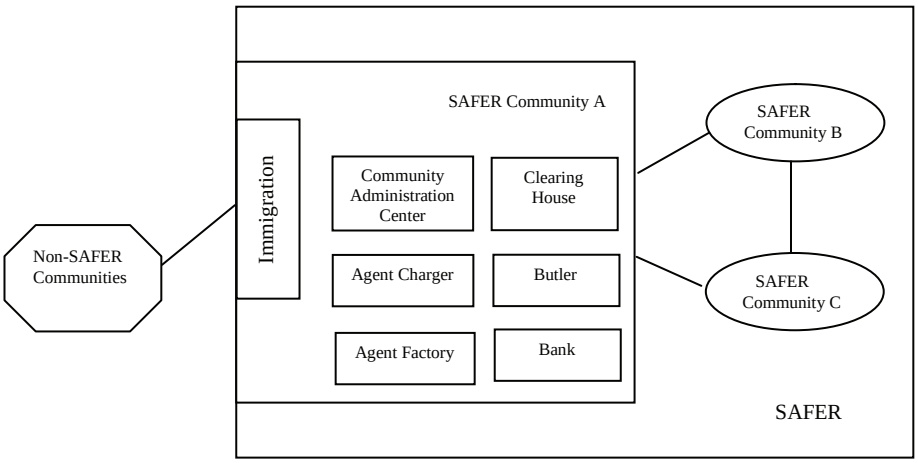
SAFER is an infrastructure to serve agents in e-commerce and establish the necessary mechanisms to manipulate them. The goal of SAFER is to recommend standard, dynamic and evolutionary agent systems for e-commerce. The SAFER architecture comprises different communities as described in Figure 1. Each community consists of the following components: owner, butler, agent, agent factory, community administration center, agent charger, agent immigration, clearing house and bank. Each component will be elaborated in the following subsections.

Community

Agents can be grouped into many communities based on certain criteria. In order to distinguish agents in the SAFER architecture from those that are not, we divide them into SAFER communities and non-SAFER communities as shown in Figure 1. We shall only discuss the SAFER community. Each SAFER community can possess a set of the facilities and individuals as described in Figure 2. Figure 2 only lists the necessary components in one community. Some community may have more entities than those depicted in the figure. For instance, there can be two agent chargers in a large community.

In order to become a SAFER community member, an applicant should apply to his local community administration center. The center will issue a certification to the applicant whenever it accepts the application. A digital certificate will be issued to prove the certified status of the applicant. To decide whether a facility or individual belongs to a community, one can look up the roster in the community administration center. A

Figure 1. SAFER architecture (1)



registered agent in one community may migrate into another community. In addition to permanent residence in a community, an agent can carry out its tasks in a foreign community. For agents to visit a foreign community, they must register in the foreign community administration center as guests. When an agent roams from one SAFER community to another, it will be checked by a trusted machine—agent immigration (Guan et al., 2003) with regard to its authorization and security before it can perform any action in this community.

Agent community is the basic unit in SAFER e-commerce. It offers factories and evolution vehicles to streamline e-commerce agents. Under these organized communities, agents can be regulated in a tidy order and perform their tasks more efficiently. The tighter structure also provides a solid base for enhancing the security of agents, which is one of the most important concerns in agent-based e-commerce systems.

Owner

Agent owners stand at the top of the SAFER architecture's hierarchy. They are the real users during the transactions and agents are acting on behalf of them. An owner has the priority and responsibility for all his agents. An owner controls his agents from creation to termination. An owner can request an agent factory (Guan et al., 2004) to fabricate agents responsible for specific e-commerce activities. Sometimes an owner needs to initiate important decisions of a transaction so that his agent can complete its tasks. For instance, negotiation agents need to request the final agreement from its owner before it can sign the contract. Each owner should register in the community administration center before he can have access to the facilities in the community. To relieve his burden, an owner can authorize a butler to handle most of his tasks.

Butler

An agent butler assists its agent owner in coordinating agents for him. In the absence of the agent owner, an agent butler will, depending on the authorization given, make decisions on behalf of the agent owner.

As agents are dispatched for certain missions, the agent owner will issue authorization to them. These authorizations may include the amount of credit an agent is allowed to spend, the range of host this agent is allowed to roam and others.

One function of the agent butler is to make payments when an agent is involved in any transaction with external parties. For example, suppose the agent owner authorizes the agent butler to handle transactions involving less than one hundred dollars. When one of the agents reaches an agreement to buy a book from Amazon.com and requests the payment from the agent butler, the agent butler can immediately issue the payment without further consulting the agent owner. The agents require the presence of agent butler in any transaction because in the SAFER architecture it is not given any capability to make payments. If the agent is allowed to make payments without consulting its owner, it will have to carry certain cash credit with it. The cash credit may be compromised in an event of agent abduction.

In addition, an agent butler also keeps track of the agent's activities and its location. For example, an information-gathering agent will send information like sites visited and information collected back to the agent butler. With this information, the agent butler may ensure that the other agents do not visit the sites again.

Another function of agent butlers is to act as receptionists in agent roaming (Yang & Guan, 2000). It services both the incoming and outgoing agents as well as coordinating agent transport.

Agent

Agent plays an active role in SAFER e-commerce. It is agent that brings to life the promising aspects in the next generation of e-commerce. All the facilities in the SAFER architecture serve agents in one way or another. Each agent has a unique identification and belongs to one specified owner. To identify itself, an agent should have a digital certificate issued by its creator. According to the tasks assigned by the owner, we can classify agents into many categories, such as negotiation agents, payment agents, mediation agents, and so on.

As an agent acts on behalf of its owner, it should have certain degree of intelligence. For example, it accepts the owner's assignment and carries out the task delegated to it. Agents have the mobility to travel through the Internet. Mobile agents can carry important information when they are roaming through the network to complete transactions. It should be immune from attacks from hackers or malicious agents. Security is thus the most crucial issue in agent roaming as well as other activities in e-commerce.

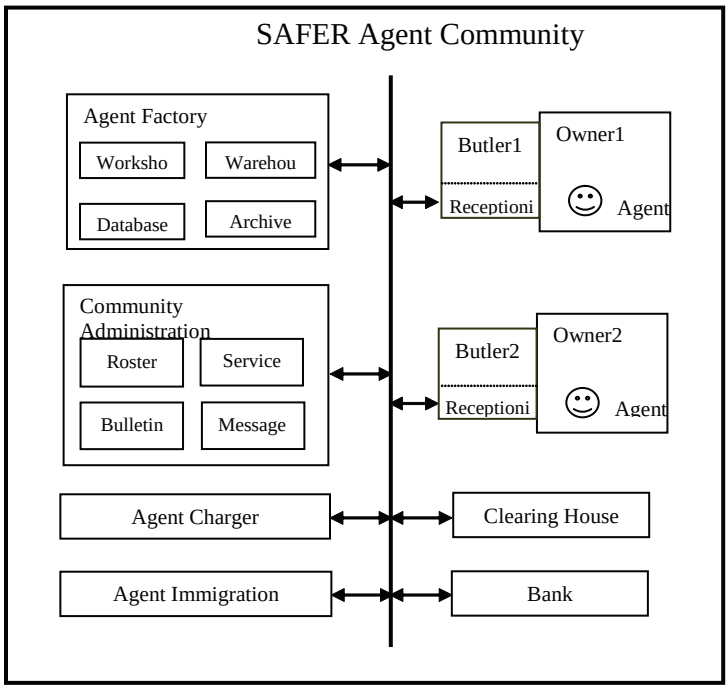
Agent Factory

Agent factory is the kernel of SAFER, as it undertakes the primary task of "creating" agents. In addition, agent factory has the responsibility to fix and check agents, which is an indispensable function in agent evolution and security.

As illustrated in Figure 2, an agent factory consists of four components, namely, workshop, warehouse, database and archive. Workshop is the site where an agent is fabricated, fixed, and checked. Database includes various ontology structures and standard modules to assemble different agents in the workshop. Archive is the set of the factory logs and information of agents that have undergone certain processes in the agent factory.

An agent factory provides an interface, such as choices of fabrication or repair instructions for owners (or butlers), to customize agents with desirable functionality. After the owner specifies the parameters and information, the agent factory starts to assemble or update the agent using the ontology structures and standard modules in the database. The agent factory also undertakes the liability to check the fitness and integrity of the agents in the community, which is essential to the evolution procedures and security protection of the agents. Any work done by the agent factory is recorded in the archive for later references.

Figure 2. SAFER architecture (2)



Community Administration Center

The community administration center is responsible for administrative matters in the community. It has the privileges of coordinating and facilitating the activities of all the entities in the community. Its aims are to assure the smooth running of routine operations and security of the whole community.

The administration center has a roster of the community, which includes basic data on the registered facilities, owners, agents and guest agents from other communities. This roster is updated periodically. When an agent factory has fabricated a new agent, it will inform the center to add the new item. When an agent is terminated, it should also be reflected in the roster. In addition, the center does a thorough routine examination of all components in the community and updates the roster periodically. If a foreign agent wants to enter this community for some purposes, it should request a "visa" from the agent immigration and the agent immigration will forward the registration to the administration center. For these reasons, the center is well aware of any incoming agents and events happening in it so that it is well guarded from any intruder.

Agent Charger

The agent charger is a trusted machine deployed to ensure agent integrity in SAFER. Since SAFER is designed for e-commerce, roaming agents must be protected from malicious attacks. One important aspect of agent protection is agent integrity. Roaming agents must not be interfered with during roaming or its execution at the remote host. The protection of agent integrity (both code integrity and data integrity) during roaming operation has been addressed in Yang and Guan (2000). In order to protect agent integrity during an agent's execution at a remote host, the concept of "agent battery" is now introduced.

Before explaining agent battery, the concept of "agent action" will first be defined. Agent action is any activity involving an agent with one or more third parties that may cause dispute or damage to another party. Typical agent actions include agent roaming, agent negotiation, and execution of transactions. Without the ability to perform "actions," an agent will be disabled like an electric toy car out of battery. Agent battery refers to a battery carried by each agent that specifies the number of "actions" it can perform. The agent battery decreases its energy level (i.e., number of "actions") by one each time before an action is executed. If the level reaches zero, the agent is not allowed to perform any more actions. In order to restore its energy level, the agent approaches an agent charger to regain its energy. Agent charger is located in the SAFER community. In large communities, there may be more than one agent charger to facilitate the charge-up operations. Before restoring an agent battery, the agent charger should inspect the agent for its fitness and integrity. The inspection should include both agent code or agent data. If an agent is found to be intact (code integrity and data integrity is not compromised), the charger can increase the battery quota in the agent. The amount of quota to be increased should be specified by the agent owner/butler. If no value is specified, the default amount will be used. In case the agent has been found interfered with during charging, the agent charger will detain the agent and informs either the agent's owner or its butler.

With this battery system, an agent is forced to go through a "medical check-up" periodically. Moreover, each agent when arriving at a machine, its battery will be checked to see if it runs out of battery and whether any compromise has been made.

Agent Immigration

In an effort to promote open architecture, SAFER is designed to allow interaction with agents and hosts from within its family and other non-SAFER architectures. This leads to another problem: how do agents roam from one community to another community?

Agent immigration is introduced to provide a mechanism in the administration of agents across community boundaries. If an agent needs to roam outside the community, it has to obtain a "visa" from the visiting community's immigration (Guan et al., 2003). A host will ensure that only foreign agents with valid visas are allowed to execute in its premise. Therefore, if an illegal agent sneaks into a community without going through agent immigration, it will not be able to perform any action.

The policy of issuing visas may differ from immigration to immigration. It is important to identify where an agent comes from and updates the information in the immigration log. If the agent causes any damage in the community, a trace is available to identify the malicious agent's owner. An agent is forbidden for entry if the immigration detects any problem. On the other hand, if the immigration exercises trusts on incoming agents, the above check can be waived. Different policy may be applied to agents from SAFER communities and non-SAFER communities since agents from non-SAFER communities are more likely to be malicious.

Clearing House and Bank

In order to facilitate financial transactions and clearance, clearing house and bank are included as separate entities in each SAFER community.

Each agent and host should open an account with the bank that resides at its originating community. The personal particulars of the agents will only be known by the local bank and are not disclosed. If a transaction takes place within a community that does not involve any party from other communities, they can make an appropriate request directly to a local bank for immediate settlement. However, if a transaction involves

parties from other communities, clearing house must be used as the medium for settlement with different banks. Different from banks, clearing house does not contain any account information as the bank does. It is merely a medium through which inter-bank settlement can be facilitated. Anonymity across different communities can be provided through the use of clearing house. The detailed payment scheme has been elaborated by Guan and Hua (2003).

AGENT FABRICATION

In SAFER, agents are fabricated by an agent factory in its community. There are many supporting arguments to adopt this mode of fabrication:

- Although some users may design agents by themselves, most users do not have the ability to do so. Also software agents in e-commerce have many types. It will be more convenient if an agent can be customized according to its own specification by using the agent factory.
- E-commerce agents implemented individually can lead to lack of standardization among owners. This may result in communication break-down.
- Adopting this mode of agent fabrication will enhance the security of SAFER e-commerce. Since information of all fabricated agents is stored in agent factories, agents can be administered more efficiently and safely.

Under SAFER, the fabrication of agents obeys prescribed routine procedures. An owner customizes new agents through the interface provided by an agent factory. When an agent factory fabricates a new agent, it chooses the corresponding ontology structure from the database according to the requests from the owners. The agent factory then assembles the agents according to both the ontology structure and the owner's specification.

Each ontology structure defines the components and construction of a specific type of agents. Different types of agents are defined with different ontology structures depending on their prototypes in agent factory. Examples are ontology structures for negotiation agents and information collection agents. The same type of agents may have different structures because of different requirements. The ontology structures are stored in the database of the agent factory.

AGENT EVOLUTION

One of the most prominent aspects of SAFER is agent evolution. As numerous agents are distributed throughout the Internet and act on behalf of different owners in different communities, collaborations and competitions exist among them. For example, agents with the same goal of finding the pricing for a certain type of computer can collaborate with one another. One agent can inform the others the Web sites it has visited and the information gathered so that other agents do not need to visit the same Web sites again. In another scenario, some agents may cooperate to negotiate with several sellers. They can share information and adjust their strategies accordingly during the negotiation process in order to reach satisfactory deals. On the other hand, competitions are inevitable when resource is limited. For example, if only a limited number of computers are available, agents will have to compete against each other to get them. In the end, some of them will succeed, while the others will fail. The successful agent may become more powerful, and the failed agent may lose some fitness. This is similar to collaborations and competitions in natural ecosystems.

The fitness of an agent is an indicator of an agent's ability to survive and adapt to the environment. The higher the fitness of an agent, the stronger it is. The evaluation of fitness is performed in agent factories and agent chargers using the following criteria:

- **Integrity of agents:** The integrity of agents may be compromised during the process of evolution, roaming or communicating. It is caused by intentional damages from malicious agents or accidental errors during legal formalities.
- **History of agents:** History of agents includes the number of tasks carried out and the quality of completed tasks. Every time an agent completes a task and reports to its owner, the owner will assess the quality and give a corresponding mark. Through analyzing the trend of agent performance by combining every task and its mark, the fitness of agent can be evaluated.
- **Evolution record:** Evolution record can be an auxiliary tool in the evaluation of agent fitness. Every result of fitness evaluation is stored in the community administration center. It shows whether an agent's growth is healthy.

If an agent charger finds the fitness of an agent too low, it can reject to recharge the agent and adopt some other measures. Furthermore, the agent charger checks the evolution record of the agent. If the fitness of an agent is decreasing rapidly, it can be suspected that the agent might have been attacked or something may have gone wrong in the working experience of the agent. The agent charger can then send it back to an agent factory for a thorough examination. The agent factory has the right to detain or terminate an agent. It will inform the community administration center as well as the owner about the measures taken.

AGENT ROAMING

A set of agent transport protocols has been designed for SAFER in Yang and Guan (2000) to allow intelligent agents to roam from host to host. The transport protocols designed provide a secure mechanism for agents in e-commerce to roam across different hosts and communities in SAFER.

Supervised agent transport protocol allows controls to agent owner/butler during an agent's roaming operation. The agent has to obtain an approval from its owner/butler before roaming to a new host. The owner/butler can thus control the agent's roaming destination and prevent the agent from moving to certain undesirable hosts. The drawback of this protocol is the lack of efficiency since each agent's movement involves the agent owner/butler. This involvement will inevitably delay the transport process and incur additional network traffics. If the agent owner/butler happens to be using a low bandwidth connection to the Internet, the situation may worsen as agents roaming in high bandwidth networks suffer from the bottleneck in low bandwidth communication with the agent owner/butler.

On the other hand, unsupervised agent transport protocol does not involve the agent owner/butler directly in the transport process. Agents do not need to request for a permission before roaming. Instead, an indirect notification of the roaming operation is sent to the agent owner/butler for recording purpose. The agent owner/butler is unable to control the agent's roaming destination directly. The advantage is the increased efficiency of agent roaming since fewer parties are directly involved in the transport process, thus leading to shorter turnaround time.

Based on different concerns on efficiency, roaming control as well as level of security, individual SAFER agents can choose to use the most appropriate transport protocol or even a combination of different transport protocols in their roaming operations.

FUTURE TRENDS

We have planned the following steps to further improve the architecture and its functions. Firstly, we have started to implement the architecture

using Java. We are trying to provide the basic modules and facilities first, as we regard SAFER as our infrastructure for further research on e-commerce. Secondly, as evolution is proposed in the SAFER architecture, its mechanism and theory presentation is being constructed. Thirdly, we are developing the payment mechanism in SAFER, as it is the essential part in e-commerce.

CONCLUSION

In this article, we have proposed the SAFER architecture for agent-based e-commerce. SAFER provides the facilities to serve agents in e-commerce and establishes the necessary mechanisms to manage and control their activities. SAFER covers the whole lifecycle of an agent from its fabrication to its termination. We elaborate the functions of the components in SAFER, and the three aspects of SAFER: fabrication, evolution & roaming. Tree structure is employed to present the agent and ontology structure in agent fabrication and evolution.

SAFER e-commerce provides an opportunity in standardization for dynamic, secure and evolutionary agent architecture. With the SAFER architecture, conducting transactions in the Internet will be more convenient, secure and efficient.

KEY TERMS

Agents: A piece of software, which acts to accomplish tasks on behalf of its user.

Anonymity: The degree to which a software system or component allows for or supports anonymous transactions.

Authentication: The process of ensuring that an individual is one who he or she claims to be.

Client: In this work, it refers to customers who pay for good and services.

Digital Certificate: A certificate that uses a digital signature to bind together a public key with an identity—information such as the name of a person or an organization, the address, and so forth. The certificate can be used to verify an agent's identity, for example.

E-Commerce: The act of conducting business transactions over networks and through computers.

Integrity: Regarding the protection of data or program code from being modified by unauthorized parties.

Security: The effort to create a secure computing platform, designed so that agents (users or programs) can only perform actions that have been allowed.

This work was previously published in Encyclopedia of Networked and Virtual Organizations, edited by G. Putnik and M. Cunha, pp. 1764-1771, copyright 2008 by Information Science Reference, formerly known as Idea Group Reference (an imprint of IGI Global).

Chapter 3.11
Concepts and Operations of Two Research Projects on Web Services and Mobile Web Services

Zakaria Maamar
Zayed University, UAE

ABSTRACT

Today, Internet technologies are enabling a wave of innovations that have an important impact on the way businesses deal with their partners and customers. Most businesses are moving their operations to the Web for more automation, efficient business processes, and global visibility. Web services are one of the promising technologies that help businesses in achieving these operations and being more Web-oriented. Besides the new role of the Internet as a vehicle of delivering Web services, a major growth in the field of wireless and mobile technologies is witnessed. Because users are heavily relying on mobile devices to conduct their operations, enacting Web services from mobile devices and possibly downloading these Web services for execution on mobile devices are avenues that academia and industry communities are pursuing. M-services denote the Web services in the wireless world. In this chapter, two research initiatives carried out at Zayed University are presented and referred to as SAMOS, standing for Software Agents for MObile Services, and SASC, standing for Software Agents for Service Composition.

OVERVIEW

Today, several businesses are adopting Web-based solutions for their operation, aiming for more process automation and more worldwide visibility. Thanks to the Web technology, users from all over the world can satisfy their needs by browsing and triggering the services of these businesses. Such services are usually referred to as Web services (Boualem, Zeng & Dumas, 2003). The advantages of Web services have already been demonstrated in various projects and highlight their capacity to

be composed into high-level business processes. For example, a vacation business process calls for the collaboration of at least four Web services: flight reservation, accommodation booking, attraction search, and user notification. These Web services have to be connected with respect to a certain flow of control (first, flight reservation, then accommodation booking and attraction search). Multiple technologies are associated with the success of Web services, namely, WSDL (Web Services Definition Language), UDDI (Universal Description, Discovery, and Integration), and SOAP (Simple Object Access Protocol) (Curbera, Duftler, Khalaf, Nagy, Mukhi & Weerawarana, 2002). These technologies support the definition, advertisement, and binding of Web services.

Besides the Web expansion, we witness the tremendous progress in the field of wireless technologies. Telecom companies are deploying new services for mobile devices. Reading e-mails and sending messages between cell phones are becoming natural. Surfing the Web, thanks to the Wireless Application Protocol (WAP), is another evidence of the wireless technology development. The next stage (if we are not already in it) for telecom and IT businesses is to allow users to enact Web services from mobile devices and, possibly, to make these Web services runnable on mobile devices. M-services (M for mobile) denote these new type of Web services (Maamar & Mansoor, 2003).

It is accepted that composing multiple services (whether Web services or M-services) rather than accessing a single service is essential. Berardi et al. (2003) report that composition addresses the situation of a client's request that cannot be satisfied by any available service, whereas a composite service obtained by combining a set of available services might be used. Searching for the relevant services, integrating these services into a composite service, triggering the composite service, and monitoring its execution are among the operations that users will be in charge of. Most of these operations are complex, although repetitive, with a large segment suitable for computer aids and automation. Therefore, software agents are deemed appropriate candidates to assist users in their operations (Jennings, Sycara & Wooldridge, 1998).

Throughout this chapter, two research initiatives that our research group is conducting at Zayed University are presented. These initiatives are respectively **SAMOS**, standing for **Software Agents for MObile Services**, and **SASC,** standing for **Software Agents for Service Composition**. Both initiatives deal with the composition of services using software agent-oriented approaches. This chapter is structured as follows. The Background section outlines the concepts that are used in our research work, such as mobile computing and software agents. The next section overviews some research projects related to mobile computing. The SAMOS Research Initiative and SASC Research Initiative sections present SAMOS and SASC in terms of architecture, types of agents, and operation. In the last section, we draw our conclusions.

BACKGROUND

Mobile Computing

Mobile computing refers to systems in which computational components, either hardware or software, change locations in a physical environment. The ability to move from one location to another is because of the progress in several technologies: component miniaturization, wireless networks, and mobile-code programming languages. Categories of mobility include (Wand & Chunnian, 2001): hardware mobility, software mobility, and combined mobility. A code that is downloaded from a server to a mobile phone combines both hardware and software mobility. The Overview of Some Research Projects Related to Mobile Computing section provides more details on mobile computing using research projects as examples.

Web Services and M-Services

A Web service is an accessible application that can be automatically discovered and invoked by other applications and humans. An application is a Web service if it is (Benatallah et al., 2003): (i) independent as much as possible from specific platforms and computing paradigms; (ii) developed mainly for interorganizational situations rather than for intraorganizational situations; and (iii) easily composable so its composition with other Web services does not require the development of complex adapters.

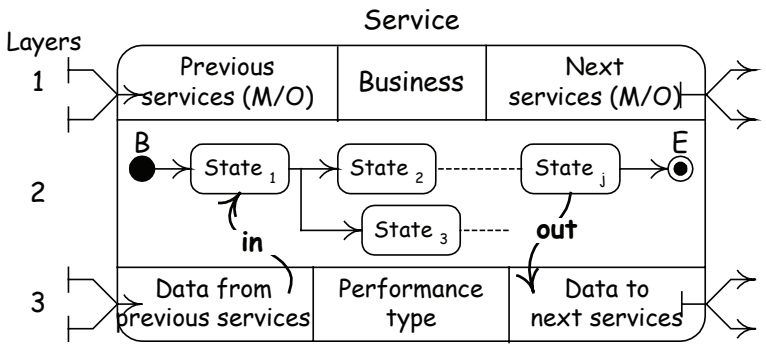
Two definitions are associated with an M-service (Maamar & Mansoor, 2003). The weak definition is to remotely trigger a Web service for execution from a mobile device. In that case, the Web service acts as an M-service. The strong definition is to wirelessly transfer a Web service from its hosting site to a mobile device where its execution happens. In that case, the Web service acts as an M-service that is: (i) transportable through wireless networks; (ii) composable with other M-services; (iii) adaptable with regard to the computing features of mobile devices; and (iv) runnable on mobile devices. In both SAMOS and SASC initiatives, only the M-services that comply with the strong definition are considered.

The differences between Web services and M-services are depicted at two levels. The first level concerns the communication medium (wired channel for Web services versus wireless channel for M-services). And the second level concerns the location of where the processing of the service occurs (server side for Web services versus user side for M-services).

In Maamar, Benatallah, and Mansoor (2003), we introduced the concept of service chart diagram as a technique for modeling and specifying the component services that participate in composite services. A service chart diagram enhances the state chart diagram of UML. In fact, the emphasis this time is on the context surrounding the execution of a service rather than only on the states that a service takes (Figure 1).

A service chart diagram wraps the states of a service into five perspectives, each perspective has a set of parameters. The state perspective corresponds to the state chart diagram of the service. The flow perspective corresponds to the execution chronology of the composite service in which the service participates (Previous services/Next services parameters; M/O respectively stands for Mandatory and Optional). The business perspective identifies the organizations (that is, providers) that make the service available (Business parameter). The information perspective identifies the data that are exchanged between the services of the composite service (Data from previous services/Data for next services parameters). Because the services participating in a composition can be either mandatory or optional, the information per-

Figure 1. Service chart diagram of a component service



spective is tightly coupled to the flow perspective with regard to mandatory data and optional data. Finally, the performance perspective illustrates the ways the service can be invoked for execution (Performance type parameter).

Software Agents

A software agent is a piece of software that autonomously acts to undertake tasks on behalf of users (Jennings et al., 1998). The design of many software agents is based on the approach that the user only needs to specify a high-level goal instead of issuing explicit instructions, leaving the how and when decisions to the agent. A software agent exhibits a number of features that make it different from other traditional components including autonomy, goal orientation, collaboration, flexibility, self-starting, temporal continuity, character, communication, adaptation, and mobility. It is noted that not all of these characteristics have to embody an agent.

Besides the availability of several approaches and technologies related to the deployment of Web services (for example, SOAP, UDDI, Salutation), they are all tailored to a context of type wired. In a similar context, all the computing resources are fixed and connected through a permanent and reliable communication infrastructure. The application of these approaches and technologies to a context of type mobile computing is not straightforward. Indeed, major adjustments are required because of multiple obstacles ranging from potential disconnections of mobile devices and unrestricted mobility of persons to power scarcity of mobile devices and possibility of capturing the radio signals while in the air. These obstacles highlight the suitability of software agents as potential candidates to overcome them. First, an agent is autonomous. Thus, it can make decisions on the user's behalf while this one is disconnected. Second, an agent can be mobile. Thus, it can move from one host to another. Continuous network connectivity is not needed. Third, an agent is collaborative. Thus, it can work with other agents that identify, for example, the providers of Web services. Last but not least, an agent is reactive. Thus, it can monitor the events that occur in the user's environment, so relevant actions can be promptly taken.

OVERVIEW OF SOME PROJECTS RELATED TO MOBILE COMPUTING

There exist several research projects that have studied how mobile devices can change the way of doing business and undertaking operations. In HP Laboratories, the authors in Milojicic et al. (2001) worked on delivering Internet services to mobile users. This work was conducted under the project Ψ for Pervasive Services Infrastructure (PSI). The Ψ vision is "any service to any client (anytime, anywhere)". The project investigated how offloading parts of applications to midpoint servers can enable and enhance service execution on a resource-constrained device.

The Odyssey project aimed at providing system support for mobile and adaptive applications (Noble et al., 1997). Odyssey defined a platform for adaptive mobile data access on which different applications, such as Web browser, video player, and speech recognition, can run on top. The Odyssey approach is to adjust the quality of accessed data to match available resources.

Ninja aimed at suggesting new types of robust and scalable distributed Internet services (Ninja, 2001). The objective in Ninja is to meet the requirements of an emerging class of extremely heterogeneous devices that would access these services in a transparent way. In Ninja, the architecture considered four elements: bases, units, active proxies, and paths. Proxies are transformational intermediaries that are deployed between devices and services to shield them from each other. A service discovery service is also suggested in Ninja for two reasons: (i) enable services to announce their presence and (ii) enable users and programs to locate the announced services.

SAMOS RESEARCH INITIATIVE

In addition to the role of the Internet as a vehicle of provisioning Web services, it is noticed that more Web services will be delivered to people who use mobile devices and, particularly, to those who are on the move most of the time (for example, sales representatives). It is also noticed that mobile devices are being enhanced with extra computing resources and advanced functionalities (Yunos, Gao & Shim, 2003). Unfortunately, the growth in the development and use of mobile devices is subject to multiple challenges. For instance, mobile devices are still bound to their batteries for operation, which leads to limit, to a certain extent, their computation performance.

It occurs that mobile users have to postpone their operations because they lack appropriate facilities running on their mobile devices (for example, an application that converts a drawing file into a format that the user's mobile device can display). In SAMOS, we support such users by allowing them: (i) to search for additional facilities, when needed; (ii) to fetch these facilities to their mobile devices; and (iii) to conduct these two operations in a transparent way. Various solutions are put forward to handle these points and are discussed throughout this part of the chapter. A solution to point (i) consists of devising brokering mechanisms. A solution to point (ii) consists of using wireless communication channels. Finally, a solution to point (iii) consists of using Software Agents (SAs) to make the search for and fetch the facilities transparent to users.

Architecture and Software Agents of SAMOS

Brokering mechanisms and SAs are considered in the design and development of SAMOS. The salient features of the architecture of SAMOS are:

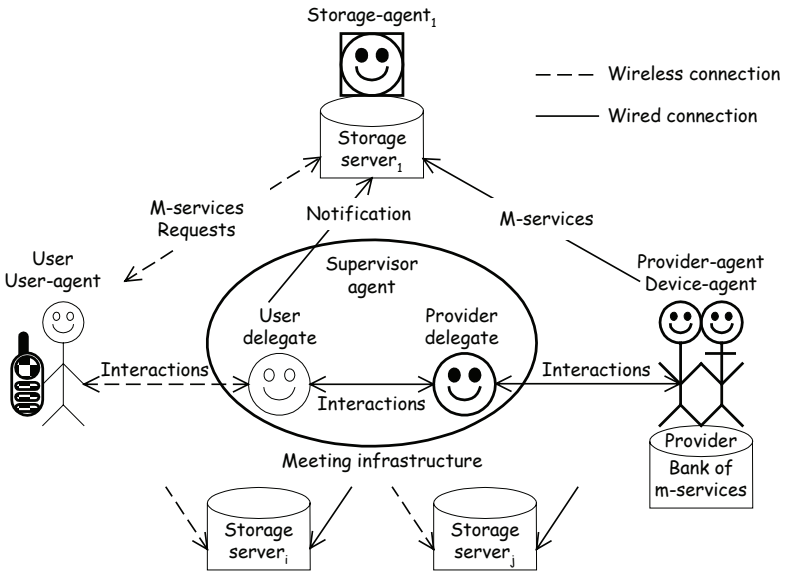
- Three types of SAs: user-agent, provider-agent, and device-agent. The first type is associated with users of M-services, whereas the second and third types are associated with providers of M-services.
- A software platform, called Meeting Infrastructure (MI), is headed by a supervisor-agent. This MI has a brokering role (Maamar, Dorion & Daigle, 2001).
- Two types of delegates, namely, provider-delegate and user-delegate. Delegates respectively interact on behalf of user-agents and provider-agents in the MI.
- Storage servers that save the sequence of M-services to be submitted to mobile devices for execution. Storage servers are spread across networks, and storage-agents are responsible for managing these servers. In SAMOS, a sequence corresponds to a composite service that has M-services as primitive components.

Figure 2 illustrates the architecture of SAMOS. It consists of four parts: user, provider, MI, and storage. The MI and storage parts are wirelessly linked to the user component, whereas the MI and storage parts are linked to the provider component with wires.

The user part consists of users and user-agents. User-agents accept users' needs, convert them into requests, and submit them to user-delegates. The supervisor of the MI creates user-delegates on requests from user-agents. To satisfy users' requests, user-delegates interact with provider-delegates.

The provider part consists of providers, provider-agents, and device-agents. Provider-agents act on behalf of providers by advertising their M-services to user-delegates through provider-delegates. Plus, provider-agents monitor the behavior of providers when new M-services are offered and, thus, need to be announced. In Figure 2, M-services are gathered into a bank on

Figure 2. Architecture of SAMOS



which provider-agents and device-agents reside. Provider-agents create provider-delegates. In the provider part, device-agents support the work of provider-agents, whereas the role of device-agents is to wrap the M-services before they are sent to mobile devices for execution. The rationale of device-agents is to consider the differences that exist between mobile devices (for example, screen size, processor power).

The MI part is a software platform in which user-delegates and provider-delegates interact in a local and secure environment (Maamar et al., 2001). In an open environment, most of the interactions occurring between requesters of services and providers of services are conducted through third parties (referred to as brokers). Despite its important role, a third party can easily become a bottleneck. To overcome this problem, requesters and providers need a common environment in which they meet and interact directly. The MI corresponds to this common environment. In SAMOS, the supervisor-agent of the MI has several responsibilities including monitoring the interactions that occur within the MI and making the MI a safe environment.

The storage part receives the sequence of M-services that will be submitted to mobile devices for performance. In SAMOS, one of the operation principles is to submit the M-services to mobile devices for execution one at a time. This restriction is due to the limited resources of these devices. However, the restriction can be handled (that is, adjust the number of M-services to be submitted) based on the computing resources of a mobile device and the bandwidth of the wireless communication channels. Several advantages are obtained from the use of storage servers. For instance, a user-agent does not have to deal with several providers. Its unique point of contact for getting the M-services is the storage-agent. The same thing applies to device-agents that will only be interacting with few storage-agents instead of multiple user-agents. Security is increased for both users and providers. Indeed, storage servers are independent platforms where security controls are carried out.

User-Oriented Components

A user-agent resides in a mobile device. First, the user interacts with the user-agent to arrange

requests. After submitting those requests to the user-delegate, the user-agent takes a standby state and waits for notifications from its user-delegate. Notifications concern the sequence of M-services that satisfies the user's requests. Before executing them on the user's device, the M-services are put in a storage server. The MI supervisor-agent suggests to the user-delegate the storage server to be used based, for example, on the server's location. To download the M-services one at a time from the storage server to the user's device, the user-agent communicates with the storage-agent. The user-agent keeps track of the execution of the M-services before it asks the storage-agent to submit further M-services. When an M-service is received, the executed M-service is deleted from the mobile device. Finally, the user-agent informs the user about the completed requests.

A user-delegate resides in the MI, acting on behalf of the user-agent. The user-delegate receives the user's requests from the user-agent. Afterward, it interacts with provider-delegates. The purpose of these interactions is to match the requests of users to the M-services of providers that are announced. In case there is a match (we assume that there is always a match), the user-delegate designs the sequence of M-services that satisfies the user's requests. Information about this sequence is sent afterward to the storage-agent. The objective is to make the storage-agent ready for receiving the M-services from device-agents. Furthermore, the user-delegate notifies the user-agent about the sequence of M-services it has prepared for its user. To set up a sequence, the storage-agent knows the M-service that comes before and after the M-services to be submitted by a device-agent (flow perspective of a service chart diagram, Figure 1). Instead of creating a user-delegate on a mobile platform and shipping that delegate to the MI, we suggested to perform this operation in the MI for two main reasons: (i) even if we expect a major improvement in the resources of mobile devices, those resources have to be used in a *rationale* way and (ii) the wireless connection that transfers the user-delegate to the MI is avoided.

Provider-Oriented Components

A Provider-agent resides in a provider site running on top of its resources such as M-services. Provider-delegates broadcast the M-services to user-agents through user-delegates. The provider-agent is in constant interaction with its provider-delegate. For instance, it notifies the provider-delegate about the negotiation strategy it has to follow with user-delegates.

A device-agent resides in a provider site. Its responsibility is to wrap the M-services according to the features of the devices to which these M-services will be submitted for performance. Initially, the M-services are sent to storage servers. The provider-agent has already submitted the contact details of the storage server to the device agent. We recall that the user-delegate informs the storage-agent of the storage server about the M-services it will receive. Double checking the information that user-delegates and provider-delegates submit to a storage-agent offers more security to the agents of SAMOS.

A provider-delegate resides in the MI, acting on behalf of a provider-agent. In SAMOS, the provider-delegate is responsible for interacting with user-delegates regarding the M-services it offers. In addition, the provider-delegate interacts with its provider-agent for notification purposes. Notifications are then forwarded to device-agents for action. We recall that the provider-agent is responsible for creating the provider-delegate and its transfer to the MI.

MI-Oriented Components

The supervisor-agent resides in the MI and has several responsibilities: it supervises the operations that occur in the MI; it mediates in case of conflicts between user-delegates and provider-delegates; it sets user-delegates and assigns them

to user-agents; it checks the identity of provider-delegates when they arrive from provider sites; and finally, it suggests to user-delegates the storage server to be used.

Storage-Oriented Components

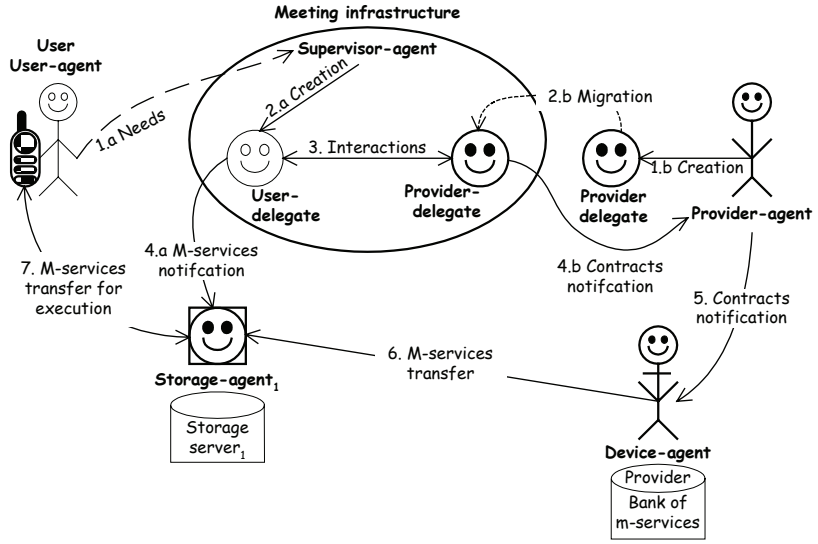
A Storage-agent runs on top of a storage server. This server saves the M-services to be sent to mobile devices for performance. According to the information on the sequence of M-services it receives from the user-delegate, the storage-agent arranges the sequence as the M-services start arriving from providers. As soon as this sequence is completed, it notifies the user-agent in order to get ready for receiving the M-services. Based on the requests it receives from the user-agent, the storage-agent submits the M-services one at a time. These M-services are ready for execution. The deletion of M-services from the storage servers and mobile devices follows certain reliability rules. These rules ensure that the M-services to be sent to a mobile device for execution are successfully received and executed.

OPERATION OF SAMOS

The operation of SAMOS consists of five stages (Figure 3): agentification, identification, correspondence, notification, and realization. The purpose of the agentification stage is to set up the different infrastructures and agents that constitute SAMOS. User-agents are established at the user level. Provider-agents and device-agents are established at the provider level, too. Finally, the meeting infrastructure and storage servers, including their storage-agent, are deployed. In Figure 3, operations (1.a) and (1.b) illustrate the agentification stage.

The purpose of the identification stage is to inform the supervisor-agent of the MI about the existence of users and providers who are interested in using SAMOS. At the agentification stage, user-agents and provider-agents are respectively installed on top of mobile devices of users and resources of providers. The outcome of the identification stage is the creation of user-delegates and the reception of provider-delegates arriving from provider-sites. Creation and reception operations occur in the MI. Provider-agents notify the supervisor-agent about their readiness to submit the

Figure 3. Operation of SAMOS



provider-delegates to the MI. User-agents inform the supervisor-agent about the users' requests they would like to submit. In Figure 3, operations (2.a) and (2.b) illustrate the identification stage.

The purpose of the correspondence stage is to enable user-delegates and provider-delegates to get together. In Figure 3, operation (3) illustrates this stage. User-delegates have requests to satisfy, and provider-delegates have services to offer. First, the user-delegate searches for the provider-delegates that have the M-services it needs. Two approaches are offered (Maamar & Mansoor, 2003):

a) The user-delegate asks the supervisor-agent to suggest a list of provider-delegates that have the services it needs.
b) The user-delegate requests from the supervisor-agent the contact details of all the provider-delegates that exist in the MI.

Independently of the approach that is adopted, the user-delegate submits its needs of services to a shortlist of selected provider-delegates. Based on different parameters, such as workload and commitments, provider-delegates answer the user-delegate. At this time of our research in SAMOS, it is assumed that providers do not have services in common. Consequently, there is no need for a user-delegate to look for the best service. Once the user-delegate and provider-delegates agree on the M-services to use, notifications are sent to different recipients as it is discussed in the next stage.

The purpose of the notification stage is to inform different agents about the agreements between user-delegates and provider-delegates. In Figure 3, operations (4.a), (4.b), (5), and (6) illustrate this stage. Regarding the user-delegate, it is in charge of informing (i) the user-agent about the sequence of M-services it has established to satisfy its user's request and (ii) the storage-agent about the sequence of M-services it will receive from different device-agents. Regarding the provider-delegate, it notifies the provider-agent about its agreements with a user-delegate. Based on the information it receives from its provider-delegate, the provider-agent forwards this information to the device-agent. This information is about the M-services that are involved and the storage server that is used. Among the actions the device-agent takes is to submit the M-services to the storage-agent of the storage server.

The purpose of the realization stage is to execute the sequence of M-services that the user-delegate has designed. User-agent and storage-agent participate in this stage. We recall that the user-delegate has already informed the storage-agent about the M-services it will receive from device-agents. Before the user-agent starts asking the storage-agent for the M-services it has, it waits for a notification message from the storage-agent mentioning that the sequence is ready for submission and, thus, for execution. In Figure 3, operation (7) illustrates the realization stage. In the realization phase, reliability is one of the concerns that have been considered in SAMOS. We consider a storage server as a backup server for the M-services. When a storage-agent sends an M-service to a user-agent, the storage-agent keeps a copy of this service at its level. The storage-agent deletes that M-service when the user-agent asks for the M-service that follows the one it has received. For the last M-service of a sequence, the user-agent sends an acknowledgment message to the storage-agent, so this M-service can be deleted.

Summary on SAMOS

In this part of the chapter, we discussed the use of M-services in the context of SAMOS. M-services are seen as a logical extension to the widespread use of Web services in the wireless world. Considering mobile devices as computing platforms is becoming a reality as the networks that make them reachable are in constant progress, offering more bandwidth and ensuring more reliability and efficiency. For instance, third-generation com-

munication systems are providing high quality streamed Internet content (Chisalita & Shahmehri, 2001). In addition to higher data rates, these systems back the provision of new value-added services to users, such as geographical positioning and mobile payment.

SASC RESEARCH INITIATIVE

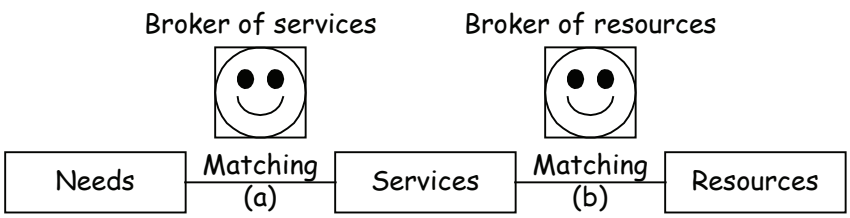
Despite that provisioning Web services is a very active area of research and development, very little has been done to date regarding their integration with M-services. Several obstacles still exist including throughput and connectivity of wireless networks, limited computing resources of mobile devices, and risks of communication channel disconnections.

A framework that composes services, whether Web services or M-services, should offer more opportunities to users to conduct operations regardless of (i) the type of services, (ii) the location of users, and (iii) the computing resources on which services will be performed. This situation is challenging due to the gap existing between wired and wireless. First, Web services are associated with fixed devices. However, M-services are associated with mobile devices. Second, the execution of Web services occurs in the server side, whereas the execution of M-services occurs in the client side (according to the strong definition of what an M-service is). Third, fixed devices are not resource-constrained which is not the case for mobile devices. Despite the multiple opportunities that could be offered to users, few research efforts are being dedicated to the composition of Web services and M-services.

Because the information space is already full of several providers of services, a broker that matches services to needs of users is one step in the design of the SASC framework (Figure 4a). On the other side, because services require resources on which they can be computed, there is a need for another broker as a second step in the design of the SASC framework (Figure 4b). This broker matches services (those that satisfy users' needs) to the resources of providers.

In the previous paragraph, it is shown that two types of providers are involved: provider of services and provider of resources (a provider can play both roles). Due to this distinction of providers, a user with a fixed or mobile device is also seen in the SASC framework as a provider of resources in the composition framework (that is, users' devices are advertised to the broker of resources). Considering users as providers of resources enables them to play an active role instead of always being limited to their traditional passive role of consumers. The rationale is to take advantage of the spare resources that are available on devices. It is observed that many of the systems are often underutilized due to geography factor. Busy hours in one time zone tend to be idle hours in another zone. Therefore, demands for computational resources can be met with hosts that have idle resources. For the needs of the SASC initiative, the term composite service denotes the set of component services (whether

Figure 4. Needs versus services and services versus resources



composite services, Web services, or M-services) that take part in a composition.

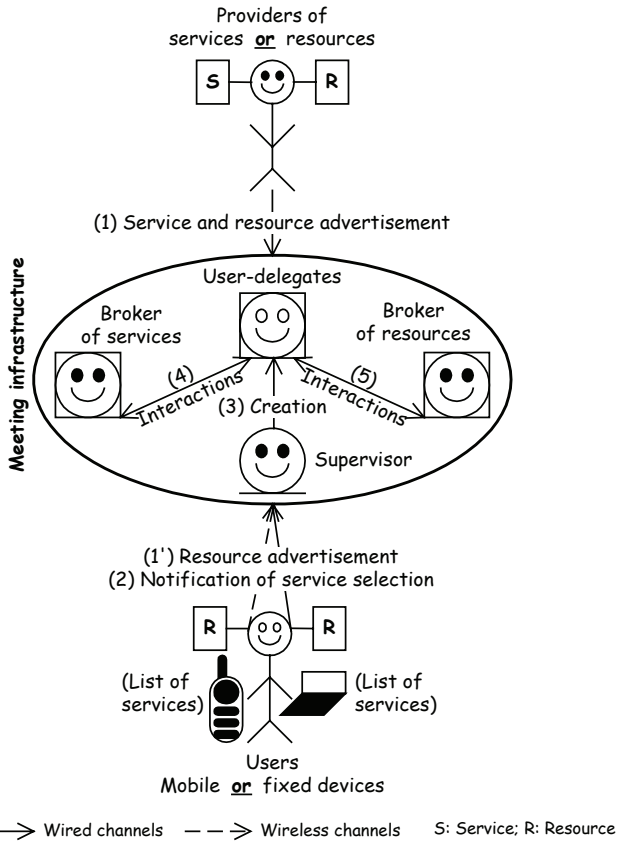
Architecture and Software Agents of SASC

Figure 5 is the agent-based architecture upon which the SASC framework is deployed. The architecture has three parts. The first part corresponds to providers of services (S) or resources (R). The second part corresponds to consumers of services (that is, users) with their fixed or mobile devices. Finally, the third part corresponds to the meeting infrastructure (similar to the one that is used in SAMOS) on which brokers carry out the matching operations between needs of users and services of providers and, later on, between services of providers and resources of providers (Figure 4). The meeting infrastructure connects the provider and consumer parts. To keep Figure 5 clear, the different agents that populate the architecture are not represented. The core agents of the framework are briefly described below.

Provider-agents are specialized into two types: resource-provider-agents and service-provider-agents. Resource-provider-agents handle the execution of the services of service-provider-agents. In the MI, resource-delegates and service-delegates, respectively, represent resource providers and service providers (delegates are agents but are given a different name to avoid confusion).

User-agents reside in the devices of users and are specialized into two types: fixed-user-agents (for users of fixed devices) and mobile-user-agents

Figure 5. Architecture of SASC



(for users with mobile devices). In the meeting infrastructure, user-delegates represent users to whom their needs are submitted.

Broker-agents are specialized into two types (Figure 4): service-broker-agent and resource-broker-agent. A service-broker-agent receives (i) notifications from service-delegates about their offers of services and (ii) requests from user-delegates about their needs of services. Whereas a resource-broker-agent receives (i) notifications from resource delegates regarding their respective offers of resources and (ii) requests from service-delegates regarding their needs of resources.

The supervisor-agent is in charge of the MI. For instance, it creates user-delegates and checks the security credentials of service-delegates and resource-delegates once both arrive from their original host. It should be noted that the security of delegates is beyond the scope of this chapter. However, the security of the services that run on computing resources is discussed in Maamar, Hamdi, Mansoor, and Bhati (2003).

Rationale of User/Resource/Service-Delegates

- Because mobile devices are resource-constrained, several authors, such as Jailani, Othman, and Latih (2002) and Messer, Greeberg, Bernadat, and Milojicic (2002), observe that it is appropriate to offload computing from mobile devices to fixed ones. In SASC, once the service-broker-agent matches users' needs to providers' services, the next step for a user-delegate is to integrate the component services into a composite service. This integration requires resources that have to be used in a *rationale* way when it comes to mobile devices. Therefore, it is preferable to undertake the development of composite services in the MI rather than in mobile devices. In addition, it may happen that the user-delegate needs further information from a broker to complete its work on a composite service. Since the user-delegate already resides in the MI, it locally interacts with the broker. This constitutes another argument in favor of using user-delegates. Because of the advantages that local interactions offer, even users of fixed devices are encouraged to develop their composite services in the meeting infrastructure.
- When there is a match between the needs of a user and the offers of services, the service-broker-agent locally notifies the user-delegate and remotely notifies the relevant service-provider-agents. Since remote exchanges are subject to obstacles (for example, network reliability, transfer safety), providers of services are associated with service-delegates. Service-delegates are transferred from the sites of their respective provider-service-agents to the MI. After the first match is over, the service-delegate informs the resource-broker-agent about its needs of resources; certain services have been selected and, thus, need to be executed. Once the resources are identified, the service-delegate remotely interacts with the resource-provider-agents about the modalities of using their resource. Similarly to service-delegates, it is more convenient if the interactions between service-delegates and resource-provider-agents occur locally. Therefore, resource-provider-agents have resource-delegates to act on their behalf in the meeting infrastructure.

Operation of SASC

The operation of SASC consists of six stages: initialization, advertisement, search for services, search for resources, refinement, and completion. Below is a summary of the main actions that occur in each stage.

Initialization stage:

- Agentify users and providers.

- Create supervisor and brokers and deploy them in the meeting infrastructure.
- Embody agents with operation mechanisms.

Advertisement stage:
- Create service-delegates and resource-delegates.
- Transfer delegates to the meeting infrastructure.
- Check delegates before they enter the meeting infrastructure.
- Advertise services and resources to brokers.

Search for services stage:
- Create user-delegates in the meeting infrastructure.
- Submit users' needs to user-delegates.
- Interact with service-broker-agent.
- Match user's needs with providers' services.
- If positive match, return list of service-delegates to user-delegate.

Search for resources stage:
- Interact with resource-broker-agent.
- Match selected service with providers' resources.
- If positive match, return list of resource-delegates to service-delegates.
- Select a specific resource-delegate for a service.
- Transfer service for execution to resource-delegate site.

Refinement stage:
- Combine outcomes of search for services and search for resources stages.
- Submit new details (version and processing type) on service to user-delegate.
- Finalize selection of service-delegate by user-delegate.

Completion stage:
- Work on next service based on details of previous service.
- Select a specific resource-delegate for a service.
- Transfer service for execution to resource-delegate site.
- Submit new details (version and processing type) on service to user-delegate.
- Finalize selection of service-delegate by user-delegate.Keep running completion stage until all services are processed.

The purpose of the initialization stage is to perform the agentification of the components of SASC (that is, provider and user). Each provider/user is associated with an agent that exhibits a behavior in terms of resources to have, services to offer, and needs to satisfy. User-agents and provider-agents are respectively installed on top of users' devices and providers' resources/services. Moreover, further agents (supervisor, service-broker, and resource-broker) are created in the MI. Afterwards, information on "services versus needs" is loaded into the knowledge base of the service-broker-agent (operation done by the administrator of SASC). Likewise, information on "resources versus services" is loaded into the knowledge base of the resource-broker-agent. Finally, the supervisor-agent is embodied with the mechanisms of creating user-delegates as well as verifying and installing service-delegates and resource-delegates.

The purpose of the advertisement stage is to notify the brokers about the available services and resources that are made available to the user community. As a first step, service/resource-provider-agents create service/resource-delegates and transfer them to the MI. Because mobile devices are resource-constrained, the supervisor-agent creates the resource-delegates on behalf of the users of these devices. Mechanisms that embody a service/resource-delegate are several, including how to announce itself to the supervisor-agent,

how to register at the service/resource-broker-agent, and how to notify its respective service/resource-provider-agent. When service/resource-delegates access the meeting infrastructure, they register at the appropriate broker to submit their offers of services/resources. It should be noted that service-delegates have a dual role (Figure 4): (i) as a provider of services when they interact with the service-broker-agent and (ii) as a consumer of resources when they interact with the resource-broker-agent. The purpose of the search for services stage is to look for the services that satisfy a user's needs. On reception of the needs, the supervisor-agent creates a user-delegate to be in charge of user satisfaction. First of all, the user-delegate interacts with the service-broker-agent. The purpose is to identify the services of service-delegates that satisfy the user's needs. In case certain services are identified, the service-broker-agent notifies the user-delegate and the service-delegate of these services. Because service-delegates may have services in common, the user-delegate has to select a particular service-delegate. However, the user-delegate delays its selection until further details on services are provisioned. These details concern the cost, version, and processing type of each service.

The purpose of the search for resources stage is to identify the resources that support the execution of the services (that is, those that have been identified in the search for services stage). In the MI, service-delegates trigger the matching between services and resources. The identification of the resources is conducted service per service. As it will be described, the selection of a resource for any service depends on the version and type of processing (that is, remote processing or local processing) of the direct predecessor service of this service. On receiving the service-delegates' requests, the resource-broker-delegate identifies the appropriate resource-delegates. Since several resource-delegates can support the execution of the same service, a service-delegate has to select a resource-delegate. In SASC, the selection strategy consists of minimizing the cost of running a service on a resource considering the version and type of processing of this service. At this time of the operation of SASC, each service-delegate knows exactly for its service the version and type of processing to offer to the user-delegate.

The purpose of the refinement stage is to improve the outcome of the search for services stage. Since a service-delegate is aware of the version and type of processing of the service it will offer to the user-delegate, the service-delegate prepares a cost for that service. In its offer, the service-delegate includes the cost of running the service on a resource. After it receives all the offers from service-delegates, the user-delegate selects for a service a particular service-delegate. The user-delegate minimizes the cost of getting the service from all the service-delegates. When the user-delegate selects a service-delegate, this service-delegate submits to the resource-provider-agent the following details: (i) the service this resource-provider-agent will receive for processing; (ii) the version of this service; (iii) the user-delegate that will trigger the processing of this service; and (iv) the way this service will be invoked for processing. Completion is the final stage in the operation of SASC. Here, the selection of any service directly depends on the version and type of processing of its direct predecessor service. In addition to the cost criterion that was used in the previous stages, another selection criterion is now included, namely, location. Location criterion aims at gathering the maximum number of services for execution in the same computing site[1]. By computing site, it is meant: location of resource-provider-agents and current location of the user-delegate. By gathering services in the same computing site, the following advantages are obtained: (i) extra moves of the user-delegate to distant sites of resource providers are avoided and (ii) extra remote communication and data exchange messages between user-delegates and resource-provider-agents are avoided, too. Therefore, the location criterion is privileged over the

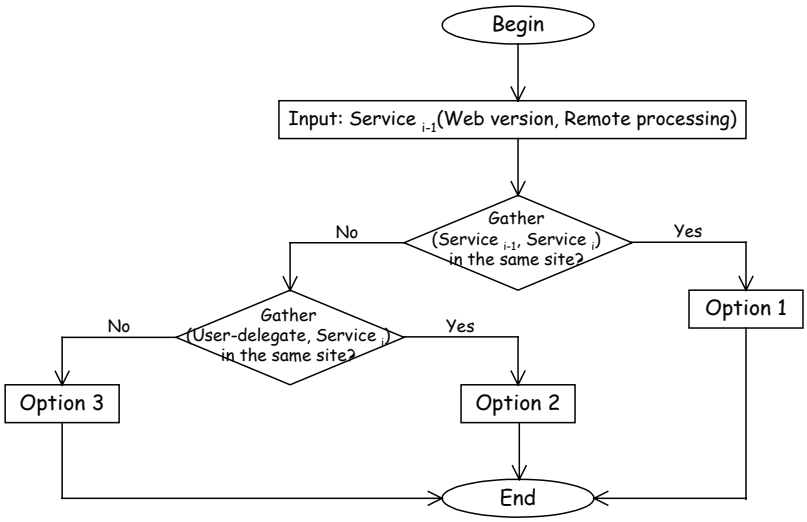
cost criterion. When the details on a service are known, the user-delegate requests from the service-delegates to identify the resource-delegates for the next service. The work on service$_{(i)}$ is decomposed into three cases: Web version and remote processing of service$_{(i-1)}$, Web version and local processing of service$_{(i-1)}$, and M-version and local processing of service$_{(i-1)}$. To keep the chapter self-contained, only the first case is presented.

Web Version and Remote Processing of Service$_{(i-1)}$ Case

Since the processing of the Web version of service$_{(i-1)}$ has been remotely conducted, this means that the user-delegate is in a different site to the execution site of service$_{(i-1)}$. Three exclusive options are offered to the user-delegate to make a decision on service$_{(i)}$ (Figure 6).

- Option 1: the processing of service$_{(i)}$ takes place in the site of service$_{(i-1)}$ in order to comply with the location criterion. Therefore, the user-delegate requests from the service-delegates of service$_{(i)}$ to check with the resource-broker-agent what follows: does resource-delegate$_{(i-1)}$ support the remote processing of the Web version of service$_{(i)}$? If yes, then the service-delegates have to select resource-delegate$_{(i-1)}$. Afterwards, the user-delegate selects a service-delegate based on the cost criterion. As a result, the Web versions of service$_{(i)}$ and service$_{(i-1)}$ will be both installed in site$_{(i-1)}$ of resource-delegate$_{(i-1)}$. The user-delegate will remotely process them.
- Option 2: the processing of service$_{(i)}$ takes place in the site of the user-delegate in order to comply with the location criterion. Option 2 exists because resource-delegate$_{(i-1)}$ does not support the remote processing of the Web version of service$_{(i)}$. Therefore, the user-delegate requests from the service-delegates of service$_{(i)}$ to check with the resource-broker-agent what follows: does the resource-delegate of the current site of the user-delegate support the local processing of the Web version of service$_{(i)}$? If yes, then the service-delegates have to select resource-delegate$_{(i-1)}$. Afterwards, the user-delegate selects a service-delegate

Figure 6. Application of location criterion to service selection



based on the cost criterion. As a result, the Web version of service$_{(i-1)}$ and the Web version of service$_{(i)}$ will be located in different sites. However, the user-delegate will locally process service$_{(i)}$.

- Option 3: the processing of service$_{(i)}$ takes place in any site (different from the site of the user-delegate and the site of service$_{(i-1)}$). Option 3 happens because the site of the user-delegate does not support the local processing of the Web version of service$_{(i)}$. In that case, the location criterion does not hold. Search for services and search for resources stages as previously described are carried out in order to define the version and type of processing of service$_{(i)}$ and the respective resource-delegate.

Summary on SASC

Future computing environments will involve a variety of devices with different capacities in terms of processing power, screen display, input facilities, and network connectivity. Furthermore, a variety of services will be offered to users making the use of these devices important in their performance. In this second part of the chapter, we presented SASC that aims at composing services whether Web services or M-services. The backbone of SASC is a software agent-based architecture that integrates several agents such as user, provider, service, and resource. SASC also aims at provisioning services independently of the location of users and the resources they may be using. Service provisioning has relied on two selection criteria (execution cost and resource location) to identify which resources should be assigned to which services.

CONCLUSION

In this chapter, we presented the research initiatives that are carried out @ Zayed University on Web services and Mobile Web services. Among these initiatives, we cited SAMOS, standing for Software Agents for MObile Services, and SASC, standing for Software Agents for Service Composition. New issues that are related to mobile Web services and their integrations with traditional Web services are raised, varying from low bandwidth and high latency of wireless networks to screen sizes of mobile devices. To deal with these issues, software agents are considered due to their various features. For instance, a software agent is autonomous. Thus, it can make decisions on the user's behalf while this one is disconnected. Second, a software agent can be mobile. Thus, it can move from one host to another. Continuous network connectivity is not needed. The major progress happening in the wireless field will be offering the right mechanisms to users to conduct their daily activities over a variety of mobile devices. Three major factors should boost the penetration and expansion of mobile Web services, namely: personalization, time-sensitivity, and context-awareness.

ENDNOTE

[1] The use of the location criterion is backed by the work of Chakraborty, Perich, Joshi, Finin, and Yesha (2002). In this work, a reactive service composition architecture for pervasive computing environments has been designed. The architecture consists of five layers: network, service discovery, service composition, service execution, and application. We focus on the service execution layer. During the execution of services, this layer might want to optimize the bandwidth required to transfer data over the wireless links between services and, hence, execute the services in an order that minimizes the bandwidth utilization. This optimization is similar to the location criterion. With that criterion, the cross-network traffic between the resources can be reduced, which avoids extra data exchanges between distant resources.

INTRODUCTION

Mobile commerce or m-commerce is defined as the exchange or buying and selling of commodities, services, or information on the Internet through the use of Internet-enabled mobile handheld devices (Hu, Lee, & Yeh, 2004). It is expected to be the next milestone after electronic commerce blossoming in the late-1990s. Internet-enabled mobile handheld devices are one of the core components of a mobile commerce system, making it possible for mobile users to directly interact with mobile commerce applications. Much of a mobile user's first impression of the application will be formed by his or her interaction with the device, therefore the success of mobile commerce applications is greatly dependent on how easy they are to use. However, programming for handheld devices is never an easy task not only because the programming languages and environments are significantly different from the traditional ones, but also because various languages and operating systems are used by handheld devices and none of them dominates.

This article gives a study of handheld computing, especially J2ME (Java 2 Platform, Micro Edition) programming, for mobile commerce. Various environments/languages are available

for client-side handheld programming. Five of the most popular are (1) BREW, (2) J2ME, (3) Palm OS, (4) Symbian OS, and (v) Windows Mobile. They apply different approaches to accomplishing the development of mobile applications. Three themes of this article are:

1. Introduction of handheld computing, which includes server- and client- side computing.
2. Brief introductions of four kinds of client-side computing.
3. Detailed discussion of J2ME and J2ME programming.

Other important issues such as a handheld computing development cycle will also be discussed.

BACKGROUND

Handheld computing is a fairly new computing area and a formal definition of it is not found yet. Nevertheless, the authors define it as follows: Handheld computing is the programming for handheld devices such as smart cellular phones and PDAs (personal digital assistants). It consists of two kinds of programming: client- and server-side programming.

The definitions of client- and server- side computing are given as follows:

- **Client-Side Handheld Computing:** It is the programming for handheld devices and it does not need the support from server-side programs. Typical applications created by it include (1) address books, (2) video games, (3) note pads, and (4) to-do list.
- **Server-Side Handheld Computing:** It is the programming for wireless mobile handheld devices and it needs the support from server-side programs. Typical applications created by it include (1) instant messages, (2) mobile Web contents, (3) online video games, and (4) wireless telephony.

This article will focus on the client-side computing. The server-side computing is briefly given next.

Server-Side Handheld Computing

Most applications created by this kind of programming, such as instant messaging, require network programming such as TCP/IP programming, which will not be covered in this chapter. The most popular application of server-side handheld computing is database-driven mobile Web sites, whose structure is shown in Figure 1. A database-driven mobile Web site is often implemented by using a `three-tiered client/server architecture` consisting of three layers:

1. **User Interface:** It runs on a handheld device (the client) and uses a standard graphical user interface (GUI).
2. **Functional Module:** This level actually processes data. It may consist of one or more separate modules running on a workstation or application server. This tier may be multi-tiered itself.
3. **Database Management System (DBMS):** A DBMS on a host computer stores the data required by the middle tier.

The three-tier design has many advantages over traditional two- or single- tier design, the chief one being: the added modularity makes it easier to modify or replace one tier without affecting the other tiers.

CLIENT-SIDE HANDHELD COMPUTING

Various environments/languages are available for client-side handheld programming. Five of the most popular are (1) BREW, (2) J2ME, (3) Palm OS, (4) Symbian OS, and (5) Windows Mobile. They apply different approaches to accomplishing

the development of mobile applications. Figure 2 shows a generalized development cycle applied by them and Table 1 gives the comparison among the five languages/environments. The second half of this article is devoted to J2ME details and brief introductions of the other four are given in this section.

BREW (Binary Runtime Environment for Wireless)

BREW is an application development platform created by Qualcomm Inc. for CDMA-based mobile phones (Qualcomm Inc., 2003). CDMA is a digital wireless telephony transmission technique and its standards used for 2G mobile telephony are the IS-95 standards championed by Qualcomm. BREW is a complete, end-to-end solution for wireless applications development, device configuration, application distribution, and billing and payment. The complete BREW solution includes

- BREW SDK (software development kit) for application developers,
- BREW client software and porting tools for device manufacturers, and
- BREW distribution system (BDS) that is controlled and managed by operators—enabling them to easily get applications from developers to market and coordinate the billing and payment process.

Table 1. A comparison among five handheld-computing languages/environments

	BREW	J2ME	Palm OS	Symbian OS	Windows Mobile
Creator	Qualcomm Inc.	Sun Microsystems Inc.	PalmSource Inc.	Symbian Ltd.	Microsoft Corp.
Language/ Environment	Environment	Language	Environment	Environment	Environment
Market Share (PDA) as of 2004	N/A	N/A	2nd	N/A	1st
Market Share (Smartphone) as of 2005	?	N/A	3rd	1st	2nd
Primary Host Language	C/C++	Java	C/C++	C/C++	C/C++
Target Devices	Phones	PDAs & phones	PDAs	Phones	PDAs & phones

Figure 1. A generalized system structure of a database-driven mobile Web site

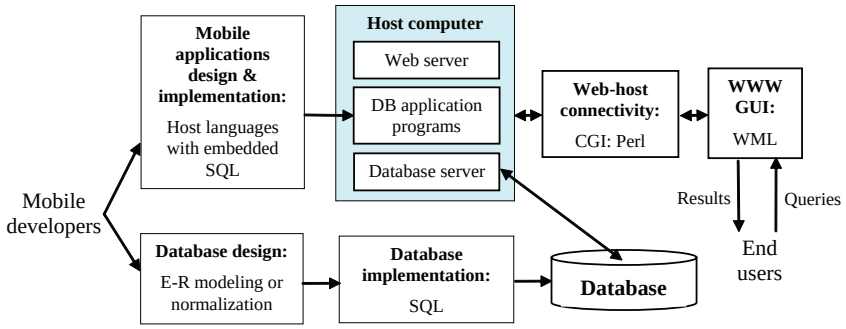

Figure 2. A generalized client-side handheld computing development cycle

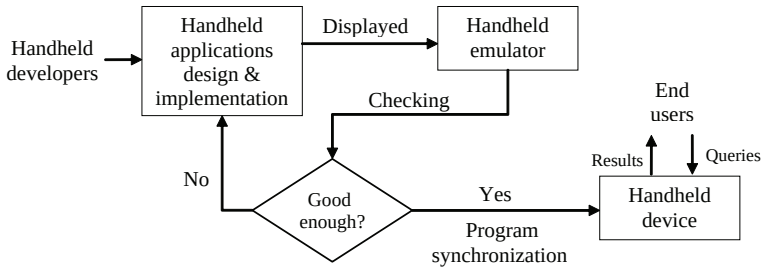

Palm OS

Palm OS, developed by Palm Source Inc., is a fully ARM-native, 32-bit operating system running on handheld devices (PalmSource Inc., 2002). Palm OS runs on almost two out of every three PDAs. Its popularity can be attributed to its many advantages, such as its long battery life, support for a wide variety of wireless standards, and the abundant software available. The plain design of the Palm OS has resulted in a long battery life, approximately twice that of its rivals. It supports many important wireless standards, including Bluetooth and 802.11b local wireless and GSM, Mo-bitex, and CDMA wide-area wireless networks. Two major versions of Palm OS are currently under development:

- **Palm OS Garnet:** It is an enhanced version of Palm OS 5 and provides features such as dynamic input area, improved network communication, and support for a broad range of screen resolutions including QVGA.
- **Palm OS Cobalt:** It is Palm OS 6, which focuses on enabling faster and more efficient development of smartphones and integrated wireless (WiFi/Bluetooth) handhelds.

As of August 2005, no hardware products run Palm OS Cobalt and all devices use Palm OS Garnet. Likely as a result of Palm OS Cobalt's lack of adoption, PalmSource has shifted to developing Palm OS Cobalt's APIs on top of a Linux kernel.

Symbian OS

Symbian Ltd. is a software licensing company that develops and supplies the advanced, open, standard operating system—Symbian OS—for data-enabled mobile phones (Symbian Ltd., 2005). It is an independent, for-profit company whose mission is to establish Symbian OS as the world standard for mobile digital data systems, primarily for use in cellular telecoms. Symbian OS includes a multi-tasking multithreaded core, a user interface framework, data services enablers, application engines, integrated PIM functionality, and wireless communications. It is a descendant of EPOC, which is a range of operating systems developed by Psion for handheld devices.

Windows Mobile

Windows Mobile is a compact operating system for mobile devices based on the Microsoft Win32 API (Microsoft Corp., 2005). It is designed to be similar to desktop versions of Windows. In 1996, Microsoft launched Windows CE, a version of the Microsoft Windows operating system designed specially for a variety of embedded products, including handheld devices. However, it was not well received primarily because of battery-hungry hardware and limited functionality, possibly due to the way that Windows CE was adapted for handheld devices from other Microsoft 32-bit desktop operating systems. Windows Mobile includes three major kinds of software:

Figure 3. A screenshot of KToolbar after launching

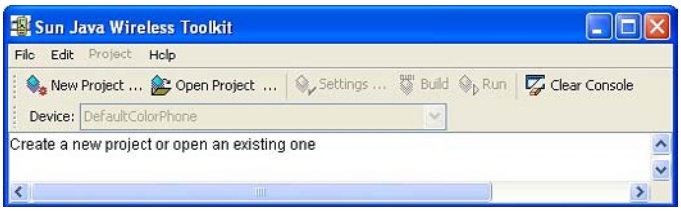

Figure 4. A screenshot of a pop-up window after clicking on the button New Project of KToolbar

- **Pocket PCs:** Pocket PC enables you to store and retrieve e-mail, contacts, appointments, games, exchange text messages with MSN Messenger, browse the Web, and so on.
- **Smartphones:** Smartphone supplies functions of a mobile phone, but also integrates PDA-type functionality, such as e-mails, instant messages, music, and Web surfing, into a voice-centric handset.
- **Portable Media Centers:** Portable media centers let users take recorded TV programs, movies, home videos, music, and photos transferred from Microsoft Windows XP-based PC anywhere.

Windows Mobile-Based Pocket PCs

Pocket PCs were designed with better service for mobile users in mind and offers far more computing power than Windows CE. It provides scaled-down versions of many popular desktop applications, including Microsoft Outlook, Internet Explorer, Word, Excel, Windows Media Player, and others. It also includes three major kinds of software:

- **Pocket PC:** It puts the power of Windows software into a Pocket PC, giving you time to do more with the people and things that matter.
- **Pocket PC Phone Edition:** It combines all the standard functionality of a Windows Mobile-based Pocket PC with that of a feature-rich mobile phone.
- **Ruggedized Pocket PC:** It lets you do more of what matters to you even in the toughest user environments.

Windows Mobile-Based Smartphones

Windows Mobile-based smartphone integrates PDA-type functionality into a voice-centric handset comparable in size to today's mobile phones. It is designed for one-handed operation with keypad access to both voice and data features. The Smartphone is a Windows CE-based cellular phone. Like the Pocket PC, all Smartphones regardless of manufacturer share the same configuration of Windows CE. Also, Smartphones come bundled with a set of applications such as an address book, calendar, and e-mail program.

J2ME (JAVA 2 PLATFORM, MICRO EDITION)

J2ME provides an environment for applications running on consumer devices, such as mobile phones, PDAs, and TV set-top boxes, as well as a broad range of embedded devices (Sun Microsystem Inc., 2002a). Like its counterparts for the enterprise (J2EE), desktop (J2SE) and smart card (Java Card) environments, J2ME includes Java virtual machines and a set of standard Java APIs defined through the Java Community Process, by expert groups whose members include device manufacturers, software vendors, and service providers.

J2ME Architecture

The J2ME architecture comprises a variety of configurations, profiles, and optional packages that implementers and developers can choose from, and combine to construct a complete Java runtime environment that closely fits the requirements of a particular range of devices and a target market. There are two sets of J2ME packages, which target different devices:

- **High-End Devices:** They include connected device configuration (CDC), foundation and personal profile.
- **Entry-Level Devices and Smart Phones:** They include connected limited device configuration (CLDC) and mobile information device profile (MIDP).

Configurations comprise a virtual machine and a minimal set of class libraries and they provide the base functionality for a particular range of devices that share similar characteristics, such as network connectivity and memory footprint. Profiles provide a complete runtime environment for a specific device category.

J2ME Programming

This sub-section gives an example of J2ME programming (Sun Microsystem Inc., 2004). Other client-side handheld programming is similar to this. Figure 3 shows the Sun Java Wireless Toolkit©, which is a toolbox for developing wireless applications that are based on J2ME's CLDC and MIDP. The toolkit includes the emulation environments, performance optimization and tuning features, documentation, and examples that developers need to bring efficient and successful wireless applications to market quickly. The following steps show how to develop an MIDP application, a simple "Hello, World!" program, under Microsoft Windows XP:

1. Download Sun Java Wireless Toolkit 2.3 Beta, which includes a set of tools and utilities and an emulator for creating Java applications that run on handheld devices, at http://java.sun.com/products/sjwtoolkit/download-2_3.html .
2. Run MIDlet, an MIDP application, development environment `KToolbar` as shown in Figure 3 by selecting the following Windows commands:

   `Start ▶ All Programs ▶ Sun Java Wireless Toolkit 2.3 Beta ▶ KToolbar`

3. Create a new project by giving a project name such as `HelloSuite` and a class name such as `HelloMIDlet` as shown in Figure 4. After the project HelloSuite is created, the KToolbar will display the message shown in Figure 5, which tells where to put the Java source files, application resource files, and application library files.
4. Create a J2ME source program and put it in the directory `C:\WTK23\apps\HelloSu-`

`ite\src\`. Figure 6 gives a J2ME example, which displays the text "Hello, World!" and a ticker with a message "Greeting, world."

5. Build the project by clicking on the `Build` button. The `Build` includes compilation and pre-verifying.
6. Run the project by clicking on the `Run` button. An emulator will be popped up and displays the execution results of the built project. For example, Figure 7 shows an emulator displays the execution results of HelloSuite.
7. Upload the application to handheld devices by using USB cables, infrared ports, or Bluetooth wireless technology.

Figure 5. A screenshot of KToolbar after a project HelloSuite created

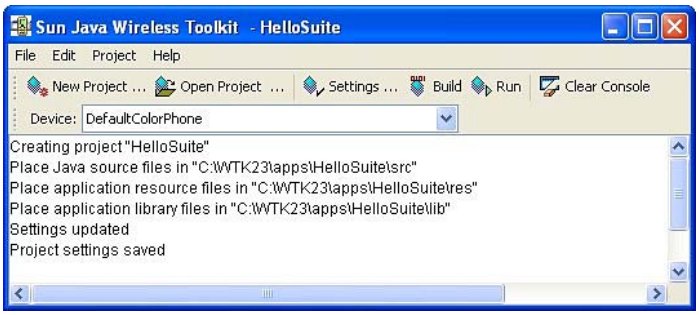

Figure 6. An example of an MIDlet program HelloMIDlet.java

C:\WTK23\apps\HelloSuite\src\HelloMIDlet.java

```
// This package defines MIDP applications and the interactions between
// the application and the environment in which the application runs.
import  javax.microedition.midlet.*;

// This package provides a set of features for user interfaces.
import  javax.microedition.lcdui.*;

public class HelloMIDlet  extends MIDlet  implements CommandListener {

  public void  startApp( ) {
    Display  display     = Display.getDisplay( this );
    Form     mainForm    = new  Form    ( "HelloMIDlet" );
    Ticker   ticker      = new  Ticker  ( "Greeting, World" );
    Command  exitCommand = new  Command( "Exit", Command.EXIT, 0 );

    mainForm.append            ( "\n\n          Hello, World!" );
    mainForm.setTicker         ( ticker );
    mainForm.addCommand        ( exitCommand );
    mainForm.setCommandListener( this );
    display.setCurrent         ( mainForm );
  }

  public void  pauseApp ( ) { }

  public void  destroyApp( boolean unconditional ) {
    notifyDestroyed( );
  }

  public void  commandAction( Command c, Displayable s ) {
    if ( c.getCommandType( ) == Command.EXIT )
      notifyDestroyed( );
  }
}
```

Figure 7. A screenshot of an emulator displaying the execution results of HelloSuite

Mobile Information Device Profile (MIDP) Packages

Table 2 shows the packages provided by the MIDP (Sun Microsystem Inc., 2002b). The packages javax.* are the extensions to standard Java packages. They are not included in the JDK or JRE. They must be downloaded separately.

FUTURE TRENDS

A number of mobile operating systems with small footprints and reduced storage capacity have emerged to support the computing-related functions of mobile devices. For example, Rearch In Motion Ltd.'s BlackBerry 8700 smartphone uses RIM OS and provides Web access, as well as wireless voice, address book, and appointment applications (Research In Motion Ltd., 2005). Because the handheld device is small and has limited power and memory, the mobile OSs' requirements are significantly less than those of desktop OSs.

Table 2. Mobile Information Device Profile (MIDP) package list

Package	Classes and Descriptions
User Interface	**`javax.microedition.lcdui`**: The UI API provides a set of features for implementation of user interfaces for MIDP applications.
	`javax.microedition.lcdui.game`: The Game API package provides a series of classes that enable the development of rich gaming content for wireless devices.
Persistence	**`javax.microedition.rms`**: It provides a mechanism for MIDlets to persistently store data and later retrieve it.
Application Lifecycle	**`javax.microedition.midlet`**: The MIDlet package defines MIDP applications and the interactions between the application and the environment in which the application runs.
Networking	**`javax.microedition.io`**: The MID Profile includes networking support based on the `Generic Connection` framework from the *Connected, Limited Device Configuration*.
Audio	**`javax.microedition.media`**: The MIDP 2.0 Media API is a directly compatible building block of the Mobile Media API (JSR-135) specification.
	`javax.microedition.media.control`: This package defines the specific Control types that can be used with a `Player`.
Public Key	**`javax.microedition.pki`**: Certificates are used to authenticate information for secure Connections.
Core	**`java.io`**: Provides classes for input and output through data streams.
	`java.lang`: MID Profile Language Classes included from Java 2 Standard Edition.
	`java.util`: MID Profile Utility Classes included from Java 2 Standard Edition.

Although a wide range of mobile handheld devices are available in the market, the operating systems, the hub of the devices, are dominated by just few major organizations. The following two lists show the operating systems used in the top brands of smart cellular phones and PDAs in descending order of market share:

- **Smart Cellular Phones:** Symbian OS, Microsoft Smartphone, Palm OS, Linux, and RIM OS (Symbian Ltd., n.d.).
- **PDAs:** Microsoft Pocket PC, Palm OS, RIM OS, and Linux (WindowsForDevices, 2004).

The market share is changing frequently and claims concerning the share vary enormously. It is almost impossible to predict which will be the ultimate winner in the battle of mobile operating systems.

CONCLUSION

Mobile commerce is a coming milestone after electronic commerce blossoming in the late-1990s. The success of mobile commerce applications is greatly dependent on handheld devices, by which mobile users perform the mobile transactions. Handheld computing is defined as the programming for handheld devices such as smart cellular phones and PDAs. It consists of two kinds of programming: client- and server- side programming. Various environments/languages are available for client-side handheld programming. Five of the most popular are

1. **BREW:** It is created by Qualcomm Inc. for CDMA-based smartphones.
2. **J2ME:** J2ME is an edition of the Java platform that is targeted at small, standalone or connectable consumer and embedded devices.
3. **Palm OS:** It is a fully ARM-native, 32-bit operating system running on handheld devices.
4. **Symbian OS:** Symbian OS is an industry standard operating system for smartphones, a joint venture originally set up by Ericsson, Nokia, and Psion.
5. **Windows Mobile:** Windows Mobile is a compact operating system for handheld devices based on the Microsoft Win32 API. It is a small version of Windows, and features ma ny "pocket" versions of popular Microsoft applications, such as Pocket Word, Excel, Access, PowerPoint, and Internet Explorer.

They apply different approaches to accomplishing the development of handheld applications and it is almost impossible to predict which approaches will dominate the client-side handheld computing in the future, as the Windows to desktop PCs.

KEY TERMS

Binary Runtime Environment for Wireless (BREW): BREW is an application development platform created by Qualcomm Inc. for CDMA-based mobile phones.

Client-Side Handheld Programming: It is the programming for handheld devices and it does not need the supports from server-side programs. Typical applications created by it include (1) address books, (2) video games, (3) note pads, and (4) to-do list.

Handheld Computing: It is the programming for handheld devices such as smart cellular phones and PDAs (Personal Digital Assistants). It consists of two kinds of programming: client- and server-side programming.

Java 2 Platform, Micro Edition (J2ME): J2ME provides an environment for applications running on consumer devices, such as mobile phones, PDAs, and TV set-top boxes, as well as a broad range of embedded devices.

Palm OS: Palm OS, developed by Palm Source Inc., is a fully ARM-native, 32-bit operating system running on handheld devices.

Server-Side Handheld Programming: It is the programming for wireless mobile handheld devices and it needs the supports from server-side programs. Typical applications created by it include (1) instant messages, (2) mobile Web contents, (3) online video games, and (4) wireless telephony.

Symbian OS: Symbian Ltd. is a software licensing company that develops and supplies the advanced, open, standard operating system—Symbian OS—for data-enabled mobile phones.

Windows Mobile: Windows Mobile is a compact operating system for mobile devices based on the Microsoft Win32 API. It is designed to be similar to desktop versions of Windows.

Chapter 3.13
Tools for Rapidly Prototyping Mobile Interactions

ABSTRACT

We introduce informal prototyping tools as an important way to speed up the early-stage design of mobile interactions, by lowering the barrier to entry for designers and by reducing the cost of testing. We use two tools, SUEDE and Topiary, as proofs of concept for informal prototyping tools of mobile interactions. These tools address the early stage design of two important forms of mobile interactions: speech-based and location-enhanced interactions. In particular, we highlight storyboarding and Wizard of Oz (WOz) testing, two commonly used techniques, and discuss how they can be applied to address different domains. We also illustrate using a case study: the iterative design of a location-enhanced application called Place Finder using Topiary. In this chapter we hope to give the reader a sense of what should be considered as well as possible solutions for informal prototyping tools for mobile interactions.

INTRODUCTION

The iterative process of prototyping and testing has become an efficient way for successful user interface design. It is especially crucial to explore a design space in the early design stages before implementing an application (Gould et al., 1985). Informal prototyping tools can speed up an early-stage, iterative design process (Bailey et al., 2001; Klemmer et al., 2000; Landay et al., 2001; Li et al., 2004; Lin et al., 2000). These tools are aimed at lowering the barrier to entry for interaction designers who do not have technical backgrounds, and automatically generating early-stage prototypes that can be tested with end users.

The informal look and feel of these tools and their fluid input techniques, for example using pen sketching (Landay et al., 2001), encourage both designers and end users to focus on high level interaction ideas rather than on design or implementation details (e.g., visual layouts or colors). These details are often better addressed at a later stage. In this chapter, we focus on informal tool support for the early stage design of interactive mobile technologies. In particular, we describe informal prototyping tools that we developed for two increasingly important forms of mobile interaction: speech-based interactions (Klemmer et al., 2000) and location-enhanced interactions (Li et al., 2004).

The first of these two types of interactions, speech-based, works well on mobile phones, the major platform of mobile computing. These devices often have tiny screens and buttons to increase mobility, which makes speech interaction an important alternative. Although the accuracy of speech recognition is an important concern for a successful speech-based UI, the real bottleneck in speech interface design is the lack of basic knowledge about user "performance during computer-based spoken interaction" (Cohen et al., 1995). Many interaction designers who could contribute to this body of knowledge are excluded from speech design by the complexities of the core technologies, the formal representations used for specifying these technologies, and the lack of appropriate design tools to support iterative design (Klemmer et al., 2000). SUEDE (Klemmer et al., 2000) demonstrates how tool support can be used in the early stage design of speech-based user interfaces.

The second of these two types of interactions, location-enhanced, is important because of its implicit nature. While the explicit input channels (e.g., keyboarding or mouse pointing) available on mobile technology are more limited than on the desktop, the bandwidth of implicit input (using contextual information) is greatly expanded on mobile platforms. Mobile technology is more available in our context-rich, everyday lives than traditional desktop computing. One especially promising form of context-aware computing that has begun to see commercialization is location-enhanced computing, applications that leverage one's current location as well as the location of other people, places, and things (Li et al., 2004). For example, mobile phone services allow users to locate friends and family (LOC-AID), provide real-time navigation (InfoGation) and monitor and motivate users toward their fitness goals by using phone-based GPS to measure the user's speed, distance and elevation (BonesInMotion). E911 transmits a mobile phone user's current location when making emergency calls. However, location-enhanced applications are hard to prototype and evaluate. They employ sophisticated technologies such as location tracking and their target environment is mobile and in the field. Topiary (Li et al., 2004) demonstrates how high-level tool support can be provided for lowering the threshold and cost for designers to design and test location-enhanced applications.

Using SUEDE and Topiary as proofs of concept, we highlight two techniques commonly used in informal prototyping tools: storyboarding and Wizard of Oz (WOz) testing. To overcome the technical barrier for design, both SUEDE and Topiary employ a storyboarding-based approach for specifying interaction logic. To allow easy testing of prototypes, both tools employ WOz approaches where a human wizard simulates a sophisticated, nonexistent part of the prototype such as location tracking or speech recognition. To demonstrate how these types of tool can actually help prototype and test mobile technology, we introduce a case study using Topiary to design the Place Finder application.

BACKGROUND

User interface tools have been a central topic in HCI research. An extensive review of user

interface tools can be found in (Myers et al., 2001). A large number of research prototypes and commercial products have been developed for rapid prototyping of user interfaces (Apple, 1987; Bailey et al., 2001; Hartmann et al., 2006; Klemmer et al., 2000; Landay et al., 2001; Li et al., 2004; Lin et al., 2000; Macromedia; MacIntyre et al., 2004).

In particular, informal prototyping tools are aimed at the early stages of a design process, and are used to create early-stage prototypes for testing key design ideas rather than building full-fledged final systems (Landay et al., 2001). They often result in example-based interface mockups that are able to demonstrate exploratory interactive behaviors but ignore other non-exploratory aspects of a desired system. Informal tools have shown great potential to facilitate the early stages of a design process and have been developed for various domains. For example, SILK is a tool for designing graphical user interfaces (Landay et al., 2001) that allows designers to create GUI prototypes by sketching and storyboarding. DENIM (Lin et al., 2000), a tool for the early stage design of Web sites, has become one of the most popular informal prototyping tools (downloaded over 100,000 times since 2000). Informal prototyping tools are often grounded in current practices of designers, e.g., paper prototyping (Rettig, 1994; Snyder, 2003), and lower the barrier to entry by maintaining the affordance of an existing practice. At the same time, informal tools provide extra value by allowing the easy editing and maintenance of a design, and by generating testable prototypes.

MAIN FOCUS OF THE CHAPTER

In our research, two features have emerged as being particularly valuable for rapidly prototyping mobile interactions. The first is storyboarding, which is inspired by traditional paper prototyping where designers draw key interaction flows visually on paper. Storyboarding is enhanced by electronic tool support to create the states and transitions. Many systems have been influenced by Harel's Statecharts model (Harel, 1987). Storyboarding is employed by both SUEDE and

Figure 1. SUEDE allows designers to create example scripts of speech-based interactions (top) and speech UI designs (bottom) by storyboarding.

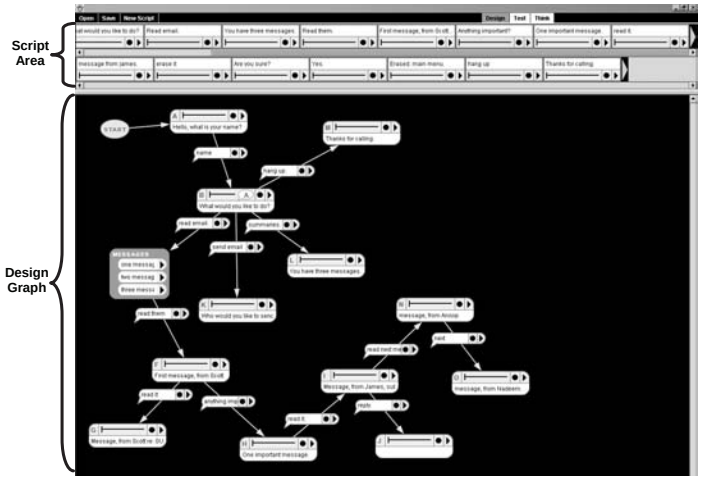

Figure 2. The active map workspace of Topiary is used to model location contexts of people, places and things and to demonstrate scenarios describing location contexts.

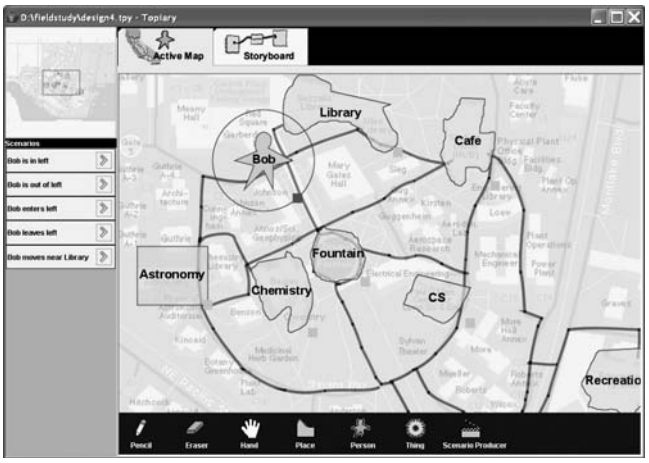

Figure 3. The designer drags Bob into the Library, with the context changing from "Bob is out of Library" to "Bob enters Library." As the entity CS (building) is unchecked, all related contexts to this place are filtered out.

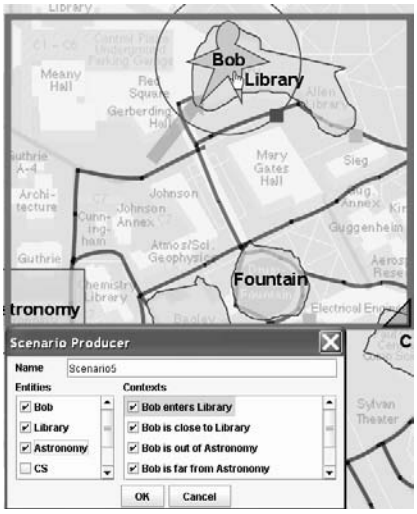


Topiary to lower the technical barrier for creating early-stage prototypes.

The second valuable feature is Wizard of Oz (WOz) testing, where a designer simulates part or all of the application logic by manipulating the interface in response to user input. This significantly reduces the time and labor required to create a testable prototype. As both speech-based interfaces and location-enhanced computing involve a necessary but sophisticated component, that is speech recognition and location tracking, respectively, both SUEDE and Topiary employed a WOz approach to avoid the complexity of introducing these components. To give an example of how this type of tool can help design and evaluate mobile technology in practice, we describe a case study for the iterative design of a PDA-based mobile Place Finder application using the Topiary.

Prototyping with Storyboards

In the early stages of design, it is important that tools allow designers to focus on the high-level concerns of interaction design, rather than forcing designers to also specify how these interactions are implemented. Storyboarding is an efficient way for designers to describe how a user interface should behave by enumerating concrete interaction sequences including both user input and interface output. These sequences should cover the key interaction paths of a proposed system in a particular design space. The concerns of early-stage prototyping are distinct from those of constructing an actual system, which focus more on completeness than exploration of the design space.

SUEDE allows two kinds of storyboarding: linear (conversation examples) and non-linear (design graphs of an actual interface) storyboarding. Designers start a design by creating simple conversation examples (see the Script Area at the top of Figure 1). These examples then evolve into the more complex, graph structure representing the actual interface design (see the design graph at the bottom of Figure 1) (Klemmer et al., 2000). The process of creating linear examples first and then forming more general design graphs is based on the existing practices of speech UI designers:

Figure 4. Topiary's Storyboard workspace allows application prototypes to be created. The lower three links (in blue) are explicit links, representing the behavior of the OK button depending where "Bob" is. The top link (in green) is an implicit link, representing an automatic transition from the Map page to the Nearest Friends page when "Anyone moves near Bob"

we have found that often, designers begin the design process by writing linear dialog examples and then use those as a basis for creating a flowchart representation of the dialog flow on paper.

Designers lay out linear conversation examples horizontally as cards in the script area. *Prompts*, colored orange, represent the system's speech prompts. They are recorded by the designer for the phrases that the computer speaks. *Responses*, colored green, represent example responses of the end user. They are the phrases that participants make in response to prompts. System prompts alternate with user responses for accomplishing a task. A designer can record her own voice for the speech on both types of cards, as well as type in a corresponding label for each of the cards. By playing the recordings from left to right, the designer can both see and hear the example interaction. For example, in Figure 1, a designer has recorded a conversation example with the following alternating prompts and responses: "message from James," "erase it," "Are you sure," "Yes." After constructing example scripts, a designer can construct an actual design of a speech-based interface using the design graph (see Figure 1). A design graph represents a dialog flow based on the user's responses to the system's prompts. To create a design graph, designers can drag prompt or response cards from a script onto the design area, or create new cards on the design area, and link them into the dialog flow. SUEDE's storyboard mechanism embodies both the input and output of a speech interface in cards that can be directly manipulated (e.g., via drag & drop), and hides the complexity of using speech recognition and synthesis. This abstraction allows designers to focus on high-level design issues.

Topiary's storyboards also embed the specification of input and output interactions into a storyboard. Before introducing Topiary's storyboards, we first discuss Topiary's *Activity Map* workspace, a component designed for creating scenarios describing location contexts of people, places and things by demonstration (see Figures 2 and 3). The created scenarios can be used as input by Topiary storyboards when prototyping location-enhanced interactions (see Figure 4). Modeling implicit input, location context in this case, is a new challenge posed by mobile computing.

Topiary's Activity Map workspace employs an intuitive map metaphor for designers to demonstrate location contexts describing the spatial relationship of people, places and things. Designers can create graphical objects on the map to represent people, places and things (see Figure 2). Designers can move people and things on the map to demonstrate various spatial relationships. For example, in Figure 2, Bob is out of the library, the astronomy building and the café. However, Bob is close to the library because Bob's proximity region, indicated by the red circle around Bob, intersects with the library. The proximity region can be resized by dragging the rectangular handle. These spatial relationships can be captured via Topiary's *Scenario Producer*. Like a screen capture tool, a designer can position a *Scenario Producer* window over entities of interest to capture spatial relationships (see Figure 3). A dialog box is then brought up that allows designers to select contexts of interest. Designers can demonstrate dynamic contextual transitions such as "entering" or "leaving" by moving entities within the recording window. For example, dragging Bob into the Library changes the event "Bob is out of Library" into "Bob enters Library" (see Figure 3).

Based on the location scenarios captured in the Active Map workspace, designers can create application prototypes in the Storyboard workspace (see Figure 4). In Topiary, a storyboard page represents a screen of visual output and a link represents transitions between pages. The key innovation in Topiary's storyboards is that scenarios created in the *Active Map* workspace can be used as conditions or triggers on links (Li et al., 2004). Designers create pages and links by sketching. Topiary has two kinds of links (see

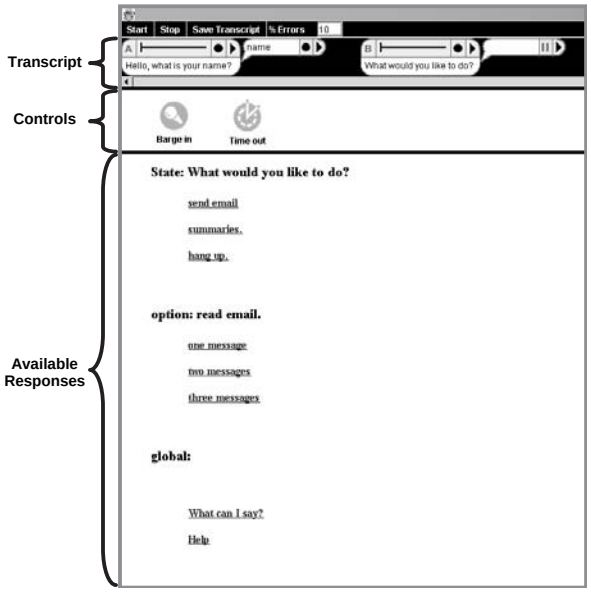
Figure 4). *Explicit links*, denoted in blue, start on ink within a page and they represent GUI elements that users have to click on, for example buttons or hyperlinks. *Implicit links*, denoted in green, start on an empty area in a page. They represent transitions that automatically take place when scenarios associated with that link occur. Explicit links model explicit interactions taken by end-users though they can be conditioned by sensed information, whereas implicit links model purely sensed data such as locations. One or more scenarios can be added to a link and multiple scenarios represent the logical AND of the scenarios. Multiple links starting from the same source represent the logical OR of transitions.

The Activity Map abstraction allows designers to focus on location contexts of interest rather than how these contexts can be sensed. Topiary's graphical storyboarding allows designers to specify rich interactions by drag & drop or sketching instead of specifying complex rules or Boolean logic expressions. From both SUEDE and Topiary, we conclude that the key to a successful informal tool is to devise an appropriate abstraction that matches designers' conceptual model for design and hides the less important aspects of exploring target interactions. Storyboards, as a meta-design metaphor, should be adapted and developed to fit within a specific domain when being applied.

Testing Using WOz Approaches

Speech-based or location-enhanced interactions resist rapid evaluation because the underlying technologies require high levels of technical expertise to understand and use, and a significant amount of effort to tune and integrate. For example, location-tracking infrastructures are not always available (e.g., GPS does not work well indoors) and they require a great deal of effort to deploy and configure. Incorporating these technologies too early in a design process may distract designers from fully exploring the design space. Consequently, we employed WOz approaches in these

Figure 5. SUEDE's Test mode is presented in a web browser and allows the wizard to focus on the current state of the UI (top) and the available responses for that state (bottom).



tools for testing early-stage prototypes. That is, a wizard (played by a designer or experimenter) simulates what these technologies would do in the final application.

Wizard of Oz (WOz) testing has been widely employed in user interface design. In a WOz test, a wizard (often played by a designer) fakes an incomplete (or nonexistent) system component to conduct early user evaluations (Dahlbäck et al., 1993). In its most basic form, a WOz test works by the wizard simulating the machine behavior entirely. There is no computation in the loop at all. Examples of this form include testing paper prototypes by having the wizard physically move around the paper-based windows and menus (Rettig, 1994) and testing potential speech interface interaction flows by having a human operator on the other side of the telephone, following a pre-specified interaction graph. When an interactive prototype has been created (at least partially), the wizard can simply use the implemented interface. As a variant of this approach, a programmer can implement a functionally complete but suboptimal interface, and have the wizard control this interface during testing as a means of eliciting users' conceptual models of the task for example (Akers, 2006).

Significant gains beyond these basic approaches can be achieved through tools designed explicitly to support a Wizard of Oz approach. The fundamental insight behind a WOz-enabled tool is that the wizard is provided with a distinct user interface from that of the end user, and that the primary goal for this interface is to enable the wizard to rapidly specify to the system what the user's input was. In SUEDE, the interaction flow and audio prompts are specified by the designer ahead of time, and the user's responses to the speech prompts are interpreted by the wizard and specified to the system using a graphical interface that is runtime-generated based on the user's current state within the interaction flow. During a test, a wizard works in front of a computer screen. The participant performs the test away from the wizard, in a space with speakers to hear the system prompts and a microphone hooked up to the computer to record his responses. During the course of the test session, a transcript sequence is generated containing the original system audio output and a recording of the participant's spoken audio input.

When the wizard starts a test session, SUEDE automatically plays the pre-recorded audio from the current prompt. The wizard interface in SUEDE displays hyperlinks that represent the set of possible options for the current state (see Figure 5); the wizard waits for the test participant to respond, and then clicks on the appropriate hyperlink based on the response. Here, the wizard is acting as the speech recognition engine. Additionally, effective wizard interfaces should provide a display of the interaction history (as well as capture this for subsequent analysis); global controls for options generally available in an interface genre but independent of a particular interface or interface state (these globals can be defined by the tool or specified by the designer); and support for simulated recognition errors. This set of functionality enables the wizard to customize the test as she sees fit, handle user input beyond what was originally designed, and test whether the application is designed in such a way that users can understand and recover from "recognition errors."

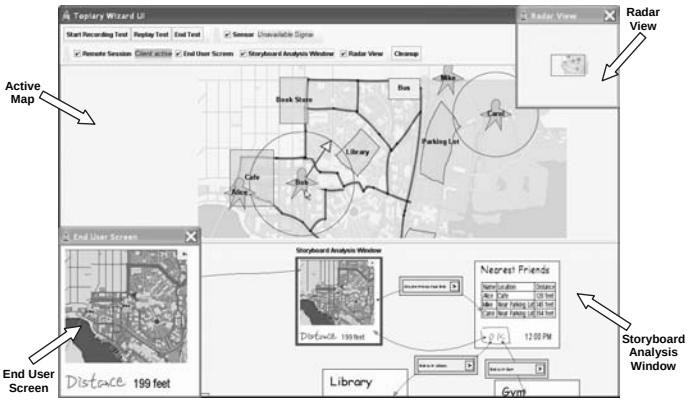
Location-enhanced interfaces introduce the additional challenge that, almost by definition, a test must be conducted while moving to be ecologically valid. To address this, Topiary's WOz interface was specifically designed for a wizard to interact with the interface while walking. Topiary automatically generates user interfaces for testing, including the Wizard UI and the End-User UI, based on the Active Map and the Storyboard workspace. The Wizard UI (see Figure 6) is where a wizard simulates location contexts, as well as observes and analyzes a test. The End-User UI is what an end user interacts with during a test and it is also shown in the End User Screen window

of the Wizard UI (see Figure 6) so that designers can monitor user interactions. The designer can also interact with the End-User Screen window for debugging purposes. The Wizard UI and End-User UI can be run on the same device (to let a designer try out a design) or on separate devices (one for the Wizard, the other for the user).

During a test, the wizard follows a user; each carries a mobile device, and these devices are connected over a wireless network. The wizard simulates location contexts by moving people and things around on the Active Map to dynamically update their location. The location changes of people and things on a map may trigger implicit transitions in the storyboard that will update the End-User UI. Topiary can also employ real location data if it is available, for more realistic testing at larger scales. A designer can choose to turn on a built-in location-tracking engine, based on Place Lab (LaMarca et al., 2005), which allows a WiFi-enabled or GSM-enabled device to passively listen for nearby access points to determine its location in a privacy-sensitive manner. In addition, a designer can analyze a design by recording a test and replaying it later. Topiary capture users' actions, like mouse movements and clicks, as well as physical paths traveled. The Storyboard Analysis window (see the bottom of Figure 6) highlights the current page and the last transition during a test or a replay session, which can help designers to figure out interaction flows.

Through our experience building SUEDE and Topiary, we have learned that effective tool support for Wizard of Oz testing comprises several key elements: the current state of the user interface (e.g., what is the current page in both tools), the current state of the user (e.g., the user's current location in Topiary) and the set of available actions (e.g., available responses in SUEDE). These elements should be provided to the wizard in an effective manner that allows the wizard to easily grasp and rapidly react. An effective Wizard interface should minimize the wizard's cognitive load by proactively maintaining a visible representation of state and having the displayed (and hence selectable) options for future action tailored to the state at hand.

Figure 6. The Wizard UI has four major parts: The Active Map (a clone of the Active Map workspace) for simulating location contexts, the End User Screen for monitoring a user's interaction or debugging a design, the Storyboard Analysis Window for analyzing interaction logic and the Radar View for easy navigation of the Activity Map.



A Case Study

To demonstrate how an informal prototyping tool can help at an early stage of the design process and how informal prototyping can inform the later design or development process, we report on our experience with the iterative design of a location-enhanced Place Finder using Topiary. A location-enhanced Place Finder embodies many features of location-enhanced, mobile applications. It allows users to find a place of interest more efficiently by leveraging the user's location (e.g., showing a path to the destination). With the help of Topiary, we were able to efficiently explore the usability issues of map-based navigation techniques on a PDA held by a user walking in the field. Map-based navigation is a key component of a Place Finder application. Based on two design iterations that involved creating five different designs and testing them with four participants in the field as well as an analysis of implementation issues, we built a high fidelity prototype of the Place Finder.

The first iteration included four different user interface designs that shared the same the underlying map of places and paths in the Active Map workspace (see Figure 2). At each iteration, a user test was conducted in the field on a college campus, using a Toshiba Tablet PC and an HP iPAQ™ Pocket PC. During each test, the wireless communication between the two devices was based on a peer-to-peer connection so that the connection was not affected by the availability of access points in the field.

Iteration #1

It took us only three hours in total to create four prototypes, each using a different navigation technique. The first design shows a map of the entire campus (see Figure 7a). The second design shows an area centered on the user and lets the user manually zoom in and out (see Figure 7b). The third design uses the user's current location to show different regions of the campus (see Figure 7c). The last design is similar to the second, except it automatically zooms in or out based on the user's current speed (see Figure 7d). This last design was based on the idea that people are reluctant to interact with a device while walking. All four designs showed the user's current location and shortest path (see the thick pink lines in Figure 7) to the target, both of which are updated dynamically by Topiary.

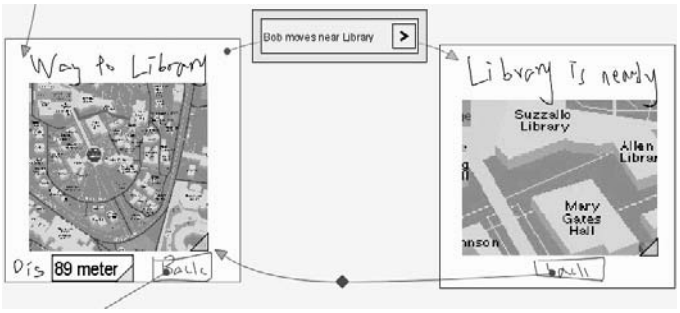
Four navigation segments were included in the test of Iteration #1, one segment for each of the four designs. These four segments were selected based on two principles. First, to smoothly connect the four experimental segments, the target of a segment should be the starting point of the following segment. Second, each segment should cover an area that requires a moderate walk, not too long or too short (e.g., an eight minute walk), and can produce a path with enough complexity to avoid simple paths (e.g., the entire path is a straight line.)

We had three participants try all four designs on a PDA in the field, with a wizard updating their location on a Tablet PC. Each experimental session lasted about one hour and each segment took about fifteen minutes to complete. During the test, we were able to make some minor changes to the design instantly in response to the participant's suggestions.

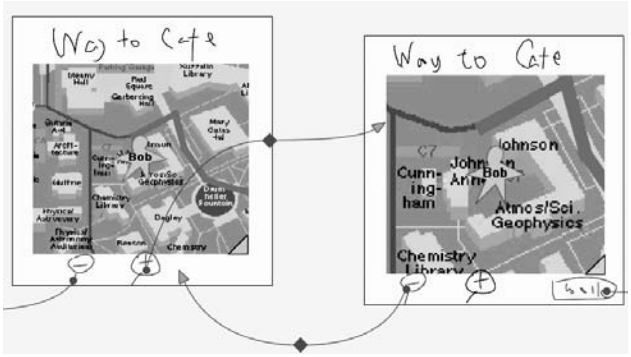
All three participants preferred the map centered on the user's current location (#2 and #4). The problem with the first design is that it shows the entire campus on a small PDA screen, which turned out to be hard to read. The third design does show more detail but it does not give a global view of the campus and the participants complained that they could not see the target until they were physically in that region, although they were still able to see the path.

Two participants preferred manual zooming to automatic zooming as they thought manual zooming gave them more control over the zoom levels. However, the other participant thought both kinds of zooming were good to use. All our participants

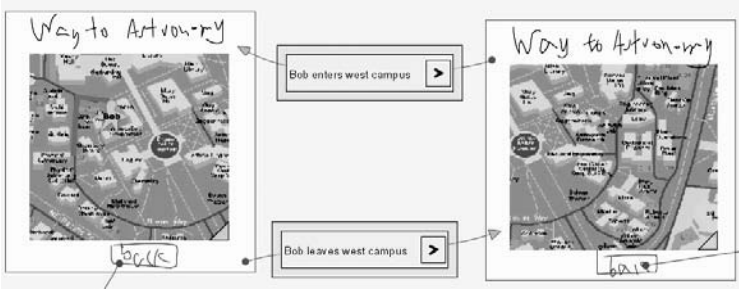
Figure 7. Storyboard fragments of the four designs in Iteration #1. A page, which holds maps and sketches, represents a screen of visual output of the user interface. Arrows (links) between pages represent transitions. The blue links represent GUI elements such as buttons for which scenarios can be used as conditions (not shown here). The green links represent transitions that can automatically take place when the associated scenarios occur.



(a) Design #1 shows the entire campus and a detailed map is automatically shown when a user gets close to a target. Here the scenario "Bob moves near library" triggers showing a detailed map around the library.

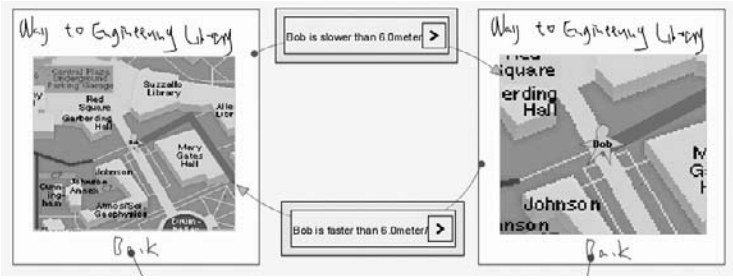


(b) Design #2 shows an area automatically centered on the user and lets the user manually zoom in or out by clicking on the sketched "+" or "–" buttons.



(c) Design #3 uses the user's current location to show different regions of the campus. Here the scenario "Bob enters (or leaves) west campus" triggers showing the west (or east) region of the campus.

continued on following page



(d) Design #4 is similar to Design #2 except it automatically zooms in or out based on the user's current speed. Here the scenario "Bob is slower (or faster) than 0.6 meter/s" triggers showing maps at different zoom levels.

thought the distance label from Design #1 was useful and they also suggested that we should flash the target when users get close to it.

One common problem with the four designs was that there was not enough orientation information provided. We originally thought users could figure out their orientation by referring to nearby buildings and the continuous change of their location on the map.

Iteration #2

Based on participant feedback and our observations during Iteration #1, we spent *one hour* creating a new design combining the best features of the four designs (see Figure 8). We added a page for users to choose automatic or manual zooming (see Figure 8a). We explored different ways of showing orientation on a map, including rotating the map, showing an orientation arrow, and showing trajectory arrows (see Figure 8b). These orientation representations are provided by Topiary. In addition, in response to the participants' request, we added the feature of flashing a target when it is nearby. We tested this new design again with three people[1]. Each test session lasted about half an hour in total. In the middle of the test, we turned on the sensor input that is built into Topiary to see how sensor accuracy affected our participants.

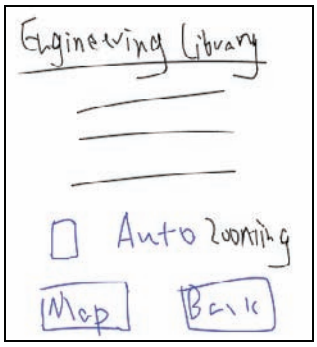
Our participants gave us many useful comments. For example, two of them suggested showing a movement trail to help to indicate orientation. Also, the inaccurate update of the user's location, either by the Wizard or by the sensor input (while it was turned on), did confuse the participants. As a result, one person suggested showing a region for the possible location instead of just a point. They also gave us some other suggestions, such as placing the distance label at the top of the screen rather than at the bottom.

Interestingly, some of our participants did not realize their location was being updated by a wizard rather than by real sensors. It was also observed that the prototype showed an optimal path to a participant who had spent three years on the campus but did not know the existence of this path. We did not know this path either and we simply drew a road network in Topiary by which this path was automatically constructed by the tool.

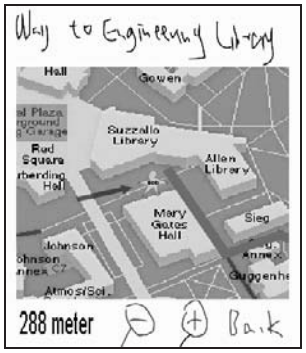
Building a High Fidelity Prototype

Through these two iterations of informal prototyping and testing, we got a rough view of what the Place Finder should be like. Then it was the time to consider implementation issues and to create a high fidelity prototype. Because we did

Figure 8. Two screens (pages) of the new design



(a) A user can select or deselect the checkbox to choose automatic or manual zooming.



(b) A map screen with zooming buttons and a trajectory arrow

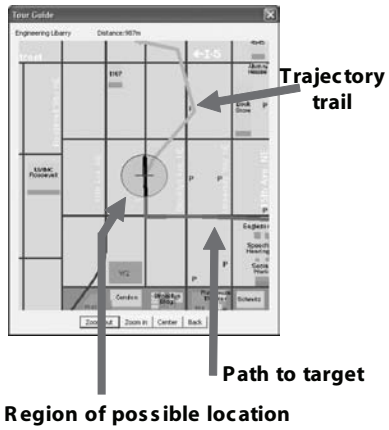
not want to add an extra device, like GPS, for the Place Finder PDA, we chose to use Place Lab for location sensing, since it requires only WiFi. However, Place Lab, like GPS, cannot provide precise orientation. As a result, we decided to show a movement trail (feedback from the earlier study) instead of showing potentially inaccurate directional arrows or employing map rotation. In addition, because the movement speed cannot be accurately measured, we cut the automatic zooming feature, although one participant showed interest in it. This also helped improve application performance on the PDA.

Based on the earlier tests and an analysis of the implementation issues, we built a high fidelity prototype in Java, using the IBM J9 SWT Java toolkit, in about *two weeks* (see Figure 9). We have used this prototype in the field for hours and it has helped us to find places that we had never been to before. We also got positive feedback from people to whom we demoed this prototype. However, performance on the PDA is still a major issue with this prototype and more profiling is necessary before widely testing it.

Lessons Learned

This study offers lessons in two areas. First, it identified usability issues as well as solutions for building map-based navigation techniques in a

Figure 9. The high fidelity prototype was built based on the informal prototypes and an analysis of implementation issues



location-enhanced Place Finder application. Second, the study gives an example of how early stage design iteration can be conducted using informal tools. The study showed obvious advantages over traditional paper prototyping since we were able to test our ideas in the field and leverage those results for later stage development.

Informal prototyping and testing in *hours* was much less expensive than directly building a high fidelity prototype over a period of *weeks* and then testing it with users. The tools allowed us to focus on interaction rather than implementation details. It turned out that little feedback from our participants was related to the informal look of the interface. *Focusing on key interactions* rather than specifying the behaviors of the entire application is important to efficiently conducting early stage design because prototyping tools often employ example-based approaches. In our study, only five places were modeled for testing the five low-fi designs. Once the early usability issues were solved, the design was scaled up to 35 places in the high fidelity prototype.

Carefully testing in the field is important for a successful early stage design because the field is where a mobile application design will be used. Testing in the field requires extra consideration when compared to controlled experiments in a lab setting. The *Wizard of Oz* technique was extremely useful in testing an early stage design since it can reasonably approximate realistic situations. On the other hand, using real sensor input, if not expensive, might help find more usability problems due to the inaccuracy of sensors in a test.

FUTURE TRENDS

Sensors such as accelerometers are becoming available on an increasing number of mobile devices to detect a user's context (e.g., movement, lighting or ambient noise) as well as other peripheral input (e.g., digital compass for the orientation of the device). With these sensors, richer interactions can be constructed. It is important for informal prototyping tools to support interaction design based on the available sensors of the platform. Multimodal interaction that combines multiple interaction modalities has shown promise. Speech-based interaction enhanced by location context is an extremely promising

research direction. By leveraging location context, a system can optimize speech recognition by focusing on phrases that have meaning in a particular context. This brings new research opportunities to the rapid prototyping of mobile technology. The two tools that we discussed in this chapter address speech-based interaction and location-enhanced computing separately. It would be interesting to combine the strengths of these types of tools for prototyping location-enhanced speech user interfaces.

CONCLUSION

Informal prototyping tools play an important role in the early stage design of interactive mobile technology. They lower the threshold for entry and reduce the cost for prototyping and testing. As a proof of concept of informal prototyping tools for mobile interaction, we discussed how SUEDE and Topiary address the design of speech-based interaction and location-enhanced interaction, respectively, the two representative types of interaction for mobile technology. We highlight two common features of these tools: graphical storyboarding and Wizard of Oz testing. To show how these tools can help an iterative design process, we reported on our experience in iteratively prototyping a location-enhanced Place Finder application, and testing its prototypes with real users in the field. The study indicated that this type of tool allowed a designer to effectively explore a design space in the early stages of design. As mobile computing becomes more powerful and prevalent, there will be more opportunities for research on informal prototyping tools for the design and evaluation of interactive mobile technology.

KEY TERMS

Graphical Storyboarding: A technique that informal prototyping tools often employ for designers to describe how an interface should behave. Like a state transition diagram (STD), it has the concepts of states and transitions. However, in graphical storyboarding these states and transitions represent high level UI components or events rather than the computational elements found in a traditional STD.

Informal Prototyping: A type of user interface prototyping used in the early stages of design in which designers explore a design space by focusing on key interaction ideas rather than visual (e.g., color or alignment) or implementation details. These details are often better considered when creating **hi-fidelity** prototypes at a later stage. Paper prototyping is a representative form of informal prototyping in which designers draw interfaces as well as interaction flows on paper.

Informal UI Prototyping Tools: A type of UI prototyping tool that fluidly supports an informal UI prototyping practice. These tools maintain an "informal" look and feel, use fluid input techniques (e.g., sketching) and can automatically generate testable, interactive prototypes.

Location-Enhanced Applications: Computer applications that leverage the location of people, places and things to provide useful services to users. For example, based on the user's current location, show the nearby restaurants or friends. By using the location context, this type of application reduces explicit input required from a user (such as mouse clicks or typing).

Sketch-Based User Interfaces: A type of user interface in which users interact with a computer system by drawing with a pen. The drawings can be recognized and interpreted as commands, parameters or raw digital ink. This type of interface has shown promise in supporting domains such

as UI design, mechanical design, architectural design and note-taking.

Speech-Based Interfaces: A type of user interface in which the user input is submitted mainly via speech. A computer system responds based on either recognized words or vocal variation of the speech. The interface output is typically auditory (e.g., when it is on a phone) or visual.

User Interface Prototyping: A practice of creating user interface mockups to test some aspects of a target interactive system.

UI Prototyping Tools: Electronic tools supporting a user interface prototyping process.

Wizard of Oz Testing: A technique for testing an incomplete interface mockup, named after the movie the *Wizard of Oz*. In this technique, a wizard (often played by a designer) fakes an incomplete (or nonexistent) system component to conduct early user evaluations, (e.g., a wizard can simulate speech recognition when testing a speech-based interface or location tracking when testing a location-enhanced application).

Chapter 3.14
Real–Time 3D Design Modelling of Outdoor Structures Using Mobile Augmented Reality Systems

Wayne Piekarski
University of South Australia, Australia

ABSTRACT

This chapter presents a series of new augmented reality user interaction techniques to support the capture and creation of 3D geometry of large outdoor structures. Named construction at a distance, these techniques are based on the action at a distance concepts employed by other virtual environments researchers. These techniques address the problem of AR systems traditionally being consumers of information, rather than being used to create new content. By using information about the user's physical presence along with hand and head gestures, AR systems can be used to capture and create the geometry of objects that are orders of magnitude larger than the user, with no prior information or assistance. While existing scanning techniques can only be used to capture existing physical objects, construction at a distance also allows the creation of new models that exist only in the mind of the user. Using a single AR interface, users can enter geometry and verify its accuracy in real-time. Construction at a distance is a collection of 3D modelling techniques based on the concept of AR working planes, landmark alignment, constructive solid geometry operations, and iterative refinement to form complex shapes. This chapter presents a number of different construction at a distance techniques, and are demonstrated with examples of real objects that have been modelled in the physical world.

INTRODUCTION

Current research in AR applications has focused mainly on obtaining adequate tracking and registration and then developing simple interfaces to present display information to the user (Azuma

et al., 2001). One important problem that has not been fully addressed is the authoring of the content that is displayed to the user. Since most AR systems are being used simply as a visualisation tool, the data is prepared offline with standard editing tools and then transferred to the AR system. While ourselves (Piekarski & Thomas, 2003) and others (Baillot, Brown, & Julier, 2001) have started to investigate outdoor AR modelling, this work is very preliminary and incomplete. Brooks states that one of the still unsolved problems in VR is the creation and capture of 3D geometry (Brooks, 1999), which is also relevant for AR models. To develop content for AR systems, we have developed a number of techniques collectively termed *construction at a distance* (CAAD). These techniques use the AR system itself to capture the 3D geometry of existing structures in the physical world, and create new 3D models of virtual objects that do not yet exist. CAAD makes use of the AR working planes and landmark alignment techniques presented in a previous paper (Piekarski & Thomas, 2004), and builds higher-level operations to perform the capture and creation of 3D models. While some of these CAAD techniques have been presented previously (Piekarski et al., Thomas, 2003), in this chapter, I describe new body-relative plane techniques and expand on previous work with a discussion of how AR working planes are used in the implementation.

The introduction section in this chapter describes the advantages of these modelling techniques over other existing methods. Next, the techniques are described over three sections and how they are implemented on a mobile outdoor AR system. An overview of the user interface that supports these techniques is discussed, followed by a discussion on the use of different viewpoints to support situational awareness. The chapter is then concluded with a discussion of possibilities for collaboration, and how the accuracy of the techniques are affected by various environmental factors.

Supplement Physical Capture L imitations

The purpose of these techniques is not to replace existing object capture methods, such as image-based reconstruction (Debevec, Taylor, & Malik, 1996) or laser scanning. These techniques are highly accurate and can produce excellent results given the proper conditions. However, there are a number of limitations and CAAD provides an alternative to existing techniques in the following ways:

- A human operator is capable of accurately estimating the geometry of planar shapes, even when partially occluded by other objects in the environment. When trees occlude the edges of a building, a human can estimate the layout based on incomplete visual information and a knowledge of the volumetric properties of buildings.
- The eye is a highly accurate input device capable of aligning along the walls of buildings (Cutting & Vishton, 1995; Piekarski et al., 2004). Accurate modelling is still possible when working from a distance and direct access to the object is not available.
- Existing capture techniques (Debevec et al., 1996) have a fixed operation time no matter what the complexity of the scene is, whereas in my methods the human can judge the most appropriate level of detail. In many cases, the user wants to create only simple shapes such as boxes to represent buildings, and so these techniques are ideal for quick operations.
- Existing techniques require the object to already exist so it can be captured, whereas my methods allow the human to specify any geometry desired. My techniques allow the creation of new shapes that do not physically exist and may be used to plan future construction work.

It is important to realise that there are limitations introduced by the resolution and accuracy of the tracking devices used to record the inputs. For example, when using a GPS accurate to 50 centimetres the object size that can be modelled is in the order of metres (such as a car), while using a 1 millimetre magnetic tracker allows much smaller objects (such as a drink can). This research does not attempt to address problems with registration or accuracy of tracking devices, but instead works within the limitations of current technology to provide the best solutions that can be achieved.

Working at a Fixed Scale

A number of VR techniques have been developed for use in modelling applications. These applications traditionally provide tools to create and manipulate objects in a virtual world, and to fly around and perform scaling operations to handle a variety of object sizes. While techniques for action at a distance such as spot lights, selection apertures, and image plane techniques (Pierce et al., 1997) have been developed, these only perform simple selections on existing objects and cannot be used to create new ones due to the lack of generating distance values. Techniques such as flying, worlds in miniature (Stoakley, Conway, & Pausch, 1995), and scaled world grab (Mine, Brooks, & Sequin 1997), can perform the creation of points by bringing the world within arm's reach, but accuracy is affected by the scale. Due to their non-exact freehand input methods, all of these systems are also limited to conceptual modelling tasks and not precision modelling. CAD systems use snapping functions or exact numerical entry to ensure accurate inputs, but require an existing reference to snap to or non-intuitive command-based entry.

Although AR environments share some similar functionality with VR, AR is unique in that it requires registration of the physical and virtual worlds. Flying and scaling operations require the breaking of AR registration and so cannot be used. Scaled world representations force the user to divert their attention from the physical world to perform miniature operations within the hands. Existing VR techniques cannot create models of objects the size of skyscraper buildings without breaking the 1:1 relationship between the user and the virtual world. With CAAD techniques, the scale of the world is fixed and only the user's head position controls the view. The virtual geometry is created using absolute world coordinates and is always registered and verifiable against the physical world in real-time. By using the physical presence of the user as an input device, the body can be directly used to quickly and intuitively control the view rather than relying on a separate input device.

Humans are much more capable of accurately estimating and specifying horizontal and vertical displacements compared to distances (Cutting et al., 1995). By using the AR working planes and landmark alignment techniques described previously (Piekarski et al., 2004), simple 2D input devices can be used to draw points in 3D. An AR working plane can be defined at any time from the body along the direction of view (maximising accuracy with landmark alignment) or relative to an existing object (maintaining the same accuracy as the source object), and the user can then move around to a different angle to draw against this surface. With AR working planes, the user is able to draw points that are at large distances and at locations that are not normally reachable, maintaining a 1:1 relationship between the virtual and physical worlds. The techniques in this chapter require any simple 2D input device with a cursor to draw against the AR working plane, with this particular implementation using a glove with fiducial-marker based tracking.

Iterative Model Refinement

CAAD relies on a set of fundamental operations that by themselves cannot generally model a physical world object. Combining a series of these fundamental operations by making iterative improvements can produce complex shapes how-

ever. As the modelling operation is taking place the user can see how well the virtual and physical objects compare, repeatedly making changes until the desired quality is gained. Constructive solid geometry (CSG) techniques used by CAD systems also rely on this principle to produce highly complicated shapes that would otherwise be difficult to specify. The ability to instantly verify the quality of models against the physical world helps to reduce errors and decrease the total modelling time. The process of iterative refinement for VR modelling is discussed by Brooks (1999), and he recommends that a breadth-first iterative refinement strategy is the most efficient. I use these VR guidelines for the proposed CAAD techniques, and take the refinement process one step further by using the unique ability of AR to compare virtual and physical worlds simultaneously.

Simplified Techniques

Some techniques have been developed previously for the interactive creation of data in virtual environments with no prior information. The CDS system by Bowman can create vertices by projecting a virtual laser beam against the ground plane (Bowman, 1996). By connecting these points together and extruding the 2D outline upwards, full 3D solid objects can be created although they are limited in complexity by being constant across the height axis. Baillot et al. performed the creation of vertices located at the intersection of two virtual laser beams drawn from different locations (Baillot et al., 2001). After defining vertices, these can then be connected together to form other shapes of arbitrary complexity, limited only by the time available to the user. Since these techniques both operate using vertex primitives that are then connected into edges, polygons, and objects, the complexity of this task increases as the number of facets on the object increases. Rather than treating objects as collections of vertices like the previously mentioned work, CAAD mainly operates using surfaces and solid objects, so an object with 10 facets can be modelled in 10 steps rather than as 20 vertices and 30 edges.

DIRECT OBJECT PLACEMENT TECHNIQUES

This section describes techniques involving the direct placement of objects within arm's reach. While not being truly CAAD, these techniques may be used as inputs for other operations. The simplest way to perform modelling is to use prefabricated objects and place them at the feet of the user as they stand in the environment, when commanded by the user. I have termed this technique street furniture, as it can be used to place down objects that commonly occur on the street (Piekarski et al., 2003). Furthermore, using the AR working planes techniques (Piekarski et al., 2003; Thomas 2004) the user is able to translate, scale, and rotate these objects in the AR environment. The street furniture method works well when objects to create are known in advance, and the user can avoid having to model the object each time. While this technique is not at a distance according to our requirements, it is the most basic and simplest operation that can be performed using a mobile outdoor AR computer. It is possible to use direct placement of markers at the feet to specify vertices and extrude the object upwards, but this is not always practical in the physical world because the user cannot stand on top of a building to mark its outline. Later techniques described in this chapter use direct placement for the creation of infinitely sized plane surfaces in the environment.

BODY-RELATIVE PLANE TECHNIQUES

This section describes a series of CAAD techniques based on the user's physical presence in the environment. Using simple head-based pointing,

the geometry of planes originating from the body can be specified, taking advantage of the user's sense of proprioception (Mine et al., 1997). Using CSG techniques, these planes can be used to easily define solid building shapes out of arm's reach. Since many buildings in the physical world can be modelled using planes, the process of modelling can be accelerated compared to the simplistic approach of creating each vertex and edge manually.

Orientation Infinite Planes

Buildings in the physical world tend to approximate collections of angled walls in many cases. A solid convex cube can be formed with the specification of six planes arranged perpendicular to each other and a CSG intersection operator. Instead of specifying these planes numerically, the user can create these same planes in an AR environment by projecting them along the line of sight. By looking along the plane of a wall of a building and aligning the two ends, the user can project an infinite plane along this wall in a similar way to AR working planes. Each plane defines a half space that when combined with a CSG intersect operation will form a finite solid shape.

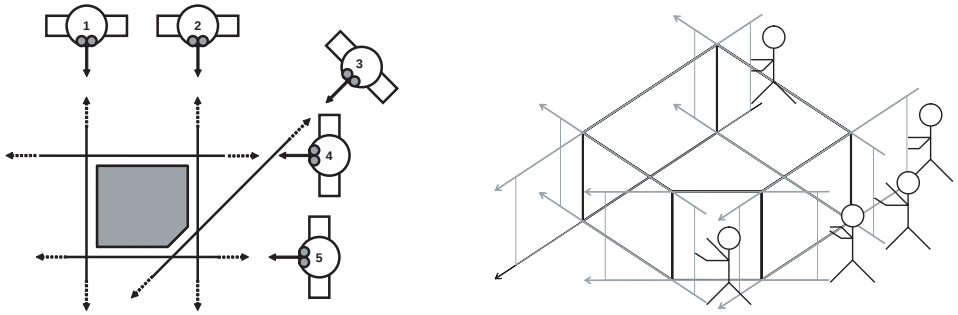
Figure 1 depicts a five-sided building and the location of the mobile AR user as they are sighting down each of the walls, showing the infinite volume being iteratively bound by the infinite planes. At the beginning of the operation, the AR system creates an (approximately) infinite solid volume that will be used for carving. When the user is aligned with a wall, they project an infinitely long vertical plane along the view direction into the world. This plane divides the previous infinite solid into two parts and the left or right portion (decided by the user) is carved away from the solid and removed. As the user sights along each wall, the solid will be reduced down to an object that is no longer infinite in the X and Y axes. At completion, a floor is automatically created at ground level, and the roof is left unbounded for carving using other techniques, since it is impractical to sight along the roof of a very tall building. The final 3D shape is stored using absolute world coordinates and reflects the geometry of the physical building.

With this technique, the object can be carved away iteratively and the user receives real-time feedback of the infinite volume being bounded, allowing immediate undo in case of a mistake. Compared to the direct methods described previously, this plane-based technique allows the capture of buildings from a distance without having to actually stand next to or on top of the building. Since the user is in direct control of the modelling process, the positions of occluded surfaces can be estimated using their knowledge of the environment. These features are useful because many existing physical capture methods require a full view of the object, GPS trackers do not work well near large buildings, and standing on top of a building may not be possible or too dangerous. This technique is also much more efficient than vertex and edge specification since each wall is handled with a single primitive that is easy to create accurately. A limitation of this technique is that using only planes and a CSG intersection to define objects restricts usage to convex buildings with no indentations, and this will be addressed further at the end of this section.

Position Infinite Planes

Another limitation of the orientation infinite planes technique is the dependence on an orientation sensing device for the head. While RTK GPS units may have reliable accuracies in the order of 2 cm, orientation sensors vary in accuracy due to problems with interference and limitations of the technology. These variations affect the placement of planes in the environment and as the distance from the user increases, angular errors cause increasing positional errors, but using techniques that can avoid the use of orientation

Figure 1. Infinite carving planes used to iteratively create a convex shape from an infinite solid



sensing should be able to produce much more accurate results.

In order to take advantage of the stability of position tracking, the orientation infinite planes technique described earlier can be modified to use two or more position points to specify orientation, making it invariant to errors in orientation tracking devices. Using the same landmark alignment concept discussed previously, the user can accurately sight along a wall and mark a position. To indicate direction, the user walks closer while maintaining their alignment and marks a second point. These two points can then be used to project an infinite carving plane. By increasing the spacing of the marker points or using a line of best fit amongst multiple points, the accuracy of this technique can be further improved.

The accuracy of this technique can be calculated based on the positional error of the GPS and the distance between the two marker points. To make this technique useful, it must have an accuracy that is better than is available using traditional orientation sensors. As an example, when a maximum allowable error of 1 degree is assumed, an RTK GPS unit with 2 cm accuracy will require a distance of 1.1 metres between the points. If 10 or more metres is used then the orientation accuracy will be orders of magnitude better than previously possible.

Fixed Infinite Planes

This technique is similar to the position infinite planes technique in that it is invariant to orientation sensing errors. The previous technique required the user to specify the orientation for each plane by using two points, but if the angles at each corner are known to be equal then only one orientation is needed and the others can be calculated automatically. The user creates the first plane using the same method described previously, but for each additional plane, only one position marker is recorded. Based on the number of positions marked, the system knows the number of walls to create and calculates the orientation for each position point based on the first plane. This technique uses nearly half the number of points and yet produces the same accuracy if the first plane is properly placed and the building meets the required properties.

CSG Operations

Many objects in the physical world are not the same shape as simple boxes, cylinders, spheres, and cones. While it may seem that many objects are too complicated to model, they may usually be described in terms of combinations of other objects. For example, the process of defining a cube with a hole using vertices is time consuming,

but can be easily specified with a CSG operation. CSG is a technique commonly used by CAD systems, supporting Boolean set operations such as inversion, union, intersection, and subtraction. The manufacture of objects in the physical world is also performed in a similar manner—a drill can be used to bore a hole very easily out of a solid cube. An example of CSG being used outdoors is applying the CSG difference operator to subtract cubes from a building shape. This could be used when the user needs to carve out indented windows. In Figure 2 part 1a and 2a, the user places a cube at a distance, and then drags it sideways until it enters the building shape. Alternatively, in Figure 2 part 1b and 2b, the cube is pushed into the surface of the building (similar to a cookie cutter), and requiring closer access to the building. As the cube is being positioned by the user, the CSG difference operator is interactively calculated and displayed to the user. Infinite planes are normally limited to producing only convex shapes, but using CSG techniques allows us to produce more complex concave shapes very intuitively.

AR WORKING PLANES TECHNIQUES

This section describes a series of CAAD techniques based on AR working planes (Piekarski & Thomas, 2004). The previous techniques are capable of placing prefabricated objects and capturing bounding boxes for large objects, but detailed modelling is not provided. Using AR working planes and a 2D input device, the user can specify much more intricate details to create realistic 3D models.

Projection Carving

The projection carving technique modifies existing objects by projecting points against surfaces and then cutting away extrusions to produce new highly concave shapes. This technique provides the ability to construct features such as zig-zag roofs and holes that are difficult or impossible to model using previously described techniques. Figure 3 depicts an example of how this technique can be used to carve two peaked roofs onto a building model. These building models may have been created using infinite planes and projection carving can be used to restrict the infinite roof to a finite volume. The AR working plane is created relative to a polygon that has been selected by the user. The object that contains the polygon is then used as the input for the upcoming carving operation. The user then creates vertices along the surface of the AR working plane and these are connected together to form a 2D concave outline. This outline is then extruded along the surface normal of the working plane and used as an input tool for a CSG difference carving operation.

The projection is performed using orthogonal extrusion from the AR working plane, and is position invariant so points can be entered from any location in front of the polygon. This enables the user to cut a flat roof on a 100 metre high building while standing at ground level and looking up. If the cursor was used to carve the object directly like a laser beam, the system would produce pyramid-shaped extrusions. For some buildings, the user may only desire to create a flat roof or a single slope, and by creating only one point the system will create a horizontal cutting plane, and with two points a diagonal cutting plane is created. More than two points implies the user wishes to cut with an outline and so it must be fully specified as in Figure 3. The CSG operation can be switched from difference to intersect if desired, with the effect being that the user can cut holes or split an object into separate parts instead of carving the outside. Used in this form, orthogonal extrusion is limited to carving operations that can be seen in a silhouette representation—other features such as indentations that are not visible from the side can not be captured with this technique. Some of these limitations can be overcome by limiting the depth of the extrusion used for carving. By using a small fixed value or controlling it by moving the

Figure 2. Box objects can be moved into a building surface to carve out windows

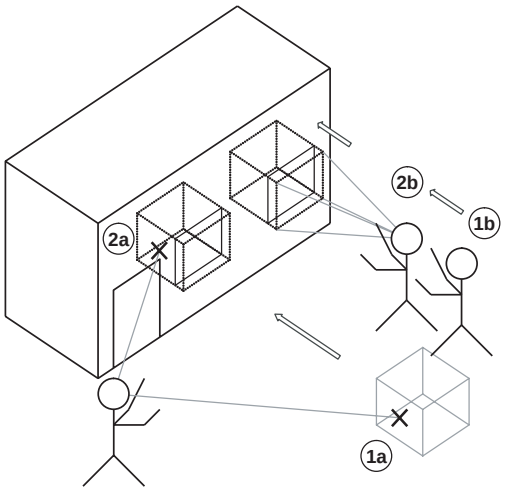


Figure 3. AR working planes are used to specify vertices and are projected along

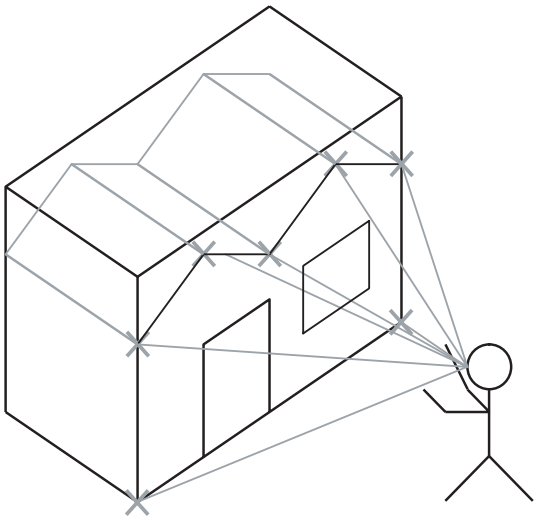

body forward or backward, the extrusion can be controlled by the user and used for features such as windows or doors.

Figure 4 depicts the projection carving operation on a box that has been edited to match the shape of a building with a pitched roof. A second example demonstrating this technique is a small automobile being modelled outdoors in Figure 5. In both cases, a larger volume is placed down and the user then intersects points against the box surface to define the silhouette. Each frame in Figure 5 shows the process of specifying the solid region that approximates the car in the physical world. The object can then be carved along any of the other faces to further refine the model until it suits the user's requirements.

Projection Colouring

Once a building has been created, the user may desire to place windows, doors, and other extra details onto the model. While it may be possible to draw these details onto a texture map (which cannot be zoomed arbitrarily), or to place extra polygons outside the building to represent these (covering the original building), the building model itself remains untouched. If these new polygons are removed or manipulated, the original solid object remains since the changes are only superficial. A more desirable scenario is that polygons of a different colour are actually cut into the subdivided surface of an object, so that if they are deleted it is possible to see features inside the object that were previously concealed. I have named this technique projection colouring, and using similar steps as projection carving, vertices are projected against an AR working plane created relative to the surface and then connected into an outline. Instead of carving away the outline, the surface is subdivided and the colour of the outlined polygon is modified. The newly coloured polygons may then be deleted or manipulated freely by the user if desired. For example, a window and door can be cut out, with the door then openable using a rotation. Individual manipulation would not be possible with only the surface texture being modified.

Surface of Revolution

When working outdoors and modelling natural features such as trees and artificial features such as fountains, box-shaped objects are usually poor approximations to use. In an attempt to model these objects, surface of revolution techniques (as used in many desktop CAD systems) have been used to capture geometry that is rotated about an axis. The user starts by creating an AR working plane in the environment, with the most intuitive way being to sight toward the central trunk of the tree and project the AR working plane along the view direction. The user then projects vertices onto the AR working plane, defining one-half of the outline of the object. After specifying the vertices along the axis of rotation, the system generates a solid object by rotating the outline around the axis. Figure 6 shows an example where the vertices of a tree have been specified with a preview shape generated, along with the final shape from an external VR view. This technique generates good results when modelling natural objects such as pine trees that are highly symmetrical about the trunk. For trees that grow with deformities and other non-symmetrical features this technique may not generate suitable approximations. To improve the approximation, previously described carving techniques may be applied to refine the model until the user is satisfied with the object.

Texture Map Capture

When implementing live AR video overlay, the system can automatically match up images from the camera to polygons in the scene. Captured models are normally only presented using a single colour and texture maps increase the realism for users without having to add extra polygons for detail. To perform texture map capture, the user stands at a location where the texture for an object's polygon is clearly visible to the camera. The user selects the polygon to activate capture mode and the system projects the polygon vertices onto the AR video overlay to map the still image as a texture. The user repeats this operation for each polygon until the object is completely textured.

The best results for this technique are obtained when the object is fully visible and fills as much of the HMD as possible. Also, keeping the surface perpendicular to the user's viewing direction ensures that the texture is distorted as little as possible. Although techniques for capturing textures of 3D models have been described previously, this has not been performed in a mobile outdoor AR environment. Previously discussed work by Debevec et al. implemented

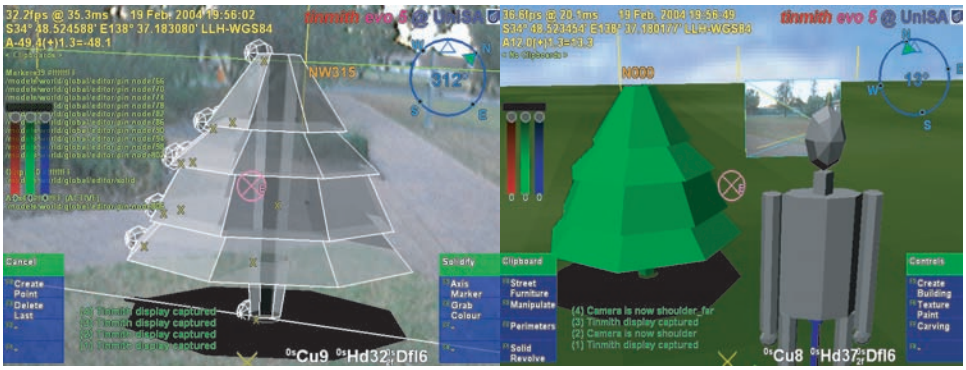
Figure 6. (a) AR view of surface of revolution tree with markers on AR working plane (b) VR view of the final surface of revolution tree model as a solid shape



the capture of 3D models from photographs and extracted textures for each facet (Debevec et al., 1996). Lee, Hirota, and State also implemented the capture of textures in AR but with surfaces being modelled within arm's reach using a wand, with the system automatically capturing textures when video frames were deemed suitable (Lee et al., 2001). The video stream used with mobile AR suffers from problems with motion blur and tracker registration, and having the user choose the moment to capture the texture generates the highest quality models.

USER INTERFACE

The user interface is made up of three components: a pointer based on the tracking of the thumbs with a set of gloves worn by the user, a command entry system where the user's fingers interact with a menu for performing actions, and an AR display that presents information back to the user. The display for the interface is fixed to the HMD's screen and presents up to ten possible commands as menu options at any one time. Eight of these commands are mapped to the fingers as depicted in Figure 7, and the user activates a command by pressing the appropriate finger against the thumb. When an option is selected, the menu refreshes with the next set of options that are available. Ok and cancel operations are activated by pressing the fingers into the palm of the appropriate hand and are indicated in the topmost boxes of the menu. The interaction cursors are specified using fiducial markers placed on the tips of the thumbs, as shown in Figure 4 and Figure 5. With the use of vision tracking for cursor position, and metallic pads for finger press detection, it is possible to control the user interface in the harsh environmental conditions experienced outdoors. As discussed previously, a 2D input device is required to specify 3D points using the AR working planes techniques. This user interface provides the necessary 2D cursor to support this, as well as the command entry capability to control the various techniques described in this chapter.

EXTERNAL VIEWPOINTS

Our user interface is typically operated in an immersive mode where virtual objects are registered with the physical world. This view is intuitive because it is similar to how the user normally experiences the physical world. This view may cause problems in situations where very large objects such as buildings may exceed the field of view of the display, objects may be too distant to clearly view, or other objects may be occluding an object of interest. The immersive view restricts the user if it is impractical or impossible for the user to move to a new viewing position. In these cases, it is more useful to work in an external VR style view such as orbital view (Koller, Mine, & Hudson, 1996), where the user sees the virtual world from an external perspective. The advantages of external views are also discussed by Brooks, who mentions that users find a local map of the world useful to show where they are, what they are looking at, and to build a mental model for navigation (Brooks, 1988).

In the external views included in this chapter, the ground and sky are both rendered using texture maps so that the user understands they are looking at a fully virtual view and are no longer immersive. Since the external view is designed to be used while wearing the HMD outdoors, the body of the user is shown in the centre of the display and motion about the physical world is updated in real-time. Top down views, such as that shown in Figure 8(a), provide an aerial perspective of the area, with the display being fixed in north up mode or rotating freely according to the user's current view direction. In this example, an aerial photograph has been used instead of a grass texture to provide additional situational awareness. Orbital views such as that shown in Figure 6(b) and Figure 8(b) link all 3DOFs of head rotation

Figure 7. Each finger maps to a displayed menu option, the user selects one by pressing the appropriate finger against the thumb

to orbiting motions at a fixed distance around the user. These external views are generally only used while stationary because the physical world is completely blocked out and the user may not be able to safely move. The user is able to adjust the camera view using body position or head rotation (as discussed previously) but not hand gestures, and can freely switch between immersive and a number of pre-programmed external views using menu commands.

COLLABORATIVE MODELLING SCENARIO

While a number of techniques can perform the modelling of simple and useful shapes, the true power of CAAD is expressed when techniques are iteratively combined to produce more complicated real-world shapes. Furthermore, the usefulness of a system is enhanced when models can be collaboratively viewed by others at the same time. Customers, architects, and developers both onsite and at remote locations could work together to design buildings and landscapes. A user with a mobile AR system would walk outside to an empty piece of land to create a landscape to preview and perhaps construct in the future. The user creates the outline of the building using infinite planes and then carves out the roof of the building. Doors and windows are then added to the surface of the object. To finish off the model, the outline of a swimming pool can be added, and various street furniture accessories such as tables and chairs are added. Within 10-15 minutes, the user has created a simple model that they can iteratively adjust until they are happy with it.

Using the distributed nature of the Tinmith-evo5 software architecture (Piekarski & Thomas, 2003), indoor users can be connected so they can monitor the progress of the modelling operation on large fixed indoor displays. Using wireless 802.11 networks, the state of the remote system is sent indoors along with two-way voice data so the users can discuss the operation in progress. State information includes the full scene graph and tracking information, so the indoor display is able to reproduce any part of the outdoor system's state as required. The only current limitation is that live video is not streamed over the network due to bandwidth limitations. The indoor users could be remote experts such as architects or developers, observing the design that the customer wants and making comments in real-time. At the completion

Figure 8. (a) Top down view with aerial photography to improve situational awareness, (b) orbital view centred on the user showing building under construction

of the design, the indoor users can extract the model as VRML and then convert it into a proper set of building plans for construction.

OPERATIONAL PERFORMANCE

The CAAD techniques rely on the position and orientation sensors for all tracking, and so increasing the accuracy of these devices will produce improved results and affect the minimum model size that can be properly captured. Errors from each sensor have different effects on the captured models since one is measured as a distance and the other as an angle. Systems such as OSGAR (Coelho, MacIntyre, & Julier, 2004) attempt to model these errors for the registration of information, dynamically adjusting the display depending on the sensor errors. However, when rendering the AR display during 3D modelling, results are also affected not only by the errors in the current tracker data, but also those from the capture process. The position sensor used in these examples is a Trimble Ag132 GPS, with an accuracy of better than 50 centimetres and working reliably amongst small buildings and light tree cover. For orientation, an InterSense IntertiaCube2 hybrid magnetic and inertial sensor is used, although the tracking is unreliable when there are magnetic distortions present in the environment or when the user is moving quickly.

When modelling a new object, the accuracy of projection-based techniques is dependant on the user's current location and the direction they are looking. For the highest accuracy, it is desirable to be as close to the object as possible, minimising the distance the projection can stray from the desired direction caused by angular errors in the orientation sensor. When viewing an existing virtual object, the registration errors with the physical world caused by the GPS will be the most accurate when viewed from a distance due to perspective, while standing very close to an object will cause these errors to be more noticeable. For registration errors caused by the InertiaCube2, these remain constant on the display at all distances due to their angular nature.

CONCLUSION

This chapter has presented my novel CAAD techniques, designed to support the capture and creation of 3D models in outdoor environments using AR. CAAD takes advantage of the presence of the user's body, AR working planes, landmark alignment, CSG operations, and iterative refinement to perform modelling tasks with mobile

AR systems. When used in an AR environment, users can capture the geometry of objects that are orders of magnitude larger than themselves without breaking AR registration or having to touch the object directly. These modelling techniques are intuitive and support iterative refinement for detail in areas that require it with AR providing real-time feedback to the user. While existing techniques are available for the capture of physical world objects, these still have limitations and also cannot be used to create models that do not physically exist. The CAAD techniques were field tested using a number of examples to show how they may be applied to real world problems. By discussing insights gained from these examples, I have identified areas for improvement that currently cause accuracy problems.

Chapter 3.15
Mobile Ad Hoc Network

Subhankar Dhar
San Jose State University, USA

INTRODUCTION

A mobile ad hoc network (MANET) is a temporary, self-organizing network of wireless mobile nodes without the support of any existing infrastructure that may be readily available on conventional networks. It allows various devices to form a network in areas where no communication infrastructure exists. Although there are many problems and challenges that need to be solved before the large-scale deployment of an MANET, small and medium-sized MANETs can be easily deployed.

The motivation and development of MANET was mainly triggered by Department of Defense (DoD)-sponsored research work for military applications (Freebersyser and Leiner, 2002). In addition, ad hoc applications for mobile and dynamic environments are also driving the growth of these networks (Illyas, 2003; Perkins, 2002; Toh, 2002). As the number of applications of wireless ad hoc networks grows, the size of the network varies greatly from a network of several mobile computers in a classroom to a network of hundreds of mobile units deployed in a battlefield, for example. The variability in the network size is also true for a particular network over the course of time; a network of a thousand nodes may be split into a number of smaller networks of a few hundred nodes or vice versa as the nodes dynamically move around a deployed area.

Ad hoc networks not only have the traditional problems of wireless communications like power management, security, and bandwidth optimization, but also the lack of any fixed infrastructure, and their multihop nature poses new research problems. For example, routing, topology maintenance, location management, and device discovery, to name a few, are important problems and are still active areas of research (Wu & Stojmenovic, 2004).

Characteristics of MANET

- Mobile: The nodes may not be static in space and time, resulting in a dynamic network topology.
- Wireless: MANET uses a wireless medium to transmit and receive data.
- Distributed: MANET has no centralized control.
- Self-organizing: It is self-organizing in nature.
-

A message from the source node to destination node goes through multiple nodes because of the limited transmission radius.

- Scarce resources: Bandwidth and energy are scarce resources.
- Temporary: MANET is temporary in nature.
- Rapidly deployable: MANET has no base station and, thus, is rapidly deployable.
- Neighborhood awareness: Host connections in MANET are based on geographical distance.

SOME BUSINESS AND COMMERCIAL APPLICATIONS OF MANET

An ad hoc application is a self-organizing application consisting of mobile devices forming a peer-to-peer network where communications are possible because of the proximity of the devices within a physical distance. MANET can be used to form the basic infrastructure for ad hoc applications.

Some typical applications are as follows:

- **Personal-area and home networking:** Ad hoc networks are quite suitable for home as well as personal-area networking (PAN) applications. Mobile devices with Bluetooth or WLAN (wireless local-area network) cards can be easily configured to form an ad hoc network. With Internet connectivity at home, these devices can easily be connected to the Internet. Hence, the use of these kinds of ad hoc networks has practical applications and usability.
- **Emergency services:** When the existing network infrastructure ceases to operate or is damaged due to some kind of disaster, ad hoc networks enables one to build a network and they provide solutions to emergency services.
- **Military applications:** On the battlefield, MANET can be deployed for communications among the soldiers in the field. Different military units are expected to communicate and cooperate with each other within a specified area. In these kinds of low-mobility environments, MANET is used for communications where virtually no network infrastructure is available. For example, a mesh network is an ad hoc peer-to-peer, multihop network with no infrastructure. The important features are its low cost, and nodes that are mobile, self-organized, self-balancing, and self-healing. It is easy to scale. A good example is SLICE (soldier-level integrated communications environment), a research project sponsored by DARPA (Defense Advanced Research Projects Agency) in this area for this need. The idea is that every soldier is equipped with a mobile PC (personal computer) with a headset and a microphone. SLICE is supposed to create mesh networks that handle voice communications while mapping whereabouts of soldiers and their companions.
- **Ubiquitous and embedded computing applications:** With the emergence of new generations of intelligent, portable mobile devices, ubiquitous computing is becoming a reality. As predicted by some researchers (Weiser, 1993), ubiquitous computers will

be around us, always doing some tasks for us without our conscious effort. These machines will also react to changing environments and work accordingly. These mobile devices will form an ad hoc network and gather various localized information, sometimes informing the users automatically.

- **Location-based services:** MANET, when integrated with location-based information, provides useful services. GPS (Global Positioning System), a satellite-based radio navigation system, is a very effective tool to determine the physical location of a device. A mobile host in a MANET, when connected to a GPS receiver, will be able to determine its current physical location. A good example is that a group of tourists using PDAs (personal digital assistants) with wireless LAN cards installed in them along with GPS connectivity can form a MANET. These tourists can then exchange messages and locate each other using this MANET. Also, vehicles on a highway can form an ad hoc network to exchange traffic information.
- **Sensor network:** It is a special kind of hybrid ad hoc network. There is a growing number of practical applications of tiny sensors in various situations. These inexpensive devices, once deployed, can offer accurate information about temperature, detect chemicals and critical environment conditions (e.g., generate wild-fire alarms), monitor certain behavior patterns like the movements of some animals, and so forth. In addition, these devices can also be used for security applications. However, these sensors, once deployed, have limited battery power, and the lifetime of the battery may determine the sensor's lifetime. Recently, several government agencies (e.g., NSF [National Science Foundation]) have funded research projects on sensor networks.

MAC-LAYER PROTOCOLS FOR MANET

An ad hoc network can be implemented very easily using the IEEE 802.11 standard for WLAN. Since the mobile nodes in WLAN use a common transmission medium, the transmissions of the nodes have to be coordinated by the MAC (media-access control) protocol. Here we summarize the MAC-layer protocols.

- **Carrier-sense multiple access (CSMA):** Carrier-sense multiple-access protocols were proposed in the 1970s and have been used in a number of packet radio networks in the past. These protocols attempt to prevent a station from transmitting simultaneously with other stations within its transmitting range by requiring each station to listen to the channel before transmitting. Because of radio hardware characteristics, a station cannot transmit and listen to the channel simultaneously. This is why more improved protocols such as CSMA/CD (collision detection) cannot be used in single-channel radio networks. However, CSMA performs reasonably well except in some circumstances where multiple stations that are within range of the same receivers cannot detect one another's transmissions. This problem is generally called a hidden-terminal problem, which degrades the performance of CSMA significantly as collision cannot be avoided, in this case, making the protocol behave like the pure ALOHA protocol (Fullmer & Garcia-Luna-Aceves, 1995).
- **Multiple access with collision avoidance (MACA):** In 1990, Phil Karn proposed MACA to address the hidden-terminal problem (Karn, 1992). Most hidden-node problems are solved by this approach and collisions are avoided.
- **Multiple access with collision avoidance for wireless LANs (MACAW):** A group of

researchers, in 1994, proposed MACAW to improve the efficiency of MACA by adding a retransmission mechanism to the MAC layer (Bharghavan, Demers, Shenker, & Zhang, 1994).

- **Floor-acquisition multiple access (FAMA):** A general problem of MACA-based protocols was the collision of control packets at the beginning of each transmission as all terminals intending to transmit sends out RTS (request-to-transmit) signals. In 1995, another protocol called FAMA was proposed, which combined CSMA and MACA into one protocol where each terminal senses the channel for a given waiting period before transmitting control signals (Fullmer & Garcia-Luna-Aceves, 1995).
- **Dual-busy-tone multiple access (DBTMA):** Another significant cause of collision in MACA-based protocols is collision between control packets and data transmission. This problem can be solved by introducing separate channels for control messages, which was proposed in the DBTMA protocol published in 1998 (Haas & Deng, 1998).

ROUTING PROTOCOLS FOR MANET

Routing issues for ad hoc networks with different devices having variable parameters leads to many interesting problems, as evidenced in the literature (Das & Bharghavan, 1997; Dhar, Rieck, Pai, & Kim, 2004; Illyas, 2003; Iwata, Chiang, Pei, Gerla, & Chen, 1999; Liang & Haas, 2000; Perkins, Royer, & Das, 1999; Ramanathan & Streenstrup, 1998; Rieck, Pai, & Dhar, 2002; Toh, 2002; Wu & Li, 2001). This is also validated by industry as well as government efforts such as DoD-sponsored MANET work (Freebersyser & Leiner, 2002). A good network routing protocol may be one that yields the best throughput and response time. However, the very nature of ad hoc networks adds to the requirement for a good routing protocol a set of more, often conflicting, requirements. Accordingly, a good ad hoc routing protocol should also be scalable and reliable. Various routing algorithms and protocols have been introduced in recent years.

Wireless devices are often powered by batteries that have a finite amount of energy. In some ad hoc networks such as sensor networks deployed in a hostile zone, it may not be possible to change a battery once it runs out of energy. As a consequence, the conservation of energy is of foremost concern for those networks. A good ad hoc routing protocol should therefore be energy efficient.

Routing protocols can broadly be classified into four major categories: proactive routing, flooding, reactive routing, and dynamic cluster-based routing (McDonald & Znati, 1999). Proactive routing protocols propagate routing information throughout the network at regular time intervals. This routing information is used to determine paths to all possible destinations. This approach generally demands considerable overhead-message traffic as well as routing-information maintenance. In a flooding approach, packets are sent to all destinations (broadcast) with the expectation that they will arrive at their destination at some point in time. While this means there is no need to worry about routing data, it is clear that for large networks, this generates very heavy traffic, resulting in unacceptably poor overall network performance. Reactive routing maintains path information on a demand basis by utilizing a query-response technique. In this case, the total number of destinations to be maintained for routing information is considerably less than flooding and, hence, the network traffic is also reduced. In dynamic cluster-based routing, the network is partitioned into several clusters, and from each cluster, certain nodes are elected to be cluster heads. These cluster heads are responsible for maintaining the knowledge of the topology of the network. As it has already been said, clustering

may be invoked in a hierarchical fashion.

Some of the specific approaches that have gained prominence in recent years are as follows: The dynamic destination-sequenced distance-vector (DSDV) routing protocol (Johnson & Maltz, 1999), wireless routing protocol (WRP; Murthy & Garcia-Luna-Aceves, 1996), cluster-switch gateway routing (CSGR; Chiang, Wu, & Gerla, 1997), and source-tree adaptive routing (STAR; Garcia-Luna-Aceves & Spohn, 1999) are all examples of proactive routing, while ad hoc on-demand distance-vector routing (AODV; Perkins et al., 1999), dynamic source routing (DSR; Broch, Johnson, & Maltz, 1999), temporally ordered routing algorithm (TORA; Park & Corson, 1997), relative-distance microdiversity routing (RDMAR; Aggelou & Tafazolli, 1999), and signal-stability routing (SSR; Ramanathan & Streenstrup, 1998) are examples of reactive routing. Location-aided routing (LAR; Haas & Liang, 1999) uses location information, possibly via GPS, to improve the performance of ad hoc networks, and global state routing (GSR) is discussed in Chen and Gerla (1998). The power-aware routing (PAR) protocol (Singh, Woo, & Raghavendra, 1998) selects routes that have a longer overall battery life. The zone-Routing protocol (ZRP; Haas & Pearlman, 2000) is a hybrid protocol that has the features of reactive and proactive protocols. Hierarchical state routing (Bannerjee & Khuller, 2001) and cluster-based routing (Amis, Prakash, Vuong, & Huynh, 2000) are examples of dynamic cluster-based routing.

FUTURE TRENDS AND CHALLENGES

MANET will continue to grow in terms of capabilities and applications in consumer as well as commercial markets. There are already quite useful applications of MANET in the military. Currently, it is not just an area of academic research, but also plays an important role in business applications for the future. This trend will continue in the future.

The usefulness of MANET also lies in how this technology will be integrated with the Internet and other wireless technologies like Bluetooth, WLAN, and cellular networks. Another important application of MANET will be in the area of sensor networks, where nodes are not as mobile as MANET but have the essential characteristic of MANET. We will continue to see more and more deployment of sensor networks in various places to collect data and enhance security. So, from that perspective, the future of MANET and its growth looks very promising along with its practical applications.

Although a great deal of work has been done, there are still many important challenges that need to be addressed. We summarize the important issues here.

- **Security and reliability:** Ad hoc networks use wireless links to transmit data. This makes MANET very vulnerable to attack. Although there is some work being done on the security issues of MANET, many important problems and challenges still need to be addressed. With the lack of any centralized architecture or authority, it is always difficult to provide security because key management becomes a difficult problem (Perkins 2002). It is also not easy to detect a malicious node in a multihop ad hoc network and to implement denial of service efficiently. Reliable data communications to a group of mobile nodes that continuously change their locations is extremely important, particularly in emergency situations. In addition, in a multicasting scenario, traffic may pass through unprotected routers that can easily get unauthorized access to sensitive information (as in the case with military applications). There are some solutions that are currently available based on encryption, digital signatures, and so forth

in order to achieve authentication and make the MANETs secure, but a great deal of effort is required to achieve a satisfactory level of security. The secure routing protocol (Papadimitratos & Haas, 2002) tries to make MANET more reliable by combating attacks that disrupt the route-discovery process. This protocol will guarantee that the topological information is correct and up to date.

- **Scalability:** Scalability becomes a difficult problem because of the random movement of the nodes along with the limited transmission radius and energy constraints of each node.
- **Quality of service (QoS):** Certain applications require QoS, without which communication will be meaningless. Incorporating QoS in MANET is a nontrivial problem because of the limited bandwidth and energy constraints. The success and future application of MANET will depend on how QoS will be guaranteed in the future.
- **Power management:** Portable handheld devices have limited battery power and often act as nodes in a MANET. They deliver and route packets. Whenever the battery power of a node is depleted, the MANET may cease to operate or may not function efficiently. An important problem is to maximize the lifetime of the network and efficiently route packets.
- **Interoperability:** Integrating MANETs with heterogeneous networks (fixed wireless or wired networks, Internet, etc.) seamlessly is a very important issue. Hosts should be able to migrate from one network to another seamlessly and make pervasive computing a reality.
- **Group membership:** In a MANET, sometimes a new node can join the network, and sometimes some existing nodes may leave the network. This poses a significant challenge for efficient routing management.
- **Mobility:** In MANETs, all the nodes are mobile. Multicasting becomes a difficult problem because the mobility of the nodes creates inefficient multicast trees and an inaccurate configuration of the network topology. In addition, modeling mobility patterns is also an interesting issue. Several researchers have been quite actively investigating this area of research.

CONCLUSION

The growing importance of ad hocs wireless network can hardly be exaggerated as portable wireless devices are now ubiquitous and continue to grow in popularity and in capabilities. In such networks, all of the nodes are mobile, so the infrastructure for message routing must be self-organizing and adaptive. In these networks, routing is an important issue because there is no base station that can be used for broadcasting.

Current and future research will not only address the issues described earlier, but will also try to find new applications of MANET. So far, the research community has been unable to find the killer app using MANET other than in military applications. So, the success of this technology will largely depend on how it will be integrated with the Internet, PANs, and WLANs. MANET will also play an important role in ubiquitous computing, when it will be able to seamlessly integrate with heterogeneous networks and devices, provide various services on demand, and offer secure and reliable communications.

KEY TERMS

CSMA: Carrier-sense multiple access is a media-access control (MAC) protocol in which a node verifies the absence of other traffic before transmitting on a shared physical medium, such as an electrical bus or a band of electromagnetic spectrum. Carrier sense describes the fact that a transmitter listens for a carrier wave before trying to send. That is, it tries to detect the presence of an encoded signal from another station before attempting to transmit. Multiple access describes the fact that multiple nodes may concurrently send and receive on the medium.

GPS: It stands for Global Positioning System. It is an MEO (medium earth orbit) public satellite navigation system consisting of 24 satellites used for determining one's precise location and providing a highly accurate time reference almost anywhere on Earth.

MAC: Media-access control is the lower sublayer of the OSI (open systems interconnection reference model) data-link layer: the interface between a node's logical link control and the network's physical layer. The MAC sublayer is primarily concerned with breaking data up into data frames, transmitting the frames sequentially, processing the acknowledgment frames sent back by the receiver, handling address recognition, and controlling access to the medium.

MANET: A mobile ad hoc network is a system of wireless mobile nodes that dynamically self-organize in arbitrary and temporary topologies.

Peer-to-Peer Network: A peer-to-peer (or P2P) computer network is any network that does not have fixed clients and servers, but a number of *peer* nodes that function as both clients and servers to the other nodes on the network. This model of network arrangement is contrasted with the client-server model. Any node is able to initiate or complete any supported transaction. Peer nodes may differ in local configuration, processing speed, network bandwidth, and storage quantity.

Routing Protocol: Routing protocols facilitate the exchange of routing information between networks, allowing routers to build routing tables dynamically.

Ubiquitous Computing: This is a term describing the concept of integrating computation into the environment rather than having computers that are distinct objects. Promoters of this idea hope that embedding computation into the environment will enable people to move around and interact with computers more naturally than they currently do.

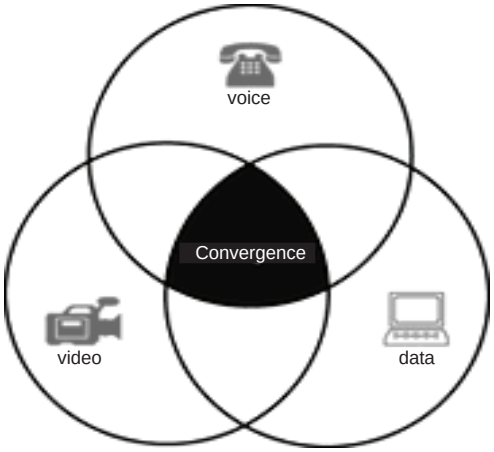
INTRODUCTION

Today, we find a large number of wireless networks based on different radio access technologies (RATs). Every existing RAT has its own merits. Now the focus is turned towards the next-generation communication networks (Akyildiz, Mohanty, & Xie, 2005), which will seamlessly integrate various existing wireless communication networks, such as wireless local area networks (WLANs, e.g., IEEE 802.11 a/b/g and HIPERLAN/2), wireless wide area networks (WWANs, e.g., 1G, 2G, 3G, IEEE 802.20), wireless personal area networks (WPANs, e.g., Bluetooth, IEEE 802.15.1/3/4), and wireless metropolitan area networks (WMANs, e.g., IEEE 802.16) to form a converged heterogeneous architecture (Cavalcanti, Agrawal, Cordeiro, Xie, & Kumar, 2005). Seamless integration does not mean that the RATs are converged into a single network. Instead the services offered by the existing RATs are integrated as shown in Figure 1.

Convergence technology is a technology that combines different existing access technologies such as cellular, cordless, WLAN-type systems, short-range wireless connectivity, and wired systems on a common platform to complement each other in an optimum way and to provide a multiplicity of possibilities for current and future services and applications to users in a single terminal. After creating a converged heterogeneous architecture, the next step is to perform a common radio resource management (RRM) (Magnusson, Lundsjo, Sachs, & Wallentin, 2004). RRM helps to maximize the use of available spectrum resources, support mixed

Figure 1. Convergence of services



traffic types with different QoS requirements, increase trunking capacity and grade of service (GoS), improve spectrum usage by selecting the best RAT based on radio conditions (e.g., path loss), minimize inter-system handover latency, preserve QoS across multiple RATs, and reduce signaling delay. A typical converged heterogeneous architecture (Song, Jiang, Zhuang, & Shen, 2005) is shown in Figure 2.

CHALLENGES

The integration of different networks to provide services as a single interworking network requires many difficult challenges to be addressed. Because existing networks do not have fair RRM, the major challenge that needs to be addressed has to be mobility management. The heterogeneous network architecture will be based on IP protocol that will enhance the interoperability and flexibility. IETF Mobile IP protocol is used to support macro mobility management. But both IP protocol and mobile IP protocol (Pack & Choi, 2004; Montavont & Noel, 2002) was not basically designed to support the real-time applications. So, during the handoff between systems, users will experience the service discontinuity, such as long service time gap or network disconnection. Besides this service discontinuity, the different service characteristics of these interworked networks may degrade the quality of service (QoS).

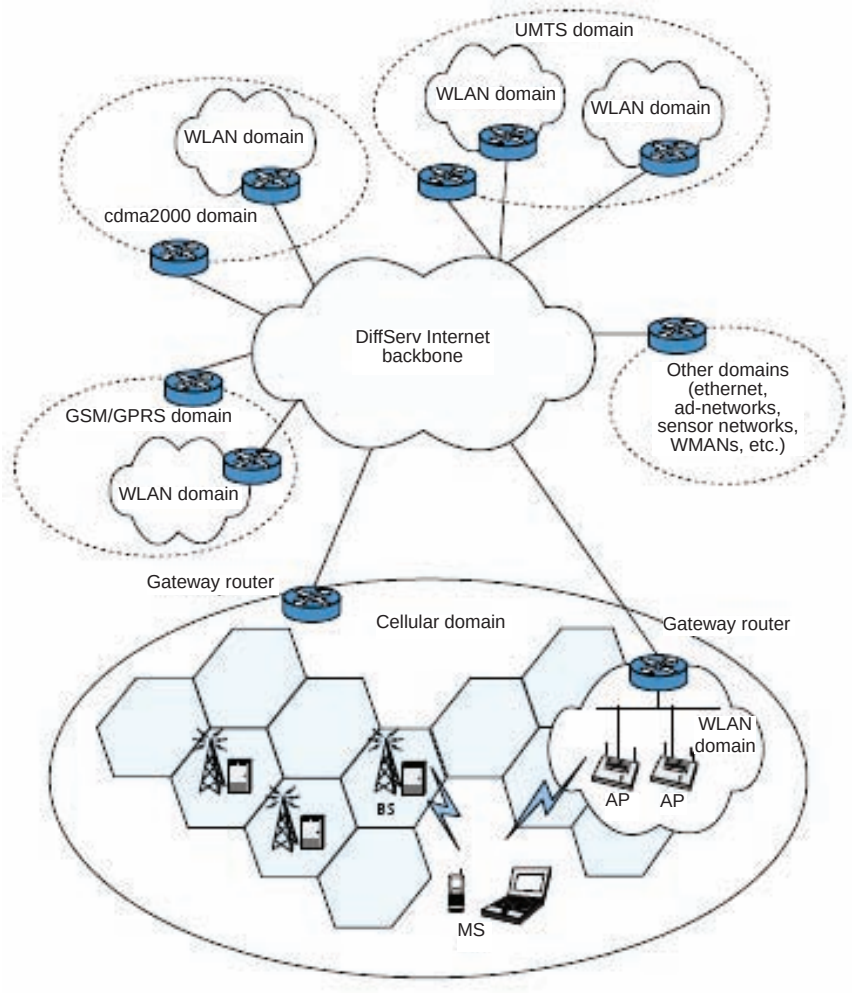
Some of the other challenges include topology and routing, vertical handoff management, load balancing, unified accounting and billing, and last but not least the protocol stack of mobile station (MS), which should contain various wireless air-interfaces integrated into one wireless open terminal so that same end equipment can flexibly work in the wireless access domain as well as in the mobile cellular networks.

PROTOCOL STACK

In a homogeneous network, all network entities run the same protocol stack, where each layer has a particular goal and provides services to the upper layers. The integration of different technologies with different capabilities and functionalities is an extremely complex task and involves issues at all the layers of the protocol stack. So in a heterogeneous environment, different mobile devices can execute different protocols for a given layer. For example, the protocol stack of a dual-mode MS is given in Figure 3.

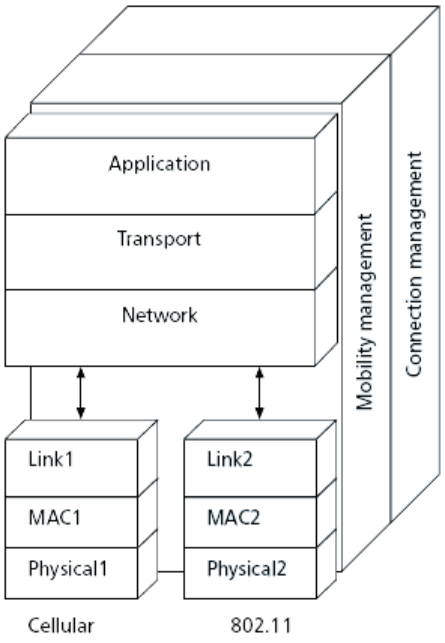
This protocol stack consists of multiple physical, data link, and medium access control (MAC) layers, and network, transport, and application layers. Therefore, it is critical to select the most appropriate combination of lower layers (link, MAC, and physical) that could provide the best service to the upper layers. Furthermore, some control planes such as mobility management and connection management can be added. These control planes can eventually use information from several layers to implement their functionalities. The network layer has a fundamental role in this

Figure 2. Converged heterogeneous network architecture



process, since it is the interface between available communications interfaces (or access technologies) that operate in a point-to-point fashion, and the end-to-end (transport and application) layers. In other words, the task of the network layer is to provide a uniform substrate over which transport (e.g., TCP and UDP), and application protocols can efficiently run, independent of the access technologies used in each of the point-to-point links in an end-to-end connection. Although there are issues in all layers, the network layer has received more attention than any other layer, and little integration-related work has been done at the lower layers. Indeed, integrated architectures are expected not to require modifications at the lower layers so that different wireless technologies can operate independently. However, this integration task is extremely complex, and it requires the support of integration architecture in terms of mobility and connection management. Seamless handoffs for "out of coverage" terminals and re-

Figure 3. Protocol stack of a dual-mode MS



source management can be provided by the two control planes.

ROUTING ISSUES

All RATS in the integrated architecture is considered as IPv6-based networks, and each element in the internetworking networks has a distinct ID number corresponding to the network routing address (Liu & Zhou, 2004). The infrastructure of a network is mapped into IPv6 addresses as shown in Figure 4. For example, the mapping of infrastructure of cellular network and IEEE 802.11 WLAN are shown in Figures 5 and 6. WLAN is given some reservation IDs, so that they can be utilized by mobile nodes under MANET mode.

VERTICAL HANDOFF MANAGEMENT

Vertical handoff is the handoff between different RATs. The major challenge in vertical handoff is that it is difficult to support a seamless service during inter-access network handoff (Wu, Banerjee, Basu, & Das, 2005; Ma, Yu, Leung, & Randhawa, 2004). The service interworking architecture and procedures, the way to provide the network and user securities, the control scheme for minimizing performance decrease caused by different service data rates, and the interworking network detection and selection methods are typical problems and to be addressed to provide stable and continuous services to users.

Unlike in the homogeneous wired networks, providing QoS for integrated architecture has some fundamental bottlenecks. This is because each radio access technology has different transmission-rate capacity over the radio interfaces, therefore the handoff between the two systems

Figure 4. Mapping infrastructure into IPv6 format

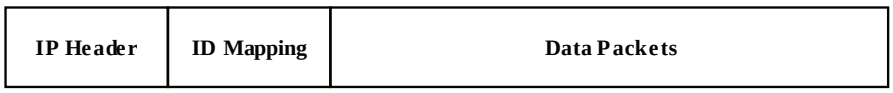


Figure 5. Mapping infrastructure of IEEE 802.11 WLAN into IPv6

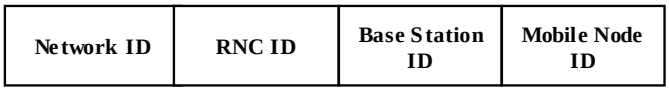
Figure 6. Mapping infrastructure of cellular network into IPv6 address



makes the maintenance of QoS connection very hard. For example, WLAN can provide a transmission speed from 11Mb/s up to 54Mb/s theoretically, while UMTS has only 144kb/s at vehicular speed, 384 kb/s at pedestrian speed, and 2 Mb/s when used indoors. If we keep the QoS resource assigned by UMTS to a connection that is actually in a WAN hotspot, the advantage of the high speed of the WLAN is not fully taken. On the other hand, if we use a WLAN parameter for a station in the UMTS network, the connection may not be admitted at all (Zhang et al., 2003). Therefore, to maintain a sensible QoS framework, one has to consider the significant difference transmission capacity between two systems especially when user handover takes place.

APPLICATIONS

Convergence technology gives the possibility to combine audio and video, data, graphics, slides and documents, and Internet services in any way you like, so as to maximize the effectiveness of the communication. Integrating all traffic types enables more versatile and efficient ways of working, not just internally to the organization, but externally to customers, partners, and suppliers. It also creates a multi-system environment where a single service could be offered at different speeds at different locations/times via separate systems. The flexibility of convergence technology provides many applications and services to the user community. Some of the applications are:

- **Find-Me-Follow-Me:** This is a customizable service that makes it easy for callers to 'find' a user. Using a Web portal customers can choose how incoming calls should be handled. Options include ringing multiple phones simultaneously, or picking the order of phones to ring sequentially. Ubiquity's SIP A/S is used to dial out, in parallel or sequentially, to the user's contact numbers. Using IVR, the user can then accept the call or forward it to voicemail.
- **InfoChannels:** This is a multimedia content subscription application that pushes information and entertainment to users in real time. Users subscribe to content services through a Web portal, and new content is delivered to their designated device (mobile phone, PDA, PC browser) as soon as it is available.
- **Rich Media Conferencing:** Speak conference director is a highly scalable, carrier-class, IP conferencing application that enables conferencing service providers (CSPs) to offer hosted audio and Web conferencing services. This easy-to-use, browser-based solution offers a complete conferencing application feature set, as well as a Web portal for scheduling, initiating, managing, and terminating multi-party conferences.

Some of the services that the convergence provides to the user community are:

- **Unified Messaging:** Same inbox handling data, voice and fax.

- **Hosted IP Voice:** A complete, outsourced telephone service offering all PBX-type features.
- **IP Fax:** Delivery of e-mail to fax and fax to e-mail in a large number of countries.
- **IP Telephony:** A combination of quality transmission globally across the WAN and the LAN, with tailored consulting and end-to-end support.
- **Voice for IP VPN:** Integrated voice and data transmission, using a specific voice.
- **Video for IP VPN:** Point-to-point video transmission over the IP VPN network, using a specific class of service, called RT Vi.
- **Virtual Contact Center Services:** Optimization of agent resources while reducing costs, by allowing the routing of calls based on the agent's skills.
- **Voiceover Wi-Fi:** Full corporate mobility with a converged voice and data wireless solution.

CONCLUSION

This article provides features about convergence technology. The convergence of all existing networks will provide access to all available services using a single-user terminal. But there are many challenges to be addressed in converging the networks. In spite of converging the networks, management of the converged network is more challengeable. This article illustrates some of the challenges, and many are still open issues. Considering all the factors discussed, convergence technology is going to provide future flexibility to the wireless communication world. The complexity of this interesting technology must be addressed in the near future.

KEY TERMS

Communication Network: Network of telecommunications links arranged so that messages may be passed from one part of the network to another over multiple links.

Grade of Service (GoS): A measurement of the quality of communications service in terms of the availability of circuits when calls are to be made. Grade of service is based on the busiest hour of the day and is measured as either the percentage of calls blocked in dial access situations or average delay in manual situations.

Heterogeneous Network: A network that consists of workstations, servers, network interface cards, operating systems, and applications from many vendors, all working together as a single unit.

Radio Access Technology (RAT): Technology or system used for the cellular system (e.g., GSM, UMTS, etc.).

Wireless Local Area Network (WLAN): Wireless network that uses radio frequency technology to transmit network messages through the air for relatively short distances, like across an office building or college campus.

Wireless Metropolitan Area Network (WMAN): A regional wireless computer or communication network spanning the area covered by an average to large city.

Wireless Personal Area Network (WPAN): Personal, short-distance area wireless network for interconnecting devices centered around an individual person's workspace.

Wireless Wide Area Network (WWAN): Wireless network that enables users to establish wireless connections over remote private or public networks using radio, satellite, and mobile phone technologies instead of traditional cable networking solutions like telephone systems or cable modems over large geographical areas.

Chapter 3.17
Document Management, Organizational Memory, and Mobile Environment

Sari Mäkinen
University of Tampere, Finland

INTRODUCTION

Wireless networks and new tools utilizing mobile information and communication technologies (ICTs) challenge the theories and practices of document management, in general, and records management, in particular. The impact of these new tools on document management as a part of organizational memory is as yet unexplored because the wireless and mobile working environment is a new concept. Recent studies of mobile environment have focused on mobile work itself or technologies used, and the aspect of document management, especially records management, has been ignored.

BACKGROUND

Records form one important part of the memory of an organization. From the organizational perspective, one method of managing intellectual resources is to augment the organization's memory. A standard connotation of organizational memory is a written record, although this is only one form of memory. Organizational memory has explicit and implicit forms and can be retained in several places like databases and filing systems, but also in organizational culture, processes, and structures (Ackerman, 1996; Walsh & Ungson, 1991). Megill (1997) specifies organizational memory to include all the active and historical information in an organization that is worth sharing, managing, and preserving for use. It is an important asset encompassing all types of documented and undocumented information that an organization requires to function effectively.

Digital documents and records can be found in every area of administration and business activities. Official records are produced in carrying out business or administrative processes, decision-making processes or procedures. These records

are vital and must be preserved for later use, as documentation and evidence and for cultural and historical reasons. Records are not preserved only for the use of the organization; they must be made accessible to individuals and customers (Young & Kampffmeyer, 2002). With a growing number of people using mobile tools, new kinds of problems are emerging. These problems arise because documents are created, processed, stored, managed, and shared through various mobile ICT tools and technologies. In a mobile working environment, it is essential that every piece of an organization's explicit memory is accessible, searchable, and preservable. This is vital, especially in the case of official and business records.

The literature on document management focuses mainly on the technologies used or the functionality of the document management systems created by practicing consultants. Academic research is rare (Bellotti & Bly, 1996; Eldridge et al., 2000; Luff, Heath & Greatbatch, 1992). Mobile working environment has been examined from the social-scientific and social interaction perspectives (Brown, Green & Harper, 2001; Katz & Aakhus, 2002). The mobile working environment in relation to the aspects of document management is an uninvestigated area and a new research topic.

ORGANIZATIONAL MEMORY

The concept of organizational memory is not new. Its roots go back to the organizational science and information-processing theories of the 1950s (Walsh & Ungson, 1991). Research on organizational memory increased especially in the 1990s in the field of information systems research. Understanding of the concept is limited, and the term is vague but commonly used. Mostly organizational memory is seen from the perspective of the organizational member. It refers to the stored information on the organization's history that can be brought to bear on present decisions (Walsh & Ungson, 1991).

The perspectives of information systems scientists on organizational memory are pragmatic, more often concentrating on the development of databases and information systems supporting organizational memory, since examining the contents of the concept is the focus of organizational scientists. Walsh and Ungson's (1991) classic study, in turn, is completely conceptual. Bannon and Kuutti (1996) claim that the concept of organizational memory does not belong exclusively to any particular research area or discipline and that a variety of definitions is available in such different fields as administrative science, organizational theory, change management, psychology, sociology, design studies, concurrent engineering, and software engineering. The viewpoint taken in archival science (see, e.g., Hedstrom, 2002; Yates, 1990, 1993) is on the historical mission of organizational memory. The purpose of archives is to retain and store the historical memory of an organization. Organizational memory research has been criticized for perceiving organizational memory as only a problem of information technology. The problem of how databases serve users is not the most essential (Koistinen & Aaltio-Marjosola, 2001).

On the basis of a through concept analysis, the definition of organizational memory is the organized knowledge of an organization, a process which is individual and distributed and past preserving, which has an effect on organizational learning, competitiveness and decision-making, and which can be supported by information technology. (Mäkinen & Huotari, 2004).

The preservation and use of organizational memory refer strictly to working life and information used in work-related settings. The empirical case studies on organizational memory pertain particularly to carrying out a task (Mäkinen & Huotari, 2004).

Schwartz, Divitini, and Brasethvik (2000) note that organizational memory has become a close

partner of knowledge management (KM), denoting the actual content that a knowledge management system purports to manage. They perceive knowledge as the key asset of the knowledge organization. They also argue that organizational memory amplifies this asset by capturing, organizing, disseminating, and reusing the knowledge. Generally, the purpose of KM is seen to make these resources available for use. This approach refers to knowledge as an object (Sveiby, 1996), and thus, brings KM close to the traditional role of information management.

Wilson (2002) argues that the information systems orientation dominates the approaches and implicit conceptions presented in the research papers, consulting practices and university curricula of KM. According to him, the theoretical foundation of this orientation is similar to that of information management research; that is, the term *knowledge* is in fact used to refer to information. Wilson argues that we cannot manage individual knowledge because it resides in human minds. Research on organizational memory information systems also supports this view by serving the needs of information retrieval and information seeking in the case of an explicit preserved form of organizational memory (Mäkinen & Huotari, 2004).

DOCUMENT MANAGEMENT IN MOBILE WORKING ENVIRONMENT

The issues of records management are not taken into account utilizing mobile tools for document management. The current need is to combine the perspectives of both document management and records management. For example, it has been suggested that about 12% of organizational knowledge is in its structured knowledge base and the majority (46%) lies scattered about organizations in the form of paper and electronic documents (Kikawada & Holtshouse, 2001). We can assume that the mobile working environment does not improve this situation.

Mobile devices can be defined in many ways. A mobile device can be described as an application of mobile technology—a technical device utilizing mobile technology and is designed to be mobile. Mobile devices, for example, include laptop computers, personal digital assistants (PDAs), mobile phones, and other handheld devices for data transfer and communication (Allen & Shoard, 2004; Weilenmann, 2003). Mobile technology is also about personal communication technologies (PCTs), which is a broader category and includes video cassette recorders, TVs, interactive voice response units (VRUs), beepers, and e-mail (Katz & Aakhus, 2002). The essential character of a mobile device is that it is mobile; it can be carried wherever you have to be and uses information and communication technology. The use of a mobile device is independent of time and space.

Even today, mobile professionals need to take paper documents with them when traveling. Paper is immediately viewable and is frequently used for ad hoc reading activities. This is still the case in spite of the amazing boom in mobile devices. The potential of combining, for example, mobile phone use with other kinds of information-related activities is being investigated in IT and telecommunications companies (O'Hara et al., 2002).

Mobile professionals have particular needs for technologies such as flexibility to accommodate their information needs in unpredictable circumstances. Mobile phone and paper documents respect this need and allow creative use while traveling (O'Hara et al., 2002).

For a mobile worker, the most important features of mobile document management are easy access, timely access, user interface, ubiquity, and compliance with security policies (Lamming et al., 2000). These features are also practical differences between document management using conventional ICT and mobile ICT. Current solutions in document management do not necessarily meet these requirements. The problems of

access are probably the most familiar to mobile workers: how to unpack and plug in a laptop in an unfamiliar environment, how to access remote documents, how to transfer a file, how to print a file, and how to secure a confidential file.

Organizational memory should be understood in a novel manner when its content, that is, documents, is managed in a wireless and mobile operating environment. The utilization of documents produced in mobile devices in knowledge processes and the problems caused by mobile environment to the lifecycle of these documents require attention regarding their creation, transfer, storage, dissemination, sharing, use, and disposal (Mäkinen, 2004).

The challenges of mobile document management and organizational memory augmentation become even more evident among communities of practice. This concept was introduced by Lave and Wenger (1991). Communities of practice are about relations among people, activity, and world in relation to other tangential and overlapping communities of practice. A newcomer learns from old-timers, and newcomers see communities of practice as an intrinsic condition for the existence of knowledge. It is a flexible group of professionals having common interests and interacting through independent tasks and embodying common knowledge (Davenport & Hall, 2002; Kimble, Hildreth & Wright, 2001). In mobile working environment communities of practice share knowledge through technological tools, but it has been argued that some types of knowledge are unsuitable for electronic storage and retrieval (Davenport & Hall, 2002).

FUTURE TRENDS

In recent years, there has been an explosion in mobile computing and telecommunications technologies. A lot of work is done outside the office in different and unpredictable locations (Allen & Shoard, 2004; Weilenmann, 2001). Mobile working environment poses challenges on organizational document management and augmentation of organizational memory. How do mobile produced documents become a part of organizational memory, and what is the relation of these documents to the intellectual capital of an organization?

The future research challenge is to increase understanding of the current state of document management and records management in mobile environments in relation to the development of organizational knowledge and intellectual capital. The focus of future research could be on the role and utilization of mobile documents produced in the joint knowledge processes and the problems caused by wireless and mobile environments, the lifecycle of these documents.

Another important research topic is the idea of access: what problems do mobile professionals have in accessing information sources of their organizations? Problems which a user encounters when trying to connect organizational information systems with mobile devices need to be studied. Using mobile devices and digital records, we also need to be convinced of the integrity of data, that it has not been modified or manipulated. If a document has been created and disseminated utilizing, for example, a mobile phone, what happens to the data when it is transferred to another information system, like document management system?

Social factors have an impact on document management practices. Wireless and mobile tools are technical innovations, but there may also be social innovations in use in the organizations when these tools are used. Organizational changes (flexible working hours), new services (use of Web pages in marketing), and new social arrangements (telework at home) are examples of social innovations. This relates to the concepts of intellectual capital and social capital.

The idea of studying communities of practice and mobile working environments provides new perspectives on mobile computing and joint value creation. It has been stated that really important

and useful information for improvement is too complex to put online. Workers might be afraid of job security and sabotage knowledge management systems (Davenport & Hall, 2002). Online communities of practice have the characteristics of material communities of practice, but they may be ephemeral, and the individuals involved may never have met.

CONCLUSION

The challenges of mobile devices and mobile working environment to document management and especially records management are varied and still largely unexplored. It is clear that the explosion of mobile computing will not improve or ease the augmentation of organizational memory, which is strictly connected to individuals.

The analysis of the concept of organizational memory suggests that its characteristics are contradictory, thereby reflecting the complex nature of the phenomenon. The explicit form of organizational memory is emphasized, but simultaneously, the individual and abstract nature of the concept are also underlined. Organizational memory, in recorded form, is concrete and palpable like paper records in an archive. However, organizational memory was also manifest implicitly and defined as invisible, mute, fuzzy, and easy to lose.

Understanding of the issues related to the management of an organizational memory is essential for enhancing the generative, productive, and representative knowledge processes in the joint value creation of different stakeholders. New knowledge is created in generative processes and with the new knowledge organization is able to provide new products and services. The new, generated knowledge is used in productive processes to provide the basis for products and services, and knowledge is transmitted to the customer as final products and services in representative processes (Huotari, 2000; Huotari & Chatman, 2001; Normann & Ramiréz, 1994).

The theoretical foundation of the organizational memory is more closely related to the multidisciplinary research area of KM and enhancement of knowledge construction based on organizational learning as a source of competitive capability than to information management. This indicates a shift from an individual organizational member's way of applying his/her own knowledge and use of information toward distributed knowledge, communication, and information and knowledge sharing, also through the use of information systems. This characteristic of the concept refers to the social nature of knowledge and information, implying that knowledge is socially constructed; that is, knowledge is a process, not an entity. The process perspective is rarely applied to studies on organizational memory, mostly in relation to an information system and its use (Ackerman & Halverson, 1998). The strategic perspective has gained more emphasis in economics (e.g., Hatami, Galliers & Huang, 2002).

KEY TERMS

Communities of Practice: A flexible group of professionals having common interests, interacting by independent tasks and embodying common knowledge (Davenport & Hall, 2002). Communities of practice are defined as a set of relations among people, activities, and the world (Lave & Wenger, 1991).

Document: Defined as a unit of recorded information structured for human consumption. Documents contain information in some structured way, and they are human creations. A document is created for a certain purpose (Megill & Schantz, 1999; Sprague, 1995).

Document Management: Covers the creation, modification, storage, and retrieval of documents required to meet users' needs and objectives (Megill & Schantz, 1999). Electronic Document Management (EDM) is the application of technology to save paper, speed up communications, and increase the productivity of business processes (Sprague, 1995).

Local Mobility: Refers to mobility within a certain space, as between rooms or floors.

Micro-Mobility: Refers to the way an artifact is mobilized and manipulated around a relatively circumscribed domain.

Mobile Device: Refers to an application of mobile technology, that is, to a technology which is designed to be mobile. Mobile devices, for example, include laptop computers, personal digital assistants (PDAs), mobile phones, and other handheld devices for data transfer and communication (Allen & Shoard, 2004; Weilenmann, 2003).

Mobility: Used here to signify the physical movement of nodes in a network or remote interaction between individuals who are far apart from each other using mobile technology. Mobility can be divided into micro mobility, local mobility, and remote mobility. (Luff & Heath, 1998; Weilenmann, 2001).

Organizational Memory: The organized knowledge of an organization, a process which is individual and distributed and past preserving, which has an effect on organizational learning, competitiveness, and decision making, and which can be supported by information technology (Mäkinen & Huotari, 2004).

Record: Regarded as process-bound information: a record is generated by work processes, structured and recorded by these work processes in order to be retrieved from the context of that work process (Thomassen, 2001). A record has four elements: recorded (physically), it contains information (content), it is an outcome of the process in which it was created (context), and it has a certain form or manifestation (structure) (Hofman, 1996). Contextual information is necessary for defining a document as a record. Unlike a document, a record needs to have contextual information. Records are also documentation of transactions, and they are preserved for evidential, historical, and cultural purposes.

Remote Mobility: Refers to remote users interacting with each other using technology.

Chapter 3.18
Business and Technology Issues in Wireless Networking

David Wright
University of Ottawa, Canada

INTRODUCTION

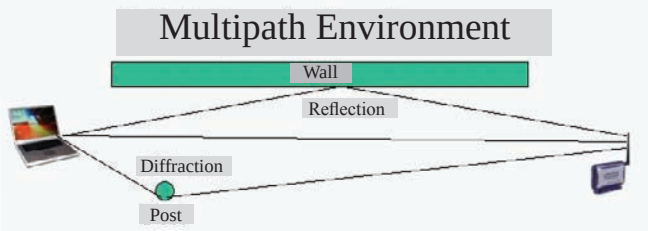
A major development in the enabling technologies for mobile computing and commerce is the evolution of wireless communications standards from the IEEE 802 series on local and metropolitan area networks. The rapid market growth and successful applications of 802.11, WiFi, is likely to be followed by similar commercial profitability of the emerging standards, 802.16e, WiMAX, and 802.20, WiMobile, both for network operators and users. This article describes the capabilities of these three standards and provides a comparative evaluation of features that impact their applicability to mobile computing and commerce. In particular, comparisons include the range, data rate in Mbps and ground speed in Km/h plus the availability of quality of service for voice and multimedia applications.

802.11 WiFi

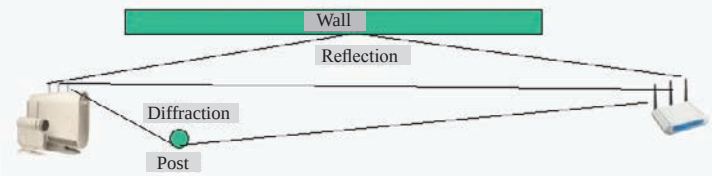
WiFi (IEEE, 1999a, 1999b, 1999c, 2003) was originally designed as a wireless equivalent of the wired local area network standard IEEE802.3, Ethernet. In fact there are many differences between the two technologies, but the packet formats are sufficiently similar that WiFi packets can easily be converted to and from Ethernet packets. Access points can therefore be connected using Ethernet and can communicate with end stations using WiFi.

WiFi can transport both real-time communications such as voice and video plus non-real time communications such as Web browsing, by providing quality of service, QoS, using 802.11e (IEEE, 2005). There are 2 QoS options. One provides four priority levels allowing real-time traffic to be transmitted ahead of non-real-time traffic, but with no guarantee as to the exact delay experienced by the real-time traffic. The other

Figure 1. (a) Receiver recovers a single signal from multiple incoming signals; (b) MIMO receiver recovers multiple signals using multiple antennas



(a)



(b)

allows the user to request a specific amount of delay, for example, 10 msecs., which may then be guaranteed by the access point. This is suited to delay sensitive applications such as telephony and audio/video streaming.

WiFi has a limited range of up to 100 metres, depending on the number of walls and other obstacles that could absorb or reflect the signal. It therefore requires only low powered transmitters, and hence meets the requirements of operating in unlicensed radio spectrum at 2.4 and 5 GHz in North America and other unlicensed bands as available in other countries.

WiFi is deployed in residences, enterprises and public areas such as airports and restaurants, which contain many obstacles such as furniture and walls, so that a direct line of sight between end-station and access point is not always possible, and certainly cannot be guaranteed when end stations are mobile. For this reason the technology is designed so that the receiver can accept multipath signals that have been reflected and/or diffracted between transmitter and receiver as shown in Figure 1(a). WiFi uses two technologies that operate well in this multipath environment: DSSS, Direct Sequence Spread Spectrum, which is used in 802.11b, and OFDM, Orthogonal Frequency Division Multiplexing, which is used in 802.11a and g (Gast, 2002). A key distinguishing factor between these alternatives, which is important to users, is spectral efficiency, that is, the data rate that can be achieved given the limited amount of wireless spectrum available in the unlicensed bands. DSSS as implemented in 802.11b uses 22 MHz wireless channels and achieves 11 Mbps, that is, a spectral efficiency of 11/22 = 0.5. OFDM achieves a higher spectral efficiency and is therefore making more effective use of the available wireless spectrum. 802.11g has 22 MHz channels and delivers 54 Mbps, for a spectral efficiency of 54/22 = 2.5 and 802.11a delivers 54 Mbps in 20 MHz channels, with a spectral efficiency of 54/20

Figure 2. WiFi handoff among access points

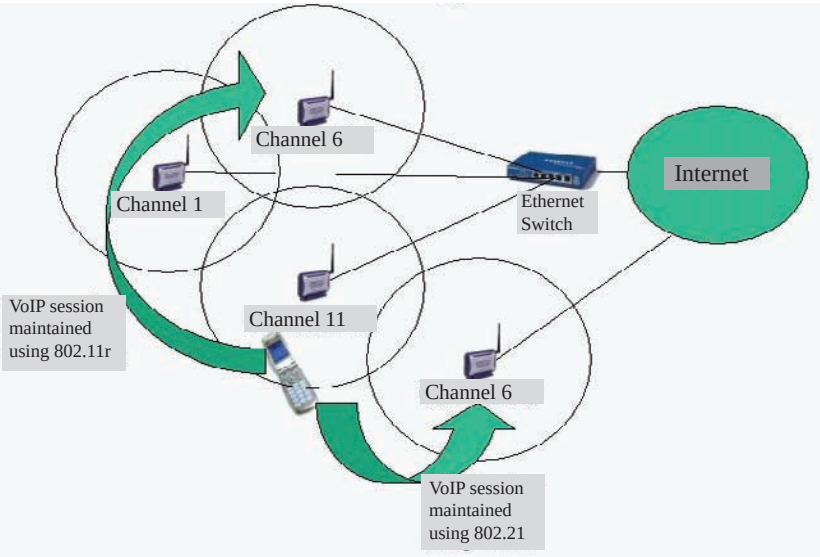


Figure 3. WiMAX traffic rate guarantees

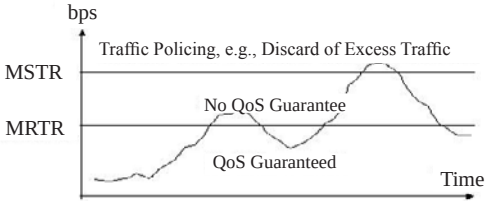
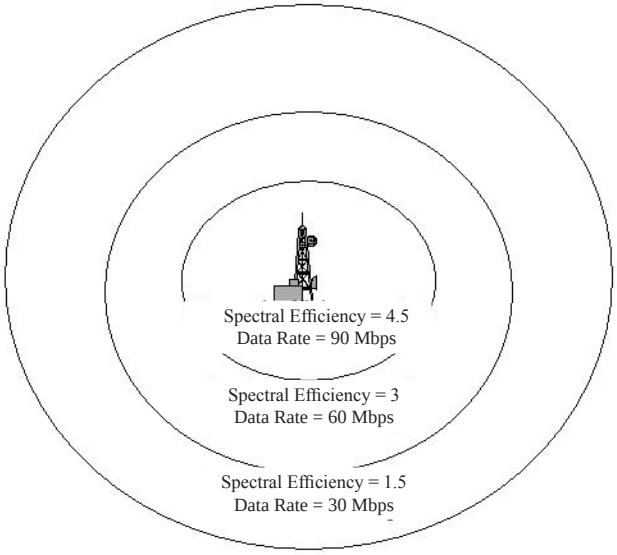


= 2.7. A recent development in WiFi is 802.11n (IEEE, 2006a), which uses OFDM in combination with MultiInput, MultiOutput, MIMO, antennas as shown in Figure 1(b). MIMO allows the spectral efficiency to be increased further by exploiting the multipath environment to send several streams of data between the multiple antennas at the transmitter and receiver. At the time of writing the details of 802.11n are not finalized, but a 4x4 MIMO system (with 4 transmit and 4 receive antennas) will probably generate about 500 Mbps in a 40 MHz channel, that is, a spectral efficiency of 500/40 = 12.5. 802.11n is suited to streaming high definition video and can also support a large number of users per access point.

The data rates in WiFi are shared among all users of a channel, however some users can obtain higher data rates than others. Network operators may choose to police the data rate of individual users and possibly charge more for higher rates, or they may let users compete so that their data rates vary dynamically according to their needs and the priority levels of their traffic. This provides considerable flexibility allowing many users to spend much of their time with low data rate applications such as VoIP, e-mail and Web browsing, with occasional high data rate bursts for audio/video downloads and data-intensive mesh computing applications.

Many deployments of WiFi use multiple access points to achieve greater coverage than the range of a single access point. When the coverage of multiple access points overlaps they should use different radio channels so as not to interfere with each other, as shown in Figure 2. For instance, in the North American 2.4 GHz band there is 79 MHz of spectrum available and the channels

Figure 4. Spectral efficiency and maximum data rates for WiMAX



of 802.11b and g are 22 MHz wide. It is therefore possible to fit 3 non-overlapping channels into the available 79 MHz, which are known as channels 1, 6 and 11. Other intermediate channels are possible, but overlap with channels 1, 6 and 11. In Figure 2, the top three access points are shown connected by Ethernet implying that they are under the control of a single network operator, such as an airport. As an end-station moves among these access points the connection is handed off from one access point to another using 802.11r (IEEE, 2006b), while maintaining an existing TCP/IP session. Movement can be up to automobile speeds using 802.11p (IEEE, 2006c). Standard technology, 802.21 (IEEE, 2006d), is also available to handoff a TCP/IP session when

Table 1. Comparative evaluation of technologies for mobile computing and commerce

	802.11, WiFi	802.16e, WiMAX	802.20, WiMobile
Range	100 metres	2-4 Km	2-4 Km
Coverage	Hot spots. Some city-wide deployments.	Designed for city-wide deployment	Designed for national deployment
Data Rate	11, 54, 500 Mbps flexibly shared among all users	Up to 90 Mbps flexibly shared among all users	> 1 Mbps per user
QoS	(a) Prioritization mechanism (b) data rate and QoS guarantees	Data rate and QoS guarantees	Data rate guarantees and QoS prioritization
Mobility Speed	100 Km/h	100 Km/h	250 Km/h
Cost	Very low unit cost access points. End-station interfaces built into phones, laptops, PDAs. Large number of access points required. Unlicensed spectrum.	Medium unit cost access points. End-station interfaces built into phones, laptops, PDAs. Licensed or unlicensed spectrum.	Medium unit cost access points. End-station interfaces built into phones, laptops, PDAs. Licensed spectrum.

a mobile end-station moves from an access point of one network operator to that of another, and this requires a business agreement between the two operators.

802.11 networks can therefore span extensive areas by interconnecting multiple access points, and city-wide WiFi networks are available in, for example, Philadelphia in the U.S., Adelaide in Australia, Fredericton in Canada and Pune in India. The broad coverage possible in this way greatly expands the usefulness of WiFi for mobile computing and electronic commerce. Enterprise users can set up secure virtual private networks from laptops to databases and maintain those connections while moving from desk to conference room to taxi to airport. A VoIP call over WiFi can start in a restaurant, continue in a taxi and after arriving at a residence.

The features of WiFi, IEEE 802.11, that are of particular importance for mobile computing and commerce are:

- Broad coverage achieved by handing off calls between access points, using 802.11r and 802.21, in cities where there are sufficient access points.
- Multimedia capability achieved by QoS, 802.11e.
- Flexibility in data rates achieved by allowing the total data rate of an access point to be shared in dynamically changing proportions among all users.
- Low cost achieved by using unlicensed spectrum, low power transmitters and mass produced equipment.

The downside to WiFi, IEEE 802.11, is limited coverage in cities that do not have extensive access point deployment.

802.16E WIMAX

802.16E (IEEE, 2006e) has a greater range than 802.11, typically 2-4 km and operates between base stations and subscriber stations. The initial IEEE standard 802.16 is for fixed applications, which compete with DSL and cable modems. Mobile applications including handoff capability among base stations, which we deal with here, are provided by 802.16E, and are based on similar but incompatible technology.

In 802.16E, WiMAX, mobility is limited to automobile speeds, up to about 100 Km/h so that it has limited use in high speed trains and aircraft. WiMAX uses the terminology "subscriber" stations, implying that customers are paying for a public service. Since the geographic range extends well into public areas, this is certainly one application. Another mobile application is a private campus network in which a central base station serves a business park or university campus. Initial deployment of WiMAX uses licensed spectrum, although low power applications in unlicensed spectrum are also specified in the standard.

WiMAX has sophisticated QoS capabilities, which allow customers to reserve capacity on the network including a reserved data rate plus quality of service. The data rate is specified by a minimum reserved traffic rate, MRTR, on which quality of service is guaranteed (Figure 3). The customer is allowed to send at a higher rate, up to a maximum sustainable traffic rate, MSTR, without necessarily receiving QoS, and above that rate, traffic will be policed by the network operator, that is, it may be discarded. The QoS parameters that can be specified by the customer are latency and jitter, plus a priority level, which is used by the base station to distinguish among service flows that have the same latency and jitter requirements. The combination of latency and jitter can be used to distinguish among service flows, and further detail on the performance of WiMAX is given by Ghosh et al. (2005).

Combinations of QoS parameters and data rates make WiMAX highly suited to mobile computing and commerce. Each subscriber can set up multiple service flows, for example, for Web browsing during a multimedia conference,

and use data rates that are quite different from those of other customers. The service provider can charge based on a combination of data rate and QoS.

WiMAX is based on OFDM, thus achieving a high spectral efficiency. There are a number of options within 802.16E for the channel widths and modulation techniques, resulting in a corresponding range of data rates and spectral efficiencies. It is important to recognize that the spectral efficiency depends on the distance between the base station and the subscriber station (Figure 4). As the signal degrades with distance it is not possible to encode so many bps within each Hz and 802.16E assigns encodings that take this into account. Closer to the base station the data rate is therefore higher. The exact distance depends on the operating environment since 802.16E uses multipath signals involving reflections and diffractions. The data rates shown in Figure 4 are the maximum achievable with the highest channel bandwidth allowed according to the standard—20 MHz—and can vary not only with distance but also according to how much forward error correction is used.

The features of 802.16E that are of particular importance for mobile computing and commerce are:

- Good range, enabling city-wide coverage with a reasonable number of base stations.
- Multimedia capability achieved by QoS, and guaranteed data rates.
- Flexibility in data rates achieved by allowing the total data rate of a base station to be shared in dynamically changing proportions among all users.

The downside to 802.16E is the cost of licensed spectrum.

802.20 WIMOBILE

At the time of writing, (1Q06), the specification of 802.20, (IEEE, 2006, f), is under development, so that less detail is available than for 802.11 and 802.16e. The key features of 802.20 are:

- It operates in licensed spectrum below 3.5 GHz.
- It is designed from the start for an all-IP environment and interfaces to IP DiffServ QoS service classes, (Grossman, 2002) which provide for prioritization of users' traffic.
- It interfaces to "Mobile IP" (Montenegro, 2001) as part of its mobility capability. Mobility includes not just automobile speed, but also high speed trains at up to 250 Km/h.
- It uses OFDM with MIMO antennas to achieve a very high spectral efficiency, so that large numbers of users can share access to a single base station.

COMPARATIVE EVALUATION

Mobile computing and commerce involves communicating from mobile devices for a variety of purposes including: data transfer for processing intensive applications and for Web browsing; voice and multimedia calls between human users; downloading audio, video and multimedia from a server, (a) streaming for real-time playout to human users and (b) file transfer for subsequent access on the mobile device. Each of these requires appropriate data rate and quality of service. Cost is also an important factor, since subscription may be required to a public network operator or an enterprise may need to build its own wireless network. Employees using mobile computing devices within a building require mobility only at pedestrian speeds. In public areas such as city streets, automobile speeds are required and between cities high speed trains may be used. The

type of mobile computing application determines which speed is appropriate. Table 1 provides a comparison among the three technologies described in this paper.

CONCLUSION

Mobile computing and commerce users have a wide range of emerging wireless communication technologies available: WiFi, WiMAX and WiMobile. Each of them offers high data rates and spectral efficiencies, and will therefore likely be available at low cost. They are the major enabling telecommunication technologies for mobile computing and are likely to be deployed in public areas and private campuses for in-building and outdoor use. WiFi is already extensively deployed and WiMAX is being deployed in Korea in 2006 and can be expected in many other countries in 2007. The WiMobile standard has not yet been specified (as of the time of writing 1Q06) and commercial equipment can be expected after WiMAX.

KEY TERMS

Direct Sequence Spread Spectrum (DSS): A transmission technique in which data bits are multiplied by a higher frequency code sequence, so that the data are spread over a wide range of frequencies. If some of these frequencies fade, the data can be recovered from the data on the other frequencies together with a forward error correction code.

Mobile IP: An Internet standard that allows a mobile user to move from one point of attachment to the network to another while maintaining an existing TCP/IP session. Incoming packet to the user are forwarded to the new point of attachment.

Multipath: A radio environment in which signals between transmitter and receiver take several different spatial paths due to reflections and diffractions.

Orthogonal Frequency Division Multiplexing (OFDM): A transmission technique in which data bits are transmitted on different frequencies. The data transmitted on one frequency can be distinguished from those on other frequencies since each frequency is orthogonal to the others.

Quality of Service (QoS): Features related to a communication, such as delay, variability of delay, bit error rate and packet loss rate. Additional parameters may also be included, for example, peak data rate, average data rate, percentage of time that the service is available, mean time to repair faults and how the customer is compensated if QoS guarantees are not met by a service provider.

WiFi: A commercial implementation of the IEEE 802.11 standard in which the equipment has been certified by the WiFi Alliance, an industry consortium.

WiMAX: A commercial implementation of the IEEE 802.16 standard in which the equipment has been certified by the WiMAX Forum, an industry consortium.

WiMobile: Another name for the IEEE 802.20 standard which is in course of development at the time of writing (1Q06).

Chapter 3.19
Mobile Phone Based Augmented Reality

Anders Henrysson
Norrköping Visualisation and Interaction Studio, Sweden

Mark Ollila
Norrköping Visualisation and Interaction Studio, Sweden

Mark Billinghurst
Human Interface Technology Laboratory, New Zealand

ABSTRACT

Mobile phones are evolving into the ideal platform for augmented reality (AR). In this chapter, we describe how augmented reality applications can be developed for mobile phones and the interaction metaphors that are ideally suited for this platform. Several sample applications are described which explore different interaction techniques. User study results show that moving the phone to interact with virtual content is an intuitive way to select and position virtual objects. A collaborative AR game is also presented with an evaluation study. Users preferred playing with the collaborative AR interface than with a non-AR interface and also found physical phone motion to be a very natural input method. This results discussed in this chapter should assist researchers in developing their own mobile phone based AR applications.

INTRODUCTION

In recent years, mobile phones have developed into an ideal platform for augmented reality (AR). The current generation of phones has full color displays, integrated cameras, fast processors, and even dedicated 3D graphics chips. It is important to conduct research on the types of AR applications that are ideally suited to mobile phones and user interface guidelines for developing these applications. This is because the widespread adoption of mobile phones means that they could be one of the dominant platforms for AR applications in the near future.

Traditionally AR content is viewed through a head mounted display (HMD). Wearing an HMD leaves the users hands free to interact with the virtual content, either directly or by using an input device such as a mouse or digital glove. However, for handheld and mobile phone based AR, the user looks through the screen and needs at least one hand to hold the device. The user interface for these applications is very different than those for HMD based AR applications. Thus, there is a need to conduct research on interaction techniques for handheld AR displays, and to produce formal user studies to evaluate these techniques.

In this chapter, we give an overview of the development path from mobile AR to mobile phone AR. We explain in detail how we developed an AR platform suited for mobile phones and discuss the uniqueness of mobile phone interaction for AR. We present sample applications and user studies performed to evaluate interaction techniques and metaphors.

RELATED WORK

The first mobile AR systems, such as Feiner's Touring Machine (Feiner, MacIntyre, & Webster, 1997), relied on bulky backpack worn computers and custom-built hardware. However, it was obvious that what was carried in a backpack would one day be held in the palm of the hand. Feiner showed the potential of mobile AR systems for outdoor context sensitive information overlay, while ARQuake (Thomas et al., 2002) showed how these same systems could be used for outdoor gaming.

At the same time these early mobile systems were being developed, Schmalstieg et al. (2002), Billinghurst, Weghorst, and Furness (1996), and Rekimoto (1996) were exploring early face-to-face collaborative AR interfaces. Billinghurst's Shared Space work showed how AR can be used to seamlessly enhance face-to-face collaboration (Billinghurst, Poupyrev, Kato, & May, 2000) and his AR Conferencing work (Billinghurst & Kato, 1999) showed how AR can be used to create the illusion that a remote collaborator is actually present in the local workspace. Schmalstieg's Studierstube (Schmalstieg et al., 2002) software architecture is ideally suited for building distributed AR applications, and his team has developed a number of interesting collaborative AR systems.

Using Studierstube, Reitmayr, and Schmalstieg (2001) brought the mobile and collaborative research directions together in a mobile collaborative augmented reality interface based on a backpack configuration. Prior to this, Höllerer, Feiner, Terauchi, and Rashid (1999) had added remote collaboration capabilities to the University of Columbia's touring machine, allowing a wearable AR user to collaborate with a remote user at a desktop computer. Piekarski and Thomas (2002) also added similar remote collaboration capabilities to their Tinmith system, once again between a wearable AR user and a colleague at a desktop computer. However Reitmayr's work was the first that allowed multiple users with wearable AR systems to collaborate in spontaneous ways, either face-to-face or in remote settings.

These projects showed that the same benefits that tethered AR interfaces provided for collaboration could also extend to the mobile platform, and new application areas could be explored, such as location based gaming.

Rekimoto's Transvision system explored how a tethered handheld display could provide shared object viewing in an AR setting (Rekimoto, 1996) (see Figure 1). Transvision consists of a small LCD display with a camera mounted on the back. Two users sit across the table and see shared AR content shown on the phone displays. The ARPAD interface (Mogilev, Kiyokawa, Billinghurst, & Pair, 2002) is similar, but it adds a handheld controller to the LCD panel. ARPAD decouples translation and rotation. A selected object is fixed in space relative to the LCD panel and can be moved by moving the panel. Rotation is performed using a trackball input device.

As significant computing and graphics power became available on the handheld platform, researchers have naturally begun to explore the use of personal digital assistants (PDAs) for AR applications as well. First, there was work such as the AR-PDA project (Geiger, Kleinnjohan, Reiman, & Stichling, 2001) and BatPortal (Ingram & Newman, 2001) in which the PDA was used as a thin client for showing AR content generated on a remote server. Then in 2003, Wagner and Schmalstieg (2003b) ported the ARToolKit (2005) tracking library to the PocketPC and developed the first self-contained PDA AR application. Unlike the backpack systems, handheld collaborative AR interfaces are unencumbering and ideal for lightweight social interactions.

Mobile phone-based AR has followed a similar development path. Early phones did not have enough processing power so researchers explored thin client approaches. For example, the AR-Phone project (Cutting, Assad, Carmichael, & Hudson, 2003) used Bluetooth to send phone camera images to a remote sever for processing and graphics overlay. However, Henrysson recently ported ARToolKit over to the Symbian phone platform (Henrysson & Ollila, 2003), while Moehring developed an alternative custom computer vision and tracking library (Moehring, Lessig, & Bimber, 2004). This work enables simple AR applications to be developed which run at 7-14 frames per second.

An additional thread that our work draws on is AR interaction techniques. As mobile AR applications have moved from a wearable backpack into the palm of the hand, the interface has changed. The first mobile AR systems used head mounted displays to show virtual graphics and developed a number of very innovative techniques for interacting with the virtual data. For example, in the Tinmith system (Piekarski et al., 2002), touch sensitive gloves were used to select menu options and move virtual objects in the real world. Kurata's handmouse system (Kurata, Okuma, Kourogi, & Sakaue, 2001) allowed people to use natural gesture input in a wearable AR interface, while Reitmayr et al. (2001) implemented a stylus based interaction method.

PDA-based AR applications do not typically use head mounted displays, but are based instead around the LCD display on the PDA or handheld device. At least one of the user's hands is needed to hold the PDA so some of the earlier mobile interaction techniques are not suitable. It is natural in this setting to use stylus input but there are other possibilities as well. In the AR-PAD project (Mogilev et al., 2002), buttons and a trackball on the display are used as input in a face-to-face collaborative AR game. Träskbäck and Haller (2004) use a tablet-PC and pen input for an AR-based refinery education tool. In Wagner's indoor navigation tool (Wagner & Schmalstieg, 2003c), user input is also a combination of stylus interaction and knowledge of display position from visual tracking of markers in the environment.

Handheld AR applications, such as the Invisible Train (Wagner, Pintaric, Ledermann, & Schmalstieg, 2005), also show an interesting combination of interacting with the AR content by interacting in the world and with the device itself. In this case, the user moves around in the real world to select the view of the virtual train set and then touches the screen with a stylus to change the position of tracks on the train set (see Figure 2). Similarly in Wagner's AR-Kanji collaborative game (Wagner & Barakonyi, 2003a), the user looks through the PDA screen to view real cards that have Kanji symbols printed on them. When the cards are seen through the screen, virtual models are seen corresponding to the translation of the Kanji characters. These can be manipulated by hand and the PDA shows the model from different viewpoints. There is very little stylus input required. These projects show that if the AR display is handheld, the orientation and position of the display can be used as an important interaction tool.

BRINGING AUGMENTED REALITY TO THE MOBILE PHONE

To bring AR to the mobile phone we had to develop a robust, lightweight tracking solution. Given the widespread adoption of built-in cameras in mobile phones, optical tracking was an obvious choice. There are various optical tracking techniques including fitting a projection of a 3D model onto detected features in the video image and matching a video frame with photos from known positions and orientations. However, we wanted to have a general tracking method suitable for interaction studies with minimal preparation. We choose to work with the ARToolKit software library, which provided a well-tested solution for optical tracking. ARToolKit can be used to calculate the 3D pose of a camera relative to a single square tracking marker.

In order to develop self-contained AR applications for Symbian based mobile phones we needed to port the ARToolKit tracking library to the Symbian operating system. The original implementation of ARToolKit uses double precision floating-points. However, both the mobile phones we are targeting and the PDA used by Wagner lack a floating-point unit, making floating-point arithmetic orders of magnitude slower than integer arithmetic. To overcome this, Wagner identified the most computational heavy functions and rewrote them to fixed-point using Intel's GPP library.

Fixed-point representations use the integer datatype to provide both range and precision. If great precision is required (e.g., for trigonometric functions), 28 of the 32 integer bits are used for precision. Since there was no equivalent fixed-point library featuring variable precision available for Symbian, we wrote our own. We did extensive performance tests to select the algorithms that ran the fastest on the mobile phone. The average speed-up compared to corresponding floating-point functions was about 20 times. We started out by porting the functions rewritten by Wagner and continued backwards to cover most of functions needed for camera pose estimation. The resulting port runs several times faster than the non fixed-point version of ARToolKit. This speed-up was essential for developing interactive applications.

To provide 3D graphics capabilities, we decided on OpenGL ES (OpenGL ES, 2002), which is a subset of OpenGL 1.3 suitable for low-power, embedded devices. To make it run on these limited devices some members of the Khronos group removed redundant APIs and functions. Memory and processor demanding functions such as 3D texturing and double precision floating-point values have been removed along with GLU. A 16:16 fixed-point data type has been added to increase performance while retain some of the floating-point precision. The most noticeable difference is the removal of the immediate mode in favor of vertex arrays. Since Symbian does not permit any global variables the vertex and normal arrays must be declared constant, which limits the dynamic properties of objects. While OpenGL ES takes care of the low level rendering there is still need for a higher-level game engine with ability to import models and organize the content into a scene graph. To import textured models from a 3D animation package we used the Deep Exploration tool from Right Hemisphere. This converts the exported model to C++ code with OpenGL floating-point vertex arrays, which are converted into OpenGL ES compatible fixed-point vertex arrays using a simple program we wrote. This conversion is not perfect since the exported OpenGL array indexing differs slightly from the OpenGL ES one.

Having this platform we were able to import complex 3D models and visualize them in an Augmented Reality application (see Figure 3). In this case, when the application recognizes the ARToolKit tracking marker a simple 3D model is overlaid on the live camera view. On a Nokia 6630 phone, this typically runs at 6-7 frames per second.

INTERACTION DESIGN FOR MOBILE PHONE AUGMENTED REALITY

In order to explore methods for virtual object manipulation in AR applications on a mobile phone, we need to consider the appropriate interaction metaphor. There are several key differences between using a mobile phone AR interface and a traditional head mounted display-based AR system. Obviously, the display is handheld rather than head worn meaning that the phone affords a much greater peripheral view of the real world. On the phone the display and input device are connected while they are separate for the HMD configuration. This means that with a mobile phone there is no need for a second device for interaction, configuration, or 2D menu browsing, which is the case for most HMD configurations.

These differences mean that interface metaphors developed for HMD-based systems may not be appropriate for handheld systems. For example, applications developed with a Tangible AR metaphor (Kato, Billinghurst, Poupyrev, Tetsutani, & Tachibana, 2001) often assume that the user has both hands free to manipulate physical input devices; this will not be the case with mobile phones. For phone-based AR applications, the user views the AR scene on the screen and needs at least one hand to hold the device.

These differences suggest that we look at the PDA applications for appropriate interface metaphors. However, there are also some key differences between a mobile phone and a PDA. The mobile phone is operated using a one-handed button interface in contrast to the two-hand stylus interaction of the PDA. It is therefore possible to use the mobile phone as a tangible input object itself. In order to interact we can move the device relative to the world instead of moving the stylus relative a fairly static screen.

Our approach is to assume the phone is like a handheld AR lens providing a small view into the AR scene. With this in mind, we assume that the user will more likely move the phone-display than change their viewpoint relative to the phone. The small form factor of the mobile phone lets us go beyond the looking-glass metaphor to an object-based approach. This means that input techniques can be developed largely based around motion of the phone itself, rather than keypad or button input on the phone.

For complex applications, we need 6 degree of freedom (DOF) manipulation. There have been many 6 DOF interface techniques developed for desktop applications, however there are a number of important differences between using a phone AR interface and a traditional desktop interface. Phone input options are limited since there is no mouse and keyboards are limited to a handful of high-end models. Limited screen resolution severely restricts the use of menus and multiple view-ports. We need input techniques that can be used one handed and only rely on a phone joypad and keypad input. Since the phone is handheld we can also use the motion of the phone itself to interact with the virtual object.

New opportunities in mobile phone interaction have emerged with the integration of cameras into the phones. Using simple image processing on the phone, it is possible to estimate the movement of the device, and implement 6 DOF manipulation. For example, we can fix the virtual object relative to the phone and then position and rotate objects by moving the phone relative to the real world. Bimanual interaction techniques can also be used; the dominant hand holding the phone and the non-dominant manipulating a real object on which AR graphics are overlaid.

SAMPLE APPLICATION: OBJECT MANIPULATION

To explore different object manipulation techniques, we have implemented tangible (isomorphic) interaction as well as keypad (isometric) interaction methods. In the tangible case, objects

are selected by positioning virtual cross hairs over them, clicking, and holding down the joypad controller. Once selected, the object is fixed relative to the phone and moves when the user moves the phone. When the joypad is released, the object orientation and position is set to the final phone orientation and position. These two transformations can also be handled separately where the orientation or position is reset upon release. The keypad interface allows the user to isolate one axis at the time.

To explore object rotation we implemented an ArcBall rotation technique (Chen, Mountford, & Sellen, 1988). The relative motion of the phone is used to rotate the currently selected object. The ArcBall allows the user to perform large 3DOF rotations using small movements. In a desktop implementation, the mouse pointer is used to manipulate an invisible ball that contains the object to be rotated. The resulting rotation depends on where on the ball the user clicked and in which direction the pointer was dragged. In our phone interface, the center of the object is projected into screen coordinates and a virtual crosshair acts as a mouse pointer rotating the object.

In the keypad/joypad method, the objects continuously rotate or translate a fixed amount for each fraction of a second while the buttons are pressed. In contrast, when the virtual object is fixed relative to the phone (tangible input), the user can move the object as fast as they can move the phone. Therefore, the user should be able to translate or rotate the objects faster using tangible input techniques than with keypad input.

To test the interaction methods and explore how they could be combined, we implemented a scene assembly application. The application consists of a minimal scene with two boxes and a ground plane (see Figure 4). The boxes can be moved freely above the ground plane. When selected, the object is locked to the phone and highlighted in white. The virtual model is fixed in space relative to the phone and so can be rotated and translated at the same time by moving the phone. When the keypad button is released the new transformation in the global (marker) space is calculated.

The keypad interface is used to modify all six degrees of freedom of the virtual objects. We chose to use the same buttons for both translation and rotation. To switch between the translation and rotation mode we implemented a semi-transparent menu activated by pressing the standard menu button on the joypad (see Figure 5). The menu layout consists of a 3 by 3 grid of icons that are mapped to the keypad buttons 1 to 9. Once the translation or rotation mode is entered the menu disappears.

In both modes, we are handling transformation in three dimensions corresponding to the x, y, and z-axes of the local object coordinate system. Since the joypad is 5-way and pressing it always means selection, it can only handle two of the dimensions. Therefore, to translate the object in the x-y plane we use the four directions of the joypad and complement it with the 2 and 5 keys for translation along the y-axis. For rotation, we use the joypad to rotate around the x and z-axis, while the 2 and 5 buttons rotate the object around the y-axis.

User Study: Object Manipulation

We performed a user study in order to test the usability of the manipulation techniques previously described. In the study, the users tried to position and orient blocks. The subject sat at a table, which had a piece of paper with a number of tracking makers printed on it. When the user looked through the phone display at the tracking marker, they saw a virtual ground plane with a virtual block on it and a wireframe image of a target block. The study was done in two parts, evaluating positioning and translating techniques separately. In the first, we tested the following three positioning conditions:

1. Object fixed to the phone (one handed).
2. Button and keypad input.
3. Object fixed to the phone (bimanual).

In each case, the goal was to select and move the block until it was inside the target wireframe block. In the second part of the experiment we tested the following rotation techniques:

1. ArcBall.
2. Keypad input for rotation about the object axis.
3. Object fixed to the phone (one handed).
4. Object fixed to the phone (bimanual).

For each condition, the virtual block was shown inside a wireframe copy and the goal was to rotate the block until it matched the orientation of the wireframe copy.

In the bimanual cases, the user was able to manipulate the tracking paper with one hand while moving or rotating the phone with the other, while in the other conditions the user wasn't allowed to move the tracking marker. When the block was positioned or rotated correctly inside the target wire-frame it changed color to yellow showing the subject that the trial was over. For each trial, we measured the amount of time it took the user to complete the trial and also continuously logged the position or rotation of the block relative to the target.

After three trials in one condition we asked the subject to subjectively rate his or her performance and how easy was it for him or her to use the manipulation technique. Finally, after all the positioning or orientation conditions were completed we asked the users to rank them all in order of ease of use.

Results

We recruited a total of nine subjects for the user studies, seven male and two female, aged between 22 and 32 years. None of the subjects had experience with 3D object manipulation on mobile phones but all of them had used mobile phones before and some of them had played games on their mobile phone.

Positioning

There was a significant difference in the time it took users to position objects depending on the positioning technique they used. Conditions **A** and **C** took less time than the keypad condition (condition **B**). Using a one factor ANOVA ($F(2,24) = 3.65$, $P < 0.05$) we found a significant difference in task completion times (see Table 1).

For each of the conditions, subjects were asked to answer the following questions:

Q1: How easy was it for you to position the object?
Q2: How accurately did you think you placed the block?
Q3: How quickly did you think you placed the block?
Q4: How enjoyable was the experience?

Using a scale of 1 to 7 where 1 = very easy, 7 = not very easy. Table 2 shows the average results.

The users thought that when the object was fixed to the phone (conditions **A** and **C**) it was easier to position the object correctly (**Q1**) but they could position the model more accurately (**Q2**) with the keypad input. A one factor ANOVA finds a near significant difference in the results for Q1 ($F(2,24) = 2.88$, $P = 0.076$) and Q2 ($F(2,24) = 3.32$, $P = 0.053$).

There was a significant difference in the other conditions. The users thought they could place the objects more quickly when they were attached to the phone (**Q3**) and the tangible interfaces were more enjoyable (**Q4**). A one factor ANOVA finds a significant difference in the results for Q3 ($F(2,24) = 5.13$, $P < 0.05$) and Q4 ($F(2,24) = 3.47$, $P < 0.05$).

The users were asked to rank the conditions in order of ease of use (1 = easiest, 3 = most difficult). Table 3 shows the average ranking. Condition **A** and **C** were the best ranked conditions. A one factor ANOVA gives a significant difference ($F(2,24) = 5.36$, $P < 0.05$).

Orientation

There was also a significant difference in the time it took users to orient objects depending on the technique they used. Table 4 shows the average time it took the users to rotate the virtual block to match the wireframe target. Conditions **A** (ArcBall) and **B** (keypad input) are on average twice as fast as the Tangible Input rotation conditions (**C** and **D**). A one-factor ANOVA finds a significant difference between these times ($F(3,32) = 4.60$, $P < 0.01$).

Subjects were also asked to answer the same survey questions as in the translation task, except **Q1** was changed "How easy was it for you to rotate the virtual object?" There were no significant differences between these survey responses. The subjects thought that the conditions were equally easy to use and enjoyable. The users were asked to rank the conditions in order of ease of use. There was also no significant difference between these results.

User Feedback

In addition to survey responses, many users gave additional comments about the experience. Several commented that when the virtual object was attached to the phone they felt like they were holding it. In contrast, when the keypad was used they felt that they were looking at a screen. They felt like they were more in control and they could use their spatial abilities when manipulating the virtual object with tangible input. In contrast, those that preferred the keypad liked how it could be used for precise movements and also how you didn't need to physically move yourself to rotate the object. Some users also commented on a lack of visual feedback about the rotation axis.

The block changed color when it was released inside the target but subjects thought it would have been good to change before it was released. They also felt visual cues showing the axis of rotation would be helpful, especially in the case of the ArcBall implementation. Those subjects that used two-handed input said that they felt they had more control because they could make gross movements with the camera and then fine tune the block position with small marker movements.

SAMPLE APPLICATION-FACE-TO-FACE COLLABORATIVE AR

To explore face-to-face collaborative AR we developed a simple two player game; AR Tennis. Tennis was chosen because it could be played in either a competitive or cooperative fashion, awareness of the other player is helpful, it requires only simple graphics and it is a game that most people are familiar with. For a multiplayer game, we needed a way to transfer data between phones. Since our game is a face-to-face collaborative application we chose Bluetooth and wrote a simple peer-to-peer communications layer that enables data to be shared between the phones.

Our tennis application uses a set of three ARToolKit markers arranged in a line. When the player points the camera phone at the markers they see a virtual tennis court model superimposed over the real world (see Figure 6). As long as one or more of these markers are in the field of view then the virtual tennis court will appear. This marker set is used to establish a global coordinate frame and both of the phones are tracked in this coordinate frame.

There is a single ball that initially starts on one of the phones. To serve the ball the player points their phone at the court and hits the "2" key on the keypad. Once the ball is in play, there is no need to use the keypad any more. A simple phys-

ics engine is used to bounce the ball off the court and respond to when the player hits the ball with their camera phones. The racket is defined as a circle centered on the z-axis in the xy-plane of the camera space. This means that holding the phone corresponds to holding a virtual racket. If there is an intersection between the racket plane and the ball, the direction of ball is reversed. The direction and position vectors of the ball are sent over to the other phone using Bluetooth. By sending the position the simulations will be synchronized each round. When receiving data the device switches state from outgoing to incoming and starts to check for collision with the racket. Both devices check for collision with the net and if the ball is bounced outside the court. If an incoming ball is missed the user gets to serve. Each time the ball is hit there is a small sound played and the phone of the person that hits the ball vibrates, providing haptic and audio multi-sensory cues.

In order to evaluate the usability of mobile phones for collaborative AR we conducted a small pilot user study. We were particularly interested in two questions:

1. Does having an AR interface enhance the face-to-face gaming experience?
2. Is multi-sensory feedback useful for the game playing experience?

To explore these questions we conducted two experiments, both using the AR tennis game we have developed.

Experiment One: The Value of AR

In this first study, we were interested in exploring how useful the AR view of the game was, especially in providing information about the other player's actions. Pairs of subjects played the game in each of the following three conditions:

A. Face-to-face AR: Where they have virtual graphics superimposed over a live video view.

B. Face-to-face non-AR: Where they could see the graphics only, not the live video input.

C. Non face-to-face gaming: Where the players could not see each other and also could see the graphics only. There was no live video background used.

In the face-to-face conditions (**A** and **B**) players sat across a table facing each other sharing a single set of tracking markers. In condition **C**, the players sat with a black cloth dividing them and each used their own tracking marker.

Players were allowed to practice with the application until they felt proficient with the game. Then they were told to play for 3 minutes in each of the conditions. The goal was to work together to achieve the highest number of consecutive ball bounces over the net. This was to encourage the players to cooperate together. After each condition the number of ball bounces was recorded and also a simple survey was given asking the subjects how well they thought they could collaborate together. Six pairs of subjects completed the pilot study, all of them male university staff and students aged between 21 and 40 years.

Experiment One Results

In general, there was a large variability in the number of ball bounces counted for each condition and there was no statistically significant difference across conditions. This is not surprising because pairs used many different strategies for playing the game. However, we did get some significantly different results from the subjective user surveys. At the end of each condition, subjects were asked the following four questions:

Q1: How easy was it to work with your partner?

Q2: How easily did your partner work with you?
Q3: How easy was it to be aware of what your partner was doing?
Q4: How enjoyable was the game?

Each questions was answered on a scale from 1 to 7 where 1 = Not Very Easy and 7 = Very Easy. Table 5 shows the average scores for each question across all conditions.

The users found each condition equally enjoyable (**Q4**). Interestingly enough, despite simple graphics and limited interactivity the enjoyment score was relatively high. However, there was a significant difference in response to the first three questions. The user felt that there was a difference between the conditions in terms of how easy it was to work with their partner (**Q1**) and how easily their partner worked with them (**Q2**). For question 1 (ANOVA $F(2,33) = 8.17$, $p < 0.05$) and for question 2 (ANOVA $F(2,33) = 3.97$, $p < 0.05$). The face-to-face AR condition was favored in both cases. Users felt that it was much easier to be aware of what their partner was doing (**Q3**) in the face-to-face AR condition with the live video background than in the other two conditions which had no video background (ANOVA $F(2,15) = 33.4$, $p < 0.0001$).

Subjects were also asked to rank the three conditions in order of how easy it was to work together. All but one of the users (11 out of 12) ranked the face-to-face AR condition first, confirming the results from the survey questions.

Experiment Two: Multi-Sensory Feedback

A second study was conducted to explore the value of having multi-sensory feedback in the collaborative AR application. In the game it was possible to play with audio and vibration feedback when the ball was hit. Players played the game in the following conditions:

A: Face-to-face AR with audio and haptic feedback.
B: Face-to-face AR with no audio feedback but with haptic.
C: Face-to-face AR with audio but no haptic feedback.
D: Face-to-face AR with no audio and no haptic feedback.

These four conditions were used to explore which of the audio and tactile options the players found most valuable. Each pair of players played in each condition for one minute, once again counting the highest number of consecutive ball bounces over the net and also completing a survey after each condition. The same six pairs who completed experiment one also completed experiment two. After finishing the conditions for experiment one they would continue to complete the conditions for experiment two, so that they were trained on the system.

Experiment Two Results

As with the first experiment, there was a wide variability in the average number of ball bounces counted and no statistical difference across conditions. However, we did get some significantly different results from the subjective user surveys. At the end of each condition subjects were asked the following three questions:

Q1: How easy was it to be aware of when you had hit the ball?
Q2: How easy what it to be aware of when your partner had hit the ball?
Q3: How enjoyable was the game?

Once again each questions was answered on a scale from 1 to 7 where 1 = Not Very Easy and 7 = Very Easy. Table 6 shows the average scores for each question across all conditions.

For awareness (**Q1** and **Q2**) the conditions using audio (**A** and **C**) were ranked the best. For

question 1 (ANOVA $F(3,44) = 11.1$, $p < 0.0001$) and for question 2 (ANOVA $F(3,44) = 6.59$, $p < 0.001$). They almost unanimously rated the condition that provided the most sensory output (audio, visual, haptic) as the most enjoyable (**Q3**) (ANOVA $F(3,44) = 6.53$, $p < 0.001$).

Subjects were also asked to rank the four conditions in order of how easy it was to work together. Almost all of the subjects ranked condition **A** best (10 out of 12 responses), followed by condition **C** (audio but no haptic feedback), then condition **B** (haptic but no audio feedback) and finally condition **D** (no audio or haptic feedback). Thus, they almost unanimously rated the condition which provided the most sensory output (audio, visual, haptic) as easiest to work in and also as the most enjoyable. There also appears to be a clear preference for audio only output over haptic output. This could be in part due to great awareness cue that audio provides for both the user and their partner when they hit the ball. With haptic only feedback, for the player that is not hitting the ball it is equivalent to having no feedback at all.

DESIGN RECOMMENDATIONS

Users found that the tangible interface metaphor provides a fast way to position AR objects in a mobile phone interface because they just have to move the real phone where the block is to go. The subjects also felt that it was more enjoyable.

However, there seems to be little advantage in using our implementation of a tangible interface metaphor for virtual object rotation. When the virtual object is fixed to the phone then the user often has to move themselves and the phone at the same time to rotate the object to the orientation they want, which takes time. Even when the person can use a second hand to rotate the tracking marker, this is still more time consuming than using the ArcBall or keypad input.

One of the main advantages of the keypad is that it just rotates the object around one axis at a time and so makes it easy for the user to understand what the rotation axis is and how to undo any mistakes. There is also a compromise between speed and accuracy that may affect performance. Tangible input techniques may be fast, but because they provide full six degree of freedom input, they may not be the best methods for precise input.

The collaborative AR game showed that face-to-face mobile games could benefit from combining computer graphics with views of the real world. The use of multi-sensory feedback, especially audio and visual is important for increasing game enjoyment. There are certain types of games that appear suitable for collaborative AR on mobile phones. If visual tracking is used then the ideal games have a focus on a single shared game space. This enables the players to easily see each other at the same time as the virtual content.

The screens on mobile phones are very small so collaborative AR games need only to use a limited amount of graphics and should mainly focus on enhancing the face-to-face interaction. For example in our tennis game a very simple ball, court, and net model was used, but this was enough to keep users happily engaged.

The use of an appropriate tangible object metaphor is also important for the usability of mobile phone AR applications. In our case we wanted the player to feel like the phone was a tennis racket hitting balls over a virtual net. This is why the phone vibrated when a ball was hit and a racquet sound was made. Once they understood this metaphor, it was easy for users to move the phone around the court space to hit the ball. Physical manipulation of a phone is very natural so it provides an intuitive interaction approach for collaborative AR games.

CONCLUSION AND FUTURE WORK

Mobile phones provide an interesting opportunity for augmented reality technology to move into the mainstream, used by millions of people. However before this happens more research has to be conducted on the best AR interaction metaphors and techniques for mobile devices.

In this chapter we present our experiences with mobile phone based AR. We have developed an optimized version of ARToolKit for the mobile phone, and then using that explored a tangible input metaphor where we use the real phone motion to interact with AR content. We developed a basic interaction application for 6DOF object manipulation, and the first collaborative AR game for mobile phones.

One of the main limitations of our platform is the tracking. To be able to track the phone position using ARToolKit, the complete marker pattern must be visible. We have begun to experiment with feature tracking to allow one corner of the marker square to be outside the viewfinder. Another problem is that the current ARToolKit tracking only works in a limited range. If the user is too close to the marker, one or more corners will fall outside of the viewfinder. Too far away and the resolution is too low for marker identification.

Though the focus will remain on optical tracking due to the widespread availability of camera phones, other tracking techniques might be commonly available and make the transition to wide-area mobile phone AR possible. Many 3G phones have built-in GPS, which enables outdoor positioning. Some phones have also electronic compasses and tilt sensors built-in. These sensors combined will make it possible to obtain the orientation and position of the device.

We will continue to explore mobile phone based augmented reality. In the future we would like to employ the 6DOF manipulation techniques in a collaborative set-up and conduct more in-depth user studies. Other applications will also be developed to explore other aspects of mobile phone AR such as content creation and interfacing with intelligent environments.

Chapter 3.20
Pen-Based Mobile Computing

Bernie Garret
University of British Columbia, Canada

INTRODUCTION

The original idea of a portable computer is credited to Alan Kay of the Xerox Palo Alto Research Center who suggested the idea in the 1970s (Kay, 1972a, 1972b; Kay & Goldberg, 1977). He envisioned a notebook-sized portable computer named the "Dynabook" that could be used for all of the user's information needs and using wireless network capabilities for connectivity.

BACKGROUND

Origins: Laptop Computers

The first actual portable "laptop" computers appeared in 1979: the Grid Compass Computer was designed in 1979 by William Moggridge for Grid Systems Corporation (Stanford University, 2003). The Grid Compass was one-fifth the weight of any model equivalent in performance and was used by NASA on the space shuttle program in the early 1980s. Portable computers continued to develop in the 1980s onwards, and most weighed around about 5 kg without any peripherals.

In 1984, Apple Computer introduced its Apple IIc model (Abbate, 1999), a true notebook-sized computer weighing about 5 kg without a monitor. The Apple IIc had an optional LCD panel monitor which made it genuinely portable and was therefore highly successful.

In 1986, IBM introduced its IBM Convertible PC with 256KB of memory; it was also a commercial success. By many, this is considered the first true laptop (mainly due to its clamshell design) that was shortly copied by other manufacturers such as Toshiba who were also successful with IBM laptop clones (Allen, 2001; Cringely, 1996). These devices retained the A4 size footprint, full QWERTY keyboards, and weighed between 3 and 4 kg (IBM, 2006). Following these innovations "tablet" PCs with a flat A4 footprint and a pen-based interface began to emerge in the 1990s.

There were several devices in the 1970s that explored the tablet, but in 1989 the Grid Systems GRiDPad was released, which was the world's first IBM PC-compatible tablet PC that featured handwriting recognition as well as a pen-based point-and-select system. In 1992, Microsoft released Microsoft Windows for Pen Computing, which had an application programming interface (API)

that developers could use to create pen-enabled applications. Focusing specifically on devices that use the pen as the primary input device, this interface has been most successfully adopted in the new breed of small, highly portable personal digital assistants (PDAs).

Personal Digital Assistants

In 1984 David Potter and his partners at PSION launched the "PSION Organiser" which retailed for just under £100 (Troni & Lowber, 2001). It was a battery-powered, 14 x 9cm, block-shaped unit with an alphabetic keyboard and small LCD screen, with 2K of RAM, 4KB of applications in ROM, and a free 8KB data card (which had to be reformatted using ultraviolet light for reuse). Compared to the much larger notebook computers of the time, it was a revolutionary device, but because of its more limited screen size and memory, it fulfilled a different niche in the market and began to be used for personal information management and stock inventory purposes (with a plug-in barcode reader).

In the late 1980s and throughout the 1990s, PSION continued to develop commercially successful small computing devices incorporating a larger LCD screen, and a new fully multi-tasking graphical user interface (before even Microsoft had got Windows up and running). These small devices were truly handheld. The PSION 3c (launched in 1991) dimensions were 165 x 85 x 22 mm, with a 480 x 160 pixel LCD screen, and the device weighed less than 400 g. A small keyboard and innovative touch-sensitive pad provided control of the cursor, and graphical icons could be selected to start applications/functions and select items from menus. The small keyboard proved difficult to use however, and the following 5c model in 1997 used an innovative foldout miniature QWERTY keyboard. These genuinely "handheld" devices with their interface innovations and ability to synchronize data with a host personal computer made the PSION models particularly successful and firmly established the personal digital assistant as a portable computing tool for professionals.

Pen-Based Interfaces for the PDA

The limitations of keyboard-based data entry for handheld devices had been recognized, and following PSION's lead, Apple Computers introduced the Newton Message Pad in 1993. This device was the first to incorporate a touch-sensitive screen with a pen-based graphical interface and handwriting-recognition software. Although moderately successful the device's handwriting recognition proved slow and unreliable, and in 1998 Apple discontinued its PDA development. However, the PDA market was now becoming firmly based upon devices using pen-based handwriting recognition for text entry, and in mid-2001, PSION, with dwindling sales and difficulties with business partnerships, ceased trading. US Robotics launched the "Palm Pilot" in 1996 using its simple "Graffiti" handwriting recognition system, and Compaq released the "iPAQ" in 1997 incorporating the new Microsoft "Windows CE/Pocket PC" operating system with the first PDA color screen.

Microsoft's relatively late entry into this market reflected the considerable research and development it undertook into developing a user-friendly pocket PC handwriting recognition interface. This remains a highly competitive field, and from November 2002 PalmSource (the new company owning the Palm Operating System) replaced the Graffiti system with Computer Intelligence Corporation's JOT as the standard and only handwriting software on all new Palm-powered devices. Computer Intelligence Corporation (CIC) was founded in conjunction with the Stanford Research Institute (SRI) based on research conducted by SRI on proprietary pattern recognition technologies (CIC, 1999). The original Graffiti system relied on the user learning a series of special characters, which while simple was irksome to

many users. The CIC JOT and Microsoft Pocket PC systems have been developed to avoid the use of special symbols or characters and allow the user to input more naturally by using standard upper and lowercase printed letters. Both systems also recognize most of the original Palm Graffiti-based special characters. In 2006 Palm introduced the Windows Mobile (Pocket PC) operating system on its own high-end devices.

The Thumb Board Text Interface

The arrival of the short messaging service (SMS), otherwise known as text messaging for cellular phones, in the late 1990s led several PDA manufacturers to adopt an alternative Thumb Board interface for their PDAs. SMS allows an individual to send short text and numeric messages (up to 160 characters) to and from digital cell phones and public SMS messaging gateways on the Internet. With the widespread adoption of SMS by the younger generation, thumb-based text entry (using only one thumb to input data on cell phone keypads) became popular (Karuturi, 2003). Abbreviations such as "C U L8er" for "See you later" and "emoticons" or "smileys" to reduce the terseness of the medium and give shorthand emotional indicators developed. The rapid commercial success of this input interface inspired the implementation of Thumb Board "keyboards" on some PDAs (such as the Palm Treo 600) for text interface. Clip-on Thumb Board input accessories have also been developed for a range of PDAs.

Tablet Format PCs

The tablet PC provides a small (usually 10 x 12" screen size) rectangular format device equipped with a sensitive screen designed to interact with a device-specific pen. The pen is used directly to write or tap on the screen. It can be used in place of a keyboard or mouse for data entry; to select, drag, and open files; to draw on the screen; and to handwrite notes and communications. Tablet PCs also incorporate handwriting recognition and conversion to text software. Unlike a touch-sensitive screen, the Tablet PC screen only receives information from the device-specific pen. It will not take information from pressure applied to the screen, so users can rest their hands on the screen and write in a more natural way. Most Tablet PCs also come with optional attachable keyboards and docking stations so they can be used in the same way as a desktop computer.

A pen-based interface for the PC was developed in the early 1990s and was originally envisaged as a challenge to the mouse. Microsoft launched "Pen Extensions for Windows 3.1" in 1991 calling it "Windows for Pen Computing." The system was designed to use plug-in slate and pen systems. However, pen-based systems would take another 10 years to become established. Shortly after its launch a number of companies introduced hardware to support it. Among them were Samsung, Fujitsu, Compaq, Toshiba, and IBM. The original IBM ThinkPad was designed as a pen-based computer. However, these pen-based systems were not well received, as many users found the Windows interface difficult to use with the stylus, and by 1995 sales of pen-based systems failed to support their further mainstream development. Bill Gates remained a strong supporter of the interface, and Microsoft decided to reintroduce pen computers as the "Tablet PC" in 2002. This time the Tablet PC specification was more successful as the use of touch-screen technologies for the pen (not well developed in the 1990s), handwriting recognition, and better integrated smaller devices made the portable tablet more acceptable for consumers.

The tablet PC has proved popular for specialist uses such as in the classroom, for creative artistic use, or more recently as the platform of choice for electronic flight planning/mapping software in aviation. A growing number of manufacturers are now producing Tablet PC hardware. However, the format still retains a far smaller proportion of the mobile PC market compared to laptops and PDAs.

MULTIMEDIA AND WIRELESS INTEGRATION

Current developments in pen-based computer interfaces are exploring the use of multimedia, voice recognition, and wireless connectivity. The expansion of memory capabilities and processor speeds for mobile computing devices has enabled audio recording, digital music storage/playback, and now digital image and video recording/playback to be integrated into these devices. This and the integration of wireless network and cellular phone technologies have expanded their utility considerably.

One of the mobile computer user. Audio is attractive for mobile applications because it can be used when the user's hands and tablet interfaces remains the output display, it can be used in conditions of low screen visibility, and it may consume less power than text-based input in the PDA. The latest PDA interface innovations include voice command and dictation recognition (voice to text), voice dialing, image-based dialing (for cell phone use, where the user states a name or selects an image to initiate a call), audio memo recording, and multimedia messaging (MMS). Several devices (e.g., the new Carrier Technologies I-Mate and Palm Treo) also incorporate a digital camera.

Wireless connectivity has enabled Internet connectivity, enabling users to access e-mail, text/graphical messaging services (SMS and MMS), and the Web remotely. These developments are gradually expanding the PDA's functionality into a true multi-purpose tool.

FUTURE TRENDS

One of the key limitations of PDA and tablet interfaces remains the output display screen size, brightness, and resolution. Issues of resolution and brightness continue to hinder many potential applications for this technology. As input technologies improve, and voice and handwriting recognition come of age, then attention to the display capabilities of these devices will need to be addressed before their full potential can be realized.

Coding PDA applications to recognize handwriting, speech, and incorporate multimedia requires additional code beyond traditionally coded interfaces. PDA application design and development environments need to support this functionality more effectively in order to promote the development of more complex mobile applications.

Data and device security are key areas for highly portable networked PDAs, and the first viruses for PDAs have started to emerge (Melnick, Dinman, & Muratov, 2004; BitDefender 2004). As multimedia interfaces develop, the specific security issues that they entail (such as individual voice recognition and prevention of data corruption of new file formats) will also need to be addressed.

CONCLUSION

Since the early models, manufacturers have continued to introduce smaller and improved portable computers, culminating in the latest generation of powerful handheld PDAs offering fast (400 MHz and faster) processors, with considerable memory (64MB of ROM and 1GB of RAM or more). This area of technological development remains highly competitive, and by necessity, the user interface for these devices has developed to fulfill the portable design brief, including the use of pen- and voice-based data input, collapsible LCD displays, wireless network connectivity, and now cell phone integration. Modern PDAs are much more sophisticated, lightweight devices and are arguably much closer to Kay's original vision of mobile computing than the current laptop or tablet computers, and possibly have the potential to replace this format with future interface developments. Indeed, if the

interface issues are successfully addressed, then it is probable that these devices will outsell PCs in the future and become the major computing platform for personal use.

KEY TERMS

Audio Memo: An audio recorded message of speech digitally recorded as an audio file on a PDA.

Laptop: A portable personal computer small enough to use on your lap.

Media Player: A device or software application designed to play a variety of digital communications media such as compressed audio files (e.g., MPEG MP3 files), digital video files, and other digital media formats.

Multimedia: Communications media that combines multiple formats such as text, graphics, sound, and video.

Multimedia Messaging Service (MMS): An emerging cellular phone service that allows the sending of multiple media in a single message,

with the ability to send a message to multiple recipients. As such it can be seen as an evolution of SMS, with MMS supporting the transmission of additional media types, including: pictures, audio, video, and combinations of the above.

Palmtop: A portable personal computer which can be operated comfortably while held in one hand.

Pen Computing: A computer that uses an electronic pen (or stylus) rather than a keyboard for data input. Pen-based computers often support handwriting or voice recognition so that users can write on the screen or vocalize commands/dictate instead of typing with a keyboard. Many pen computers are handheld devices. Also known as pen-based computing.

Personal Digital Assistant (PDA): A small handheld computing device with data input and display facilities with a range of software applications. Small keyboards and pen-based input systems are commonly used for user input.

Personal Information Manager (PIM): A software application (such as Microsoft Outlook) that provides multiple ways to log and organize personal and business information such as contacts, events, tasks, appointments, and notes on a digital device.

Short Message Service (SMS): A text message service that enables users to send short messages (160 characters) to other users. A popular service amongst young people, with 400 billion SMS messages sent worldwide in 2002 (GSM World 2002).

Smart Phone: A term used for the combination of mobile phone and PDA.

Synchronization: The harmonization of data on two (or more) different digital devices so that both contain the same data. Data is commonly synchronized on the basis of the date it was last altered.

Tablet PC: A newer type of format for personal computers. The Tablet PC provides all the power of a laptop PC, but without a keyboard for text entry. Tablet PCs use pen-based input, and handwriting and voice recognition technologies as the main form of data entry, and commonly have an A4-size footprint.

Texting: Sending short text messages by SMS.

Wireless Connectivity: The communication of digital devices between one another using data transmission by radio waves.

Chapter 3.21
The Smart Card in Mobile Communications:
Enabler of Next-Generation (NG) Services

Claus Dietze
The European Telecommunications Standards Institute (ETSI), France

ABSTRACT

This chapter gives an introduction into the smart card technology and its history by outlining the role of the smart card in mobile communications systems. The role of the smart card as a key enabler for services requiring or utilizing unambiguous user-identification is outlined. These services include multimedia and high-security services such as mobile commerce or mobile banking. Smart cards containing the described mechanisms provide the user with privacy and the capabilities to use information, personalized according to his needs, in a wide-spread system with a virtually unlimited number of services. Furthermore, the capabilities of the smart card to enhance services, to secure the issuers' revenues and to increase the usage of the services by providing a trustful platform for the user are described. Future evolutions and further developments of the smart card are illustrated, including how they pave towards new types of applications and services.

INTRODUCTION

The smart card in mobile communications is used both as a service platform and as a marketing instrument for the network operator. The (Universal) Subscriber Identity Module-(U)SIM—is the network operator's "business card" that is handed out to the end-user. The design of the artwork printed on the smart card, the packaging, and the functionality directly influence the positioning of the operator's brand in the market. The smart card as used in mobile communications enjoys a high reputation and is very important for the network operators. It does not only provide security and trust thus securing the revenues of the network operator, but is also a platform for value added services. Its importance for the network operator is

impressively expressed by one of the world-leading network operators: they included the shape of the SIM into their corporate identity and use it within their logo and advertisement. Why this is absolutely justifiable will be outlined in the following chapter.

This chapter is divided into the following seven sections:

- The first section gives a brief introduction into the structure of the chapter and subject;
- The following section derives a dedicated definition for the term "smart card in mobile communications" to create a common understanding for the remainder of the chapter;
- The next section briefly lists and describes the main different specifications for smart cards used in today's mobile communications systems;
- The next section describes the technological and commercial evolution of the early SIM towards the next generation smart card (UICC, USIM, ISIM) used for 3G and further generations. Issues such as the technological constraints as well as the enhancements of the smart card are described and their impact on the market is highlighted;
- We then illustrate the role of standardizing organizations and explain the importance of standards for the success of a mobile communications system and the smart card in particular;
- The following section details the key capabilities of current and future smart cards and describes their importance for the creation of successful mobile services;
- And finally, we give an outlook on future evolutions of the smart card in mobile communications.

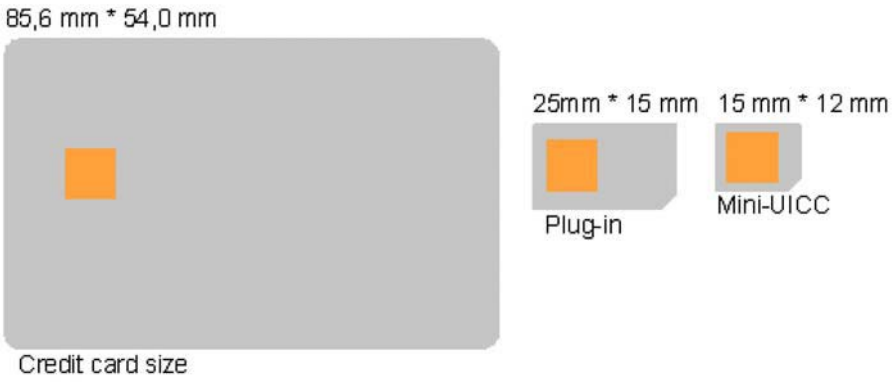
DEFINING THE "SMART CARD IN MOBILE COMMUNICATIONS"

When searching the internet or other technical literature for definitions and explanations of the term "smart card", the following can be found: "The smart card is a credit-card size plastic card containing a micro-processor". Please also refer to the Smart Card Handbook for further information on smart card technology in general. For the context of this chapter and for the usage of the smart card in mobile communications, this definition is only to some extent true and need to be modified. A more appropriate definition of what the smart card in mobile communications actually is, is developed below by examining the features and applications implemented on and executed by it. The first indication on the purpose of a particular product may in many cases be derived from its name. This also holds for a smart card in mobile communications. As, of course, everybody using a Global System for Mobile communications (GSM™) phone knows, it has been called the Subscriber Identity Module or simply the "SIM". In fact, the capability to uniquely and securely identify one single user within the network has been one of the key features for the SIM since the beginning. How this feature was extended during the evolution of the SIM will be outlined later in this chapter.

Coming back to the above cited definition of the "smart card", the following precision are made below that focus on the use of the smart card in the area of mobile communications. The first precision concerns the first part of the definition, that is, "The smart card is a credit-card size...".

Simply looking at a SIM reveals that the actual size is much smaller than the size of a regular credit card. This reduction in size was felt necessary already at a very early stage in order to allow the smart card to be inserted in smaller and smaller devices, i.e. mobile terminals. In the respective specifications and standards this small size SIM is called Plug-in or ID-000. A further reduction

Figure 1. Size reduction of SIM card



in size was introduced into the standards in the beginning of 2004 (Mini-UICC) and show that the size of the smart card should not be part of the definition.

Another physical characteristic of the SIM or the next generation smart card for telecommunication is even more important. It was one of the crucial factors for the success of the SIM. The SIM is a token that can be removed from one terminal and easily put into another one. This allows the user to transport all personal as well as end user subscription related data from one terminal to another, for example when buying a new terminal. Even in the days of tri-band terminals allowing end-users to perform calls in almost every part in the world, new access technologies arise that again benefit from the "removableness" of the SIM. Wireless Local Area Networks (WLANs) could be mentioned as just one example of where the smart card may need to be removed from the mobile terminal and put into a WLAN device. Another solution will allow the smart card in the mobile terminal to be used for the authorization of the WLAN session that runs on a different piece of hardware.

The second modification of the definition is related to the part "... size plastic card...". Due to the reduced size of the SIM (see above) only a small piece of plastic is used to hold the module containing the micro-processor. From this point of view the material that is used to hold the module should not have any significance in the definition and could be left out.

The smart card is also described as "...containing a micro-processor" for the execution of functions implemented on it. Even though the micro-processor of the smart card is its heart, the soul of the smart card is or are the applications implemented on it. The applications characterize the smart card and make it useable in dedicated markets. In addition to the micro-processor, more and more memory capacity is required in the smart card. This memory is needed in order to contain multiple applications and value added services as well as complex configuration and provisioning parameters for services such as Multimedia Messaging Service, General Packet Radio Service (GPRS) connectivity or others. Rather than defining a smart card through its possession of a micro-processor, the smart card

in mobile communications should be defined through its capabilities to execute applications and to manage specific types of data such as data which is personalized according to the individual users' needs.

As a result of the above observations the following is offered as a more accurate definition of the "smart card used in mobile communications": "The smart card in mobile communications is an individually personalized and removable authentication token. It is used to execute dedicated applications and manages specific data within the mobile communications system."

SMART CARD IN MOBILE COMMUNICATIONS SYSTEMS

Having defined the "smart card in mobile communications", we may now consider its role and the respective specifications for different mobile communications systems.

Besides the already frequently mentioned SIM used in GSM/EDGE Radio Access Network (GERAN) or USIM/UICC used in the Universal Terrestrial Radio Access Network (UTRAN), smart cards are also specified for other mobile communications systems—with the difference that in these systems the smart card is an optional component whereas it is mandatory in GERAN and UTRAN systems. The SIM specification, GSM TS 11.11, is the mother of almost every specification that was developed for other mobile communications systems. It was used as a basis for a smart card used in Terrestrial Trunked Radio (TETRA) systems that focus on emergency services as well as for the smart card used in the Digital Enhanced Cordless Telecommunications (DECT™) system and the Code Division Multiple Access (CDMA) system, just to mention three.

System Architecture

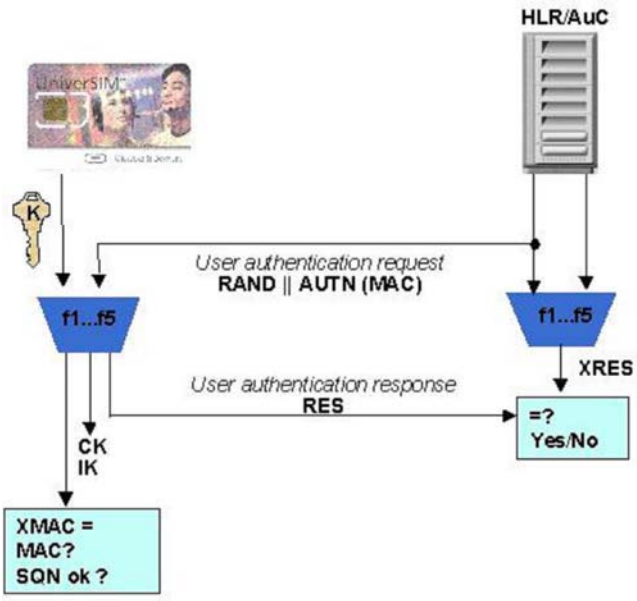
The smart card in mobile communications represents one crucial component in the network infrastructure. It mainly plays two different roles: to provide secure access and provisioning to the network and to provide additional value added services for the end user and/or the network operator. Both roles are outlined in the following two subsections.

Network System Component

The smart card as a network system component is primarily used to authenticate the subscriber to the network as in GSM or to mutually authenticate both the subscriber and the network as in UTRAN. The following Figure 2 shows the simplified authentication procedure in a UTRAN system and illustrates the role of the smart card. All authentication relevant computations on the user side are executed inside the smart card. The secret key K used for the computations never leaves the smart card and is safely stored in the secure memory area of the chip. The smart cards' counterpart for the authentication in the network is the Authentication Centre (AuC). The AuC also possesses the secret key K and is therefore able to calculate the expected response of the smart card (RES). By performing the respective calculations (using functions f1 to f5) on both the user and the network side and by comparing the results of the calculations with the values submitted by the respective counterpart, a decision on the network access can be made by both parties.

Connectivity parameters such as Multimedia Message Service (MMS) parameters and service related information such as preferred network identities are stored on the smart card. This information is used by the handset to access the appropriate networks and services. Putting the connectivity parameters on the smart card allows the user to access the network operators' services independent of the terminal used.

Figure 2. Authentication procedure

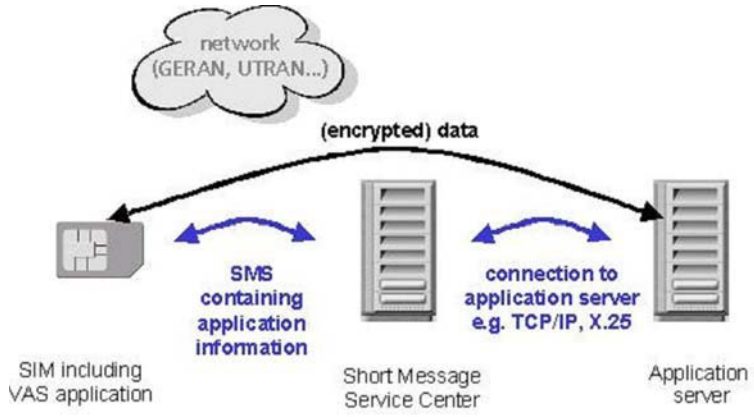


Value Added Services System Component

The Card Application Toolkit (CAT) provides a common set of commands that was derived from the SIM Application Toolkit. This framework enabled the development of additional applications that can be put on the smart card. These applications are in general linked to a network entity in the background server system. This server system is not necessarily located at the network operators premises and could also be operated and maintained by third party service providers such as news content providers or banks. An end-to-end (server-to-card) communication channel for applications stored and executed on the smart card can be established. Dedicated security mechanisms that are defined in the respective specifications (see TS 03.48 and TS 102 127 for further information) provide a secure channel between the smart card and the network entity. Application relevant data can be encrypted and will only be available for the application server and the application in the smart card.

Figure 3 illustrates today's system architecture for SMS based services in a 2G network. The SIM issues a short message that contains dedicated and application specific information. This information can optionally be encrypted. The data part contained in the short message is then routed via the Short Message Service Center (SMSC) to the application server. The application server (optionally decrypts and) interprets the contents of the message and triggers the relevant behaviour such as downloading further information to the SIM.

Figure 3. Simplified value added services architecture



GSM/EDGE Radio Access Network (GERAN) and Universal Terrestrial Radio Access Network (UTRAN)

The main (and most successful) mobile communications system that currently involves a smart card is certainly GERAN (GSM). The Subscriber Identity Module—the SIM—is specified as a mandatory component in the whole system. Therefore, all mobile terminals have to include a smart card reader that is able to contain the smart card. The technical core specifications that are being maintained and further developed by the respective standards organizations are:

- TS 11.11 the "Specification of the SIM-Mobile Equipment Interface" that started in the early days and was developed further until Release 99; and
- TS 51.011 the "Specification of the SIM-Mobile Equipment Interface" which is the corresponding document that only exists in Release 4.

The members of the 3rd Generation Partnership Project (3GPP™ concluded to freeze the SIM specifications at Release 4 and to include further enhancements to the SIM into the evolutional counterpart of the SIM in UTRAN—the Universal Subscriber Identity Module (USIM). The main specifications for the USIM are:

- TS 31.101 defining the "UICC-Terminal Interface; Physical and Logical Characteristics" of the smart card from Release 99 onwards; and
- TS 31.102 specifying the "Characteristics of the USIM Application" from Release 99 onwards.

A comprehensive overview of how the two smart card applications, the SIM and the USIM, interwork and how they could be combined on one single smart card that could be used for GERAN as well as UTRAN is also part of these specifications. A related technical report, TR 31.900 "SIM/USIM Internal and External Interworking Aspects", describes these aspects in detail. It

outlines further the key role that the smart card plays for a network operator that migrates from 2nd Generation to 3rd Generation networks.

Code Division Multiple Access (CDMA)

The second major mobile communications player in the industry is CDMA. 3GPP2, the equivalent to 3GPP for the specification of CDMA, is responsible for the definition and maintenance of the specifications for CDMA2000. 3GPP2 is a partnership project consisting of the following partners: Association of Radio Industries and Businesses (ARIB-Japan), China Communications Standards Association (CCSA-China), Telecommunications Industry Association (TIA-North America), Telecommunications Technology Association (TTA-Korea) and The Telecommunication Technology Committee (TTC-Japan).

In CDMA networks the smart card is optional, that is, all parameters such as subscription data, network settings, and security functions are stored and personalized into the handset. Due to the absence of the smart card CDMA has been facing the following issues:

- No roaming to GSM/GERAN networks for the subscriber, which means a new card and a new terminal is required when travelling abroad;
- Difficult handset exchange due to difficult transfer of personal and subscription related data from the existing to the new terminal;
- Difficult manufacturing process for terminals due to personalization of each of the terminals with user individual data; and
- No SIM Application Toolkit based services and applications available that can be easily transferred from one terminal to another.

These limitations lead to strong requests for a smart card. This request was also supported by the CDMA Development Group (CDG). Therefore 3GPP2 specified--also based on the SIM specification in TS 11.11—the requirements for the Removable User Identity Module (R-UIM) in technical specification C.S0023-0. The R-UIM is an extension of the Subscriber Identity Module (SIM) capabilities, to enable operation in a radiotelephone environment. Examples of this environment include, but are not limited to, analogue CDMA. The specification is based on the SIM specification and includes additional commands and responses necessary within the context of CDMA. The introduction of the R-UIM allows subscriber to “plastic roam” (by switching the smart card) between CDMA and GSM networks.

Digital Enhanced Cordless Telecommunications (DECT)

The European Telecommunications Standards Institute (ETSI) has developed a total of more than 30 publications (technical specifications, technical reports or technical base for regulation) for the Digital Enhanced Cordless Telephony (DECT). The first system became operative in 1992. The DECT Authentication Module (DAM), based on the SIM specification TS 11.11, was specified in the early 1990’s. This enabled a smart card to be used as an authentication token for the end user to be introduced and several specifications were approved:

- ETSI ETS 300 331 ed.1 (1995-11): Digital Enhanced Cordless Telecommunications (DECT); DECT Authentication Module (DAM); and
- ETSI ETS 300 825 ed.1 (1997-10): Digital Enhanced Cordless Telecommunications (DECT); 3 Volt DECT Authentication Module (DAM).

Mobile network operators that also operate as fixed line operators have experienced the

advantages of a smart card in a mobile communications system and are seeking to adapt services that are being used in the mobile world also to the home and fixed line environment. This is an interesting phenomenon. Even though the fixed line telephony has been used for far longer than mobile telephony, the standards for the features and the look and feel of terminals are being set by the mobile industry. This trend will also impact services being used in the mobile world that are going to be introduced in the fixed line environment. Features such as short messages and multimedia messages are being introduced into the "regular" phones, which are mainly DECT phones. The inclusion of a smart card adding further advantages to them seems to be a logical evolution of today's DECT phones. A DECT Local Area Network (DECT LAN) also appears to be an area where secure user authentication and therefore the DAM could be essential.

TErrestrial Trunked RAdio (TETRA)

TETRA is an open digital standard developed by ETSI that describes a common mobile radio communications infrastructure. This infrastructure is targeted primarily at the requirements and needs of public safety groups such as police and fire departments. The requirements comprise the need to rely on fast and accurate file communication even if no network coverage is given. These groups have been high-end users of private/professional mobile radio (PMR) or public access mobile radio (PAMR) technology. Based on digital, trunked radio technology, TETRA is targeted to be the next-generation architecture and standard for current, analogue PMR and PAMR markets. As TETRA is targeted to public safety groups, privacy and confidentiality of the data and voice communication is essential.

Again based on the SIM specification TS 11.11, a smart card, the TETRA SIM, was specified for the usage in the TETRA system. The TETRA SIM used for user authentication and storage of configuration data and phonebooks was specified by the respective ETSI technical body in the mid 1990s in:

- ETR 295 "Radio Equipment and Systems (RES); Trans-European Trunked Radio (TETRA); User requirements for Subscriber Identity Module (SIM)". This Technical Report describes the high level requirements that have to be fulfilled by the TETRA SIM. ETR 295 was published in 1996 and indicates that the SIM is an optional device within TETRA Mobile Stations (MS): thus this ETR does not preclude the implementation of MS without a SIM.
- ETS 300 812 "Terrestrial Trunked Radio (TETRA); Security aspects; Subscriber Identity Module to Mobile Equipment (SIM - ME) interface", Edition 1, was the first version of the TETRA SIM specification. It was published in 1998.
- ETS 300 812 Edition 1 was revised to EN 300 812 version 2.1.1, published in 2001.
- ES 200 812 part 1 (Physical and logical characteristics) and part 2 (Characteristics of the TSIM application), published in 2002, are the Edition2/Release 1 versions of TS 100 812-1 and TS 100 812-2 (see chapter 3.2) and are technically identical. They are intended to ensure a smooth transition to TETRA Release 2.

In line with the evolution of the smart card to a multi-application platform, the TETRA SIM specification in TETRA Release 2 split off the physical characteristics and concentrated on the definition of a TETRA SIM application. The aim was to bring convergence with the Universal SIM (USIM), to meet the needs for TETRA specific services whilst gaining the benefits of interworking and roaming with public mobile networks such as GSM, GPRS and UMTS™ TETRA Release 2 started in September 2000 in order to enhance the services and facilities of TETRA. Release 2

of the TETRA SIMs (TSIM) aligns the TETRA SIM application with 3GPP. Release 2 was previously known as Edition 3 of the TETRA SIM specifications.

EVOLUTION OF THE SMART CARD IN MOBILE COMMUNICATIONS

Evolution Of Smart Card Hardware

In 1988 the idea of introducing a smart card in mobile communications led to the first conception of the SIM. In these early days microprocessor chips that could be embedded in a smart card had only a very limited amount of memory that did not allow storage of large data sets. Therefore the first functionality implemented on the SIM focussed on the authentication algorithm. From the beginning the smart card was used to provide the end user with a secure token that enabled her/him to access the GSM service. For network operators the SIM allowed from the very beginning to manage billing and other information about their subscribers. The security features of the smart card in mobile communications were constantly enhanced and developed.

Data storage capability was discussed as early as May 1988. It was introduced for the provision of services including Short Message Service, Advice of Charge, Abbreviated Dialling Numbers and Public Land Mobile Network (PLMN) selection, but memory was a major constraint. Initially, the total memory capacity of a SIM was about 10 kB for both the operating system (read only memory—ROM) and data storage (programmable memory—EEPROM). Only in the mid-1990's did larger chips with 8 kB of programmable memory become available. Today, chips provide 128 kB to accommodate (programmable) data and applications, and at least the same amount for the operating system and other ROM-based applications. New technologies such as flash or floating EEPROM technology will soon enable the mass deployment of even larger chips, with 1 MB or more of programmable memory—today's expectations with today's available technology reach to an estimated maximum of about 16MB memory within the today's (U)SIM.

Considering the fact that comparing the 128KB with a 1MB smart card is already an increase in available memory of about 800%, the question arises how to actually use up all memory. The answer is given by the network operators: The SIM is the property and under full control of the network operator. Therefore all important information and network connectivity parameters as well as service related information should be stored and managed by the SIM.

Also, the separation of programmable and read only memory could be dissolved in favor of the programmable memory. New technologies allow the storage of the operating system in a special one-time programmable memory that can be loaded onto the smart card during the production process. This has the advantage that packages of features, tailored to the network operators' needs, could be loaded onto the smart card rather than burning the complete set of features into the ROM part of the chip. Figure 4 illustrates the traditional split of the memory into ROM and EEPROM. It shows the separation of the memory into an operating system area (ROM) and the applications and data area (EEPROM). The provisioning of the memory is fix and cannot be changed after the production of the chip. New technologies such as flash or "floating EEPROM", as shown in Figure 5, provide a more flexible memory management. The operating system, applications and data share one common memory pool. This pool is not split and can be managed according to the network operators needs.

Features that resided in ROM by default and that are not required by the network operator could be removed, freeing more memory for additional applications that are requested by the network operator or their customers. Based on this technology development cycles and thus time to

Figure 4. Traditional memory separation scenario

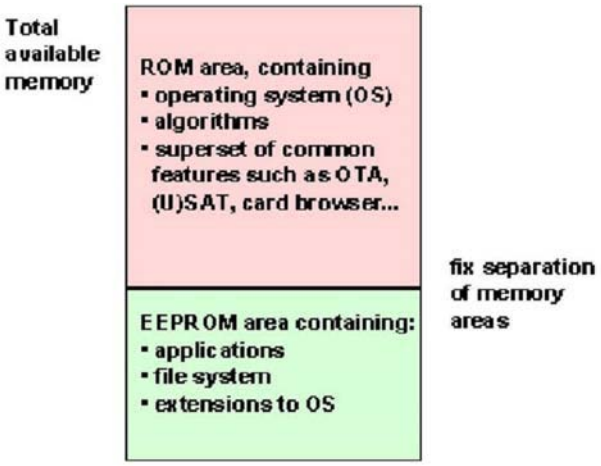


Figure 5. Flexible memory separation scenario

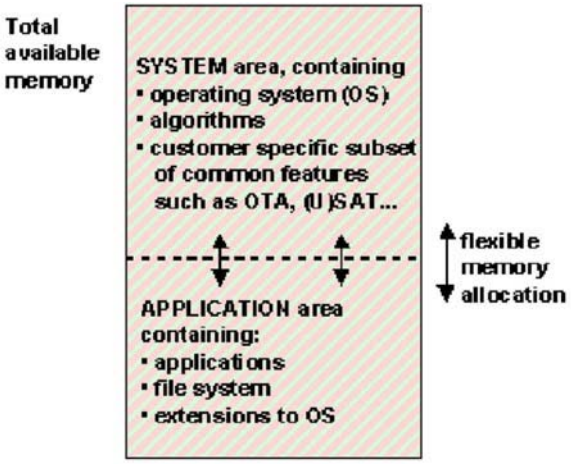

market will be reduced. Providing new operating systems and features in the ROM mask of a chip is a time consuming task. From the finalization of the development by the smart card manufacturer until the reception of first commercial samples of the chip takes between three and six months. Making the development of these components independent of the silicon manufacturer saves valuable time for the introduction of new features and enhancements for the network operator.

Along with the evolution of the memory, SIM processors have followed a similar growth pattern. From the first eight bit processors to today's chips which have the computing power of 16 bit and 32 bit processors. Dedicated crypto co-processors allow the powerful execution of asymmetric crypto-algorithms. Asymmetric

crypto-algorithms enable the smart card to play a major role in the application of Public Key Infrastructures (PKI) to regulate the use of certificates for authentication in e-transactions.

Evolution of Software and Operating System Architecture

In parallel to the evolution of the chip hardware the operating system as well as the capabilities of the operating system evolved. SIM development reached a major milestone in 1996 when ETSI approved the first technical specification for the SIM Application Toolkit (Technical Specification TS 11.14). This specification defined a set of commands and procedures to enable the card to contain applications specific to the issuer (the network operator), allowing the operator to introduce a wide range of new services including information and location based services, banking and Internet access. Today, the smart card in mobile devices operates and manipulates menus and services and authenticates users for service access. The high level of security which the SIM offers means it can secure financial transactions over a mobile phone, enabling mobile commerce. Work continues to introduce additional features. The introduction of the SIM Application Toolkit was the first step towards the opening of the SIM for additional and customer, that is network operator-specific applications. These applications had to be developed by specialists that had access to the operating system of the card and that were able to low level code the application (hard code) into the EEPROM of the SIM card. Therefore development was time consuming and expensive. Only smart card manufacturers were able to implement such applications on their cards. As different smart card vendors had their own (different) smart card operating system the development had to be done as often as the network operators have smart card suppliers.

A need for an Application Programming Interface (API) arose that, as for other computer systems, allowed applications to be developed by almost anybody and rapidly. It should be possible to run these applications interoperable on any smart card, independently of the smart card vendor. To fulfil this request, ETSI approved a high level requirements specification to introduce such an API in TS 02.19. The first API fulfilling the requirements of TS 02.19 was approved in 1998 (TS 03.19) and was based on the Java CardTM specifications developed by the Java CardTM forum. The new Java CardsTM were supposed to allow development of applets in a quick and cost efficient way. However, reality showed that even though JavaTM seemed to be the right way to go, all aims could actually not be achieved in the beginning. Interoperability on a 100% technical level needed to be slowly established and proven in the market. Using JavaTM technology does not automatically guarantee interoperability.

Smart card vendors offer development kits for their Java CardTM products (such as Sm@rtCafe Professional of JavaTM Mobile Application Designer (JMAD) from Giesecke & Devrient, Cyberflex from axalto or GemXPlore from Gemplus). New services and applications can comparatively easy be developed, leading to an increased demand of the smart card vendors' Java CardsTM. Actually, only very few application developers could profitably enter the market and offer new smart card applications to network operators. The reason is rather simple: network operators have been used to getting applications almost for free from the smart card vendor. Due to the history of application development on SIM cards and the competitive situation in the market, most of the smart card vendors continued to offer the applications for free or at least for a far less cost than an independent application developer. Nevertheless JavaTM proved to be very important within the industry especially with regards to time to market and flexibility for the network operator. It allows the one time development of services utilizing SIM Application Toolkit commands. After perambulating the learning curve

and due to the help of external organizations such as SIMalliance and ETSI, the major smart card vendors managed to provide truly interoperable Java CardsTM. That means that applets that have been developed by one party should run equally on cards of any other party that also followed the appropriate specifications for the development of the applet and the Java CardTM.

With the advent of 3G, the SIM has evolved to become the "USIM" (the Universal Subscriber Identity Module). Whereas the SIM is the definition of a complete smart card including the physical and logical characteristics (i.e., the plastic and the chip), the USIM is defined as being an application. The USIM resides on a smart card that is to be implemented according to the technical specifications for the smart card platform, the UICC. Figures 6 and 7 illustrate the different concepts. Figure 6 shows the traditional SIM architecture whereas Figure 7 illustrates the new modular concept. A smart card for 3G mobile communications consists of the UICC containing at least one USIM application.

This new approach of separating the physical and logical characteristics from the functions and applications enables the smart card to become multi-application capable. It is like having a PC with a basic operating system (being the UICC) and the Internet explorer managing the access to the network (being the USIM). The USIM provides features which equip it to play a key role in crucial aspects of 3G such as managing security access, virus intrusion, customer profiles, mutual authentication, downloading, and a new phonebook allowing the management of additional information such as fax numbers and e-mail addresses. The USIM also has the ability to store applications for network services, offering, for example, pre-paid service activation and control, information services, directory services, mobile banking, and ticketing. See later in this chapter for further information.

The UICC allows users access to global roaming by means of their smart card, irrespective of the radio access technology used. It is able to contain multiple applications, allowing smooth roaming and interworking between different services and networks, whether GSM, the new Wideband Code Division Multiple Access (W-CDMA) or other networks; the handset will be able to access a portfolio of services and applications available to users via their user profiles.

The UICC's revolutionary ability to handle true multi-applications, providing the platform for independent applications which can even run in parallel, present an interesting test of both the ingenuity of marketing experts and the ability of different market sectors and manufacturers to co-operate in the deployment of services. For instance, telecommunication operators are able to issue UICCs containing both a USIM and an electronic purse.

The UICC also contains new features such as enhanced security, further Application Programming Interfaces (APIs), new form factors, enhancement of the interface speed, access to shared multimedia sessions through the Internet Protocol Multimedia Subsystem (IMS), and, of course, backwards compatibility for network operators, allowing them a smooth transition from 2G to 3G.

Evolution Milestones

Figure 8 provides an overview on major steps achieved during the evolution and development of the smart card in mobile communications, in particular the SIM and USIM.

Supplementary information on the evolution of the SIM can be found in the article "The Subscriber Identity Module, Past, Present and Future" of Dr. Klaus Vedder in [1].

Further evolution of the smart card in mobile communications is certain as the market for GERAN and UTRAN and therefore the market for the smart card used in such systems continues to grow. To give an indication on the market size:

Figure 6. Single application smart card

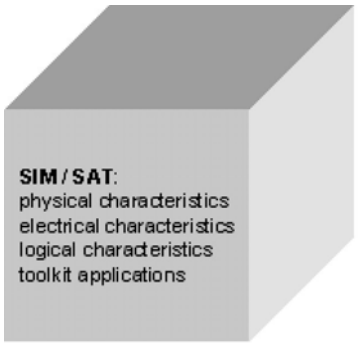

Figure 7. Multiapplication smart card

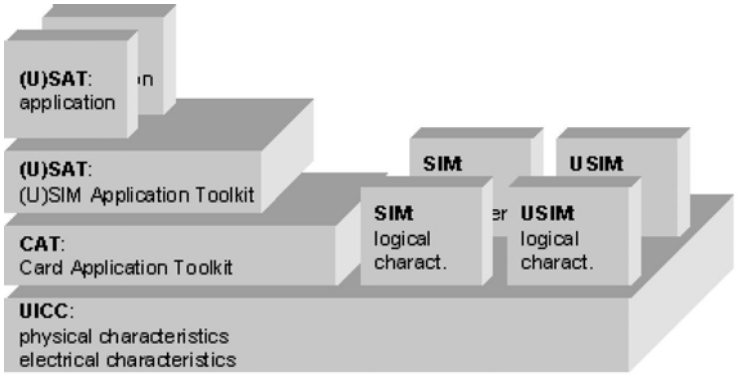

Figure 8. Evolution of the SIM

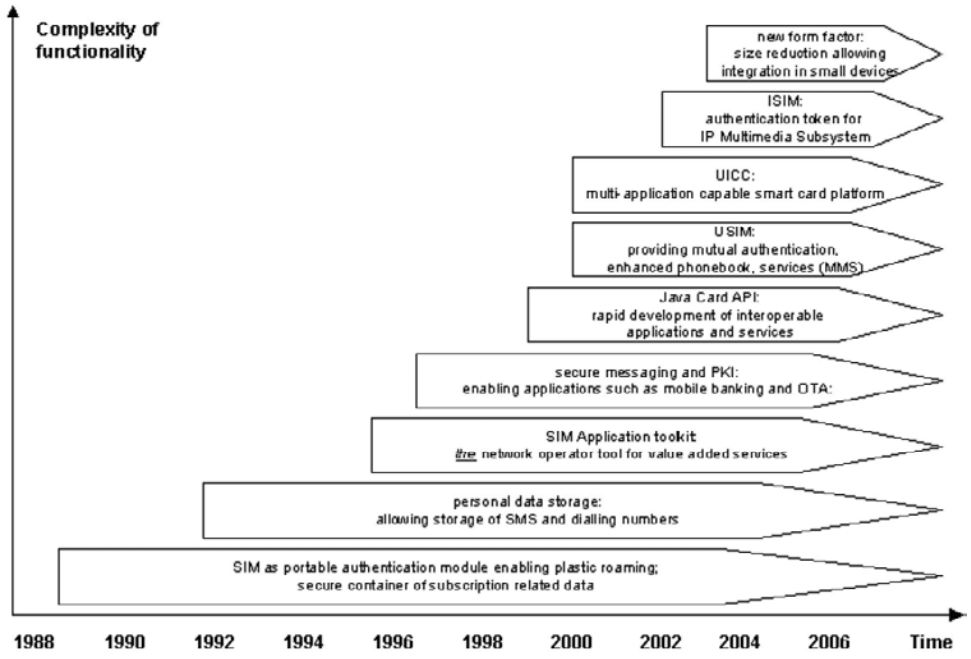


from its first delivery to the present, far more than 2 billion SIM cards have been delivered.

STANDARDIZATION

When talking about markets, features, services and business one of the main drivers for the business is in most of the cases underrepresented: standardization. Standardization is a subject that is not very often discussed in connection with services, marketing, and business but is actually one of the most important factors in the game. Standards aim to establish systems that make interoperable solutions among different manufacturers possible and therefore also reduce cost. This drives the acceptance of the system in the market. Without standardization systems like mobile communications could not have become reality on such a large scale. One can without doubt say that standardization has been the driver for the success of GSM and the SIM.

Today's purchasing decisions are more and more based on whether the solution or product is implemented according to a particular set of standards. The availability of specifications and standards was a key factor for the success of the SIM as well as the ability to provide the network operator with a standardized subscriber authentication method. The revenue of the network operator depends to a large extent on the security of the authentication and thus the billing system. It is crucial to rely on a defined method for the subscriber authentication and in addition a set of harmonized and standardized security features. The production of the relevant standards has been undertaken by ETSI.

ETSI is the recognized European Standardization Organization for telecommunications and related fields of broadcasting and information technology. From its inception in 1988, the Institute has been at the leading edge in setting security standards. It achieved an outstanding success with the standardization of the Global System for Mobile communications (GSM), which included authentication, anonymity and customer privacy. This represented the first full, worldwide, commercial deployment of encryption and smart cards, and ETSI's standardization of the SIM for GSM has helped make it the most widely deployed smart card ever.

With the closure of ETSI committee SMG9 (Special Mobile Group 9) in the year 2000, which was responsible for specifying the SIM, and the establishment in December 1998 of the 3rd Generation Partnership Project (3GPP), of which ETSI is a founding partner, ETSI's work on the SIM application, i.e. the non-platform and non-generic part, was transferred to 3GPP's Technical Specification Group TSG-T3. T3's task is to further evolve the SIM application to meet the demands of the new 3rd generation (3G) mobile network.

Further smart card-related work continues within ETSI's Smart Card Platform Project (EP SCP), which was founded in 2000 as the successor of SMG9. EP SCP is the focal point in ETSI for the standardization of the common Integrated Circuit (IC) card platform for 2G (e.g. GSM) and 3G mobile communications systems, the UICC. (As described earlier, the UICC comprises the platform specifications implemented on the smart card, together with all resident applications based on them. It also contains the USIM as an application for access to the 3GPP system, and/or the R-UIM application for access to the 3GPP2 system.) The work of EP SCP provides a common platform on which others, including organizations from the financial sector, can base their system-specific applications.

In addition, EP SCP has worked to make the specifications for GSM independent of the bearer network and, as part of the process, new deliverables have been approved. These specifications provide standardized security mechanisms for the interface between a network entity (e.g. a toolkit application) and an entity in the UICC. They also make available a standardized method for the secure, remote management of files and applica-

tions on the UICC. A requirements specification for a generic API, the UICC-API, was approved in 2002, and the work on a corresponding functional and architectural specification was completed in May 2003. This allows the rapid development of interoperable card-based applications (applets).

The upshot of these developments is that, while the SIM retains its original function of authentication, it has evolved to become both a service platform offering multiple value added services and a multi-application platform providing interoperability and interworking between different access technologies.

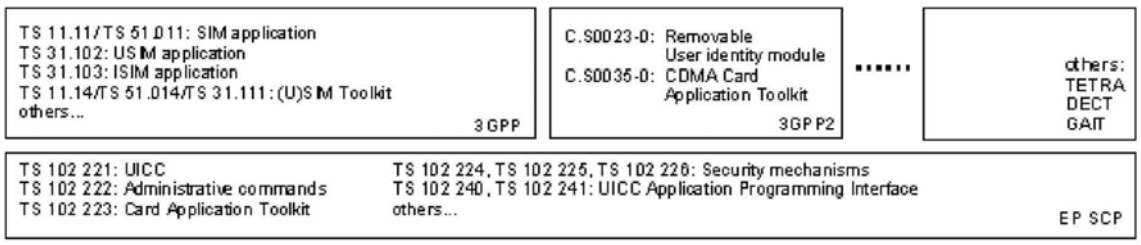
Further advancements of the UICC platform and the applications based on it will create new possibilities. For example, the new form factor specified by EP SCP allows the development of smaller devices, for example, for data transmission only, and offer additional communication and financial applications. New chip technology and the continuation of standardization work will advance the capabilities of smart cards to the point where they are really personal mini-computers. This development in turn will enable new applications, which will drive the growth of other new technologies, particularly 3G mobile.

The following Figure 9 illustrates the responsibility and interdependencies of the different standards producing bodies. ETSI project Smart Card Platform (EP SCP) is the initiator of common and application independent platform specifications. It is responsible for the creation and maintenance of these platform specifications on which other committees such as 3GPP and 3GPP2 base their system and application specifications such as the SIM, USIM and CDMA Card Application Toolkit.

Institutes such as ETSI, and partnership projects (such as 3GPP and 3GPP2) between different institutions, are important for the generation of specifications and standards. It is very easy to imagine that a set of specifications for a system such as 3G is a huge effort and that the different parties that are going to base their products and services on these specifications heavily contribute to such standards. Hundreds of member companies from all over the world develop their products and services based on the standards they produce under the umbrella of the institutes and partnership projects.

Clearly, decision-making and Intellectual Property Rights (IPRs) are or could become quite an issue among the member companies. For these reasons ETSI and 3GPP respectively, created working procedures and established an IPR policy under which the specifications are produced, with the aim of minimizing these issues. This framework is accepted by the different parties when they become a member and sign the membership agreement of the institute.

Figure 9. Organisation of standards and responsibility of standards bodies



The development of specifications/deliverables is consensus driven. The way decisions are made is well defined in the rules and working procedures. Given the diversity of interests, it is remarkable that, in the long history of standardization, the use of the ultimate decision-making tool where no consensus can be reached, — the vote — is very rare. In the case of standardization for smart cards in telecommunication, up to now only one single vote has been; this was in December 2003 in ETSI Project Smart Card Platform, and concerned the introduction of the new form factor for the smart card.

Last but not least, the fruitful collaboration between the different standardization organizations and their collaboration with the industry partners ensures that the standards meet market requirements.

2G, 3G AND NG SERVICES BASED ON THE SMART CARD

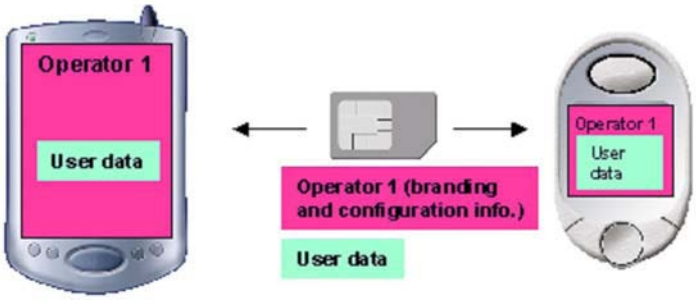
Smart card technology has consistently and reliably provided solutions to current and future requirements and challenges. The smart card evolution cycles become ever shorter, whilst the capabilities of the smart card increase as dramatically as for any other product in the information technology domain. Even though those capabilities increase, the key features of the smart card in mobile communications remain the same, yet are subject to enhancements and evolution. This section explores those key features and discusses the services and applications that utilize these key features. It concludes with a review of some of the work areas that are currently being considered by the smart card specification groups. They are listed and briefly described to illustrate just some example areas of further enhancements and future trends.

Security Mechanisms

One of the main features of the smart card is to provide security: security when authenticating the subscriber to the network (and also the network to the subscriber) by performing cryptographic operations as well as security mechanisms to protect security relevant data from unauthorized access. Security means trust and the level of trust depends on the relevance of the performed transaction (and the connected value). The end user need to trust the stability and security of the system when performing dedicated operations that in particular have some financial impact. These services include: digital signature to sign commercial transactions; mutual authentication of subscribers and service providers to get access to special (with cost) services; storage of secret user data such as keys or PINs to grant access to the secret or personal data on the smart card; secure authentication to access Virtual Private Networks for company subscriptions; providing features to secure copyrights (Digital Rights Management) when for example transferring valuable content from one terminal to another terminal; preventing theft of mobile terminals by connecting the smart card and some secret data to the terminal; and many more.

As the smart card is the token which uniquely identifies a subscriber in the network it is also an ideal container for all subscriber individual data that is not related to the authentication procedure. Such data could either be personal data stored on the smart card by the end user or data that is used by specific applications (e.g. application toolkit services) running on the smart card and managed by the card or application issuer. Personalized applications that behave according to the individual needs or characteristics of every single end user can be envisaged. Personalized applications are commonly used within the Internet. Once subscribed to a bookstore and as soon as some articles have been purchased, an individual customer profile is created. This customer profile

Figure 10. Personalisation of terminal by smart card



will then initiate the application to behave in a personalized way when visiting the bookstore again. Starting with a personal greeting reaching to a tailored product offering for the customer to more easily find the appropriate book. Services of this kind are also introduced to the mobile world. The creation of Web pages for the terminal that can be displayed on the screen mirror the Internet behaviour on the mobile world.

As smart card applications are used for billing services the security of the smart card has also been subject to attacks. Appropriate countermeasures were developed by the industry to fend off such attacks, for instance, power analysis on the chip and measurement of the required power consumption during dedicated operations could be used to determine security relevant data. Random waiting periods to the processor and the use of processors with constant and steady power consumption were some of the introduced countermeasures.

Personal Identity and Data Management

The smart card is a removable device allowing an easy transfer of personal data (such as phone numbers) from one mobile terminal to another and of course to allow plastic roaming (in different networks, see also sections above).

Life cycles of terminals and smart cards, and the necessity to change the terminal from time to time for reasons of functionality, forces the end user to also transfer all personal data from the existing terminal to the new terminal. This has to be done whilst keeping all relevant authentication parameters and mechanisms, as access to the network still needs to be provided. In order to ensure a smooth migration from one terminal to another without any tools, the smart card and all personal data stored on it can be easily ported from one terminal to another by simply taking it out of the reader and putting it into the reader of the new terminal. With the increasing number of services and a resulting increasing amount of personal data to be stored, the migration became more and more inconvenient and complex for the user if the data was stored in the terminal. Dedicated connectivity parameters and settings for the network and some services can easily be ported as well as additional keys and PINs for high security applications such as mobile stock trading and virtual private network access. The same applies to personal data such as phone numbers, email addresses and templates stored on the smart card. Equally, applications that are stored on the

smart card remain available to the end user when the exiting terminal is replaced by a new one. For the network operator, branding information and connectivity parameters that are stored on the smart card are available on any terminal.

Value Added Service Platform

The smart card is a platform for value added services. As mentioned above, a standardized framework to develop services exists for the smart card. This framework is supported by virtually all terminals in an harmonized way. The framework comprises the Card Application Toolkit (SIM application toolkit in 2G and USIM application toolkit in 3G) allowing the creation of applications that utilize the capabilities of the terminal with regards to the user interface (keyboard, display...) and the radio interface and bearers (set up call, set up GPRS connections...). Value added services starting with simple information services such as weather information or horoscope can be rolled out. But also more complex applications involving 3rd parties (such as a financial institution or a WLAN operator) are generated and can be easily put on the smart card. The SIM Application Toolkit and/or USIM Application Toolkit provide mechanisms to also retrieve location information and allow the development of location-based services. Dedicated routines and procedures on the smart card are defined for the execution of call control features that allow the restricted or dedicated use of subscriptions related to the calls that can be set up. In order to offer flexible solutions, a dynamic approach exists for the interpretation or execution of applications on the smart card. A smart card browser was defined that allows development of applications that are stored on a Web server and that are dynamically downloaded to the smart card and interpreted accordingly. Besides the evolution of the smart card hardware, the toolkit is one of the areas that has developed most rapidly in order to reflect the new technologies and make them available from and for smart card applications. All major smart card vendors offer development tools to generate applications based on the card application toolkit standards by even providing a graphic interface to the developer. Adding the Java CardTM API to the smart card allowed an even faster and easier way to develop applications for the smart card (see also section 4.2).

Today's smart cards offer true multi-application capabilities. New generation smart cards are multi-application capable. This means that completely independent applications can run on the same physical smart card. Whereas in the "old" days the smart cards contained one application and the SIM was a specification of both the logical and the physical characteristics, the new concept is to separate the physical aspects from the application specific characteristics. This allows the combination of completely independent applications on the same smart card platform. For example, a credit card application could be combined with a USIM application on the same smart card. These applications are completely independent from each other. That means that the credit card application (e.g. EMV) does not rely on the mechanisms provided by the USIM application. Whereas today a banking application uses the bearers offered by the mobile communication system, an infrared interface could be used for the payment transaction if the credit card application was separate. The SIM application (remember, the SIM is now an application and not a complete smart card anymore) or any other application may be located on the same card. The maximum number of applications running on the same smart card is only limited by the available memory space. The multi-application capability of the smart card enables network operators to prepare for a smooth transition from 2G to 3G by providing both the 2G and the 3G application on the same smart card. This concept will permit the network operators to also smoothly migrate from 3G to any further generation system. Considering the technical capabilities and the increase in memory available on the smart card, concepts are

developed to rent out a specific part of the memory on the card to a third party. This allows them to offer their services to the customer base of the network operator. Any third party could provide applications such as ticketing or banking in case the network operator itself decided to concentrate on other core business rather than offering all services and applications by himself.

Service Deployment and Management

The smart card is owned by the network operator. Even though the smart card is physically possessed by the end user, it is still the property of the network operator. As the smart card is the only token being under full control of the network operator, the network operator is independent from the type and model of mobile terminal used by the customer. The smart card enables the network operator or service provider to offer applications according to standardized methods on all different types of mobile terminals. These services will then be available to practically all customers. Operators are putting one generic service enabling application on the smart card that can be managed and enhanced remotely. This generic service application is a flexible tool that adjusts itself depending on the terminal in use and depending on the subscribers needs. It is a platform for specific applications such as infoservices, banking or any other type of application. This ensures that the network operator can base at least some or parts of their most important services on the smart card. So, as more and more smart terminals and personal digital assistants (PDAs) with mobile communications capabilities enter the market, the smart card with its features will still be the property of the network operator and remains independent of the terminal.

Services are easily deployed. Service deployment need to be fast and cost efficient. Bringing new applications and services into the market is essential and has direct impact on revenue. The Java CardTM concept allows different parties to develop applications that can be placed on the smart card for mobile communications. Rapid development times represent one important factor for the rapid supply of new services. More complex, however, is the provisioning and management of these services in the field. Services need to be brought to the customer (see also section 4.2). Three principles for the deployment of services are:

- Delivery of smart cards already containing the new application;
- Update of the smart card in the shop / at the point of sale; this update is done either offline (by an autonomous PC system) or online (connected to a background server system); and
- Update of the smart card by using over the air mechanisms.

Logistics for the shipment of smart cards is well established in the industry. In general, network operators order only a limited number of different smart card types. This makes the deployment of applications based on the smart card rather simple. It can be done by using the established way of delivering the smart cards to the end user via the network operator's shop or by fulfilment services offered by the smart card manufacturer. Application could be loaded onto the smart card already during the production phase and delivered to the end user already containing all relevant services. In case new applications need to be brought onto cards that are already deployed in the field, they can be updated and applications can be uploaded on the smart card on the air interface (over the air — OTA) by using standardized mechanisms (e.g. TS 03.48/TS 23.048) and available "bearers" such as SMS or GPRS. The configuration of the smart card can also be done at the point of sale using dedicated tools to update the card in a card reader. At the point of sale the smart card is removed from the terminal and inserted into

a card reader connected to a personal computer. The employee in the network operators' shop is then able to configure the card according to the subscribers' requirements and the available new applications.

OTA capabilities of the smart card include the possibility to remotely manage the file system and the applications of the smart card. By means of existing bearers (such as SMS and GPRS) an OTA server is able to create, delete and modify files on the smart card. The smart card contents can be read out and sent to the background server, whilst new file contents can be written on the smart card from the background server. The OTA mechanisms can be utilized to update provisioning information for services such as MMS and to perform adjustment of parameters for bearers such as GPRS. Additionally, in the area of user equipment management (UEM) some relevant terminal related information could be stored and maintained on the smart card. The OTA capabilities even permit entire applications to be downloaded onto, and managed on, the smart card. Management of applications include provision of the application to the customer, update of the application or the application status, activation or deactivation due to business or technical reasons, re-activation, and finally deletion from the card. The OTA server system is capable of managing each individual card by storing information on the applications and services loaded, the memory space available for further applications any many more. This provides the marketing departments of the network operator a powerful tool to determine which kind of service is accepted, how frequently it is being used and what the effort was to deploy a new service to which category of subscriber.

Interworking Aspects

Platform for the interworking of different access technologies such as WLAN and 3GPP networks. The smart card offers a secure authentication platform to access networks. As wireless communication is a huge success in the market new types of wireless communication systems have been developed and further technologies may exist in the future. WiFi hotspots in public areas require secure authentication just as it is required in 2G and 3G networks. Billing for the usage of a service is only possible if there is a way to secure the network against unauthorized access. As the smart card is already used for authentication of the subscriber by the 2G or 3G operator, an enhancement of either the smart card, the authentication system or both is a natural step. This enhancement could then be used to authenticate the user and to grant him access to the WLAN access network. Combining the authentication functionality of different systems on one single smart card and using the same terminal to access different access technologies (e.g. whichever is cheaper to fulfil the end users needs) makes the smart card an interworking token. Furthermore (as mentioned previously) the smart card enables the issuer to prepare for a smooth transition from 2G to 3G and beyond to nG systems by providing the related authentication application (WLAN, 2G, 3G...) on the smart card. Interworking aspects between the WLAN systems and the existing 2G/3G networks are currently investigated by standardization groups. For the smart card two options are considered. Firstly, to use the existing SIM and/or USIM application to provide secure access to WLANs, for example, by implementing the IETF standards Extensible Authentication Protocol EAP-SIM or EAP-AKA. Secondly, to develop a new independent application that reside in parallel to the SIM and the USIM application on the UICC, the smart card platform. Which ever way will be decided, the smart will be an integral part within the system.

IP Multimedia Systems as specified by 3GPP allow IP based services to be used within the 3G context in the mobile world. The authentication to this kind of IP based services such as multimedia video streaming is being done by means of an application based on the smart card. The IMS Sub-

scriber Identity Module (ISIM), as defined in TS 31.103 "Characteristics of the ISIM application" allows secure access to IM services. This opened the way of the smart card into the authentication for IP based services and underlines the importance of the smart card for secure authentication of both subscribers and networks.

Last but not least, the smart card is fully standardized and harmonized. All required specifications for the implementation of services based on the smart card and for the smart card itself are available and mature. This allows an interoperable and harmonized implementation of services. Harmonization can be interpreted as at least twofold. The first interpretation is the harmonization of applications within the network operator group. Core applications can be defined for each subsidiary of the network operator that can then be easily adjusted according to individual local needs. The second interpretation is the harmonization of services among terminals. Different terminals (and PDAs etc.) behave in the same specified way and execute the applications stored on the smart card in the same way. As there is a much broader diversification of terminal operating systems compared to only one smart card operating system, network operators would have to develop their services for each different type of terminal operating system.

Current Work Areas and Next Generation Smart Card

The above described set of features is not exhaustive, it covers the most distinctive ones, allowing the derivation of an unlimited number of services and applications. In addition to the features described so far, some concrete enhancements are currently being discussed in the respective standardization groups, and are briefly outlined below:

- Multimedia Broadcast/Multicast Service (MBMS) security: In order to protect the Multimedia Broadcast/Multicast Service some security mechanisms need to be implemented to prevent unauthorized users to get access to the MBMS service. As the smart card is a proven token for containing security functionality, these mechanisms and features are being enhanced in order to also provide the requested level of security for the new service.
- Voice Group Call Services: The one-to-one communication channel within the 2G and 3G network need to be extended to a many-to-many communication. The related network authentication of the multiple members of the group that want to communicate to each other at the same time as well as the authentication of the individual members within the group is crucial. The classic authentication procedure based on the smart card needs to be enhanced to allow users to join or perform a group call. This service is especially important for emergency services and is already available in systems other than 2G or 3G, such as TETRA or TETRApol.
- UICC Security Services Module (USSM): The UICC may contain several applications, each dealing with keys and realizing crypto-services. Some keys might be shareable even though there are no standardized mechanisms to share keys and indicate allowed functions to authorized applications. To allow applications on the UICC to use shared security objects, it is essential to introduce standardize mechanisms to administer and to use these shared objects on the UICC. The USSM will consist of security objects (keys, PINs, etc.) including information on allowed functions and authorized applications, an API for administrative functions to administer objects of the USSM, and an API for cryptographic functions (non-administrative) to be used by applications.
- Advanced Communication: The demands on the classic smart card communication

channel are driving it beyond its design and intents. Bearer independent protocols allow UICC applications to access communication channels whose native speed is greater than needed for classic terminal/UICC traffic. Higher level protocols such as network and transport protocols are starting to appear on some bearers. The channel is multiplexed between multiple applications using a number of different techniques. This work item considers the evolution of the smart card communication channel with respect to transfer rate, size and protocol.

- Large Files: Applications such as multimedia or identification applications require data storage capabilities that are reaching the current file size maximum of 65,535 bytes. Increasing the maximum file size beyond this limit impacts a wide range of size fields, parameters and commands within the standards. This work item will upgrade the standard in a synchronized and harmonized manner by providing backward compatibility.
- Reduced voltage class: The aim of this work item is to respect the requirement to prolong the lifetime of the terminal's battery. In order to address this need the electrical characteristics of a new (1.2V) UICC-ME interface (the Class D operating conditions) has been defined and is awaiting final agreement.
- Next Generation UICC: This work item identifies and evaluates commercially-viable hardware and software technologies needed to define a next generation smart card platform. The scope of the work item includes, but is not limited to, the possible role of memory management units, ASIC co-processors, proof-carrying code, new memory architectures, natural clocks, multi-tasking operating systems, embedded electrical sources, free-running oscillators, integrated biometrics sensors, universal byte codes, alternative form factors, new chip carriers, and high-speed communication channels. One of the essential characteristics of these new technologies that will be catalogued is their impact—positive and negative—on the security of the UICC platform.

OUTLOOK

In Information Technology memory space and processing power has never been enough. This holds for the personal computer as well as for almost every component in the system. Displays have been too small, the resolution not good enough, battery lifetime was too short and the size of the battery too large. The smart card was therefore also seen as offering too little memory and not enough processing power. Today's multimedia applications and services demand more and more memory space for the storage of application or service related data such as pictures, movies and configuration data. But one thing needs to be remembered when demanding more memory, more processing power or more whatever: the smart card today already has the processing power of the early personal computers (PCs) concentrated on just a few square millimeters of silicon. And it is not the size but the effectiveness and the clever design of applications and services that make the service successful (and, of course, its market relevance).

The capabilities of the smart card will increase both physically (hardware) and logically (features implemented as software). From a hardware point of view, which has been the main constraining factor for the smart card, new technologies will enable a noticeable increase of memory capacity. Memory sizes of megabytes seem to be possible in near term and continued chip development appears to promise even multiple megabyte capacity in the mid term. The development of memory cards for digital and video cameras, together with the size reduction that is envisaged for these com-

ponents, gives a good indication of the potential for smart cards.

As in the PC world, chip technologies and processor capacities continue to evolve. We can foresee smart cards with the capability to execute complex security calculations such as asymmetric en- and decryption. Equally, the development costs for new high-end smart cards can be compared with those in the PC area. The prices of the PCs are more or less always stable, whilst the capabilities of the system, such as memory, processing power and software packages included, steadily increase.

Much interest is shown in smart cards with a contact-less interface for areas such as public transportation. The combination of contact and contact-less technology in mobile communications devices would also enable future services to be deployed by means of the mobile terminal. New standards such as near field communication (NFC) where an active component in the terminal could act as a card reader for contact-less cards could dramatically enhance the uses of the smart card.

Where the hardware capabilities of the smart card permit, and suitable opportunities exist, merging markets are foreseen. Transferring applications that reside on physically different smart cards onto the new multi application smart card makes sense for a number of applications, especially those that require the possibility to communicate with external entities or a personal card reader. Such applications are the ideal candidates to be incorporated into the smart card for mobile communications.

Mobile communication is a growing market: new applications and new areas of use are established regularly. Niche markets or markets that traditionally could not be served due to physical limitations of current technology will be served by new products. Telematics, just to give one example, is one of the areas that could not be served with a full range capability due to the limitation of the temperature range of existing hardware and chip products. The continuous development of these components is expected to allow increases in the temperature range to a degree that is acceptable in telematic systems.

Further reductions in size or even a completely new design and architecture of the smart card is part of the investigations carried out by the ETSI Project Smart Card Platform. The UICC next generation is a work item that has been set up by the committee to search for a smart card solution and architecture that will meet the future requirements. As well as possible size reductions, the definition of new communication protocols, new file systems and other enhancements are being considered as required by future markets. A new file system that reflects the capabilities of the smart card to store megabytes of data will enable the smart card to ease the management of data storage on the card. This will make it much easier for the issuer of the card to maintain and to manage the data related to the services on the card.

The evolution from a one-application card to a multi-application card is paralleled by evolution of the operating system. Multi-tasking operating systems and other state of the art personal computer features are required and may be added one by one to the smart card. This allows the addition of further applications that run in parallel or in background mode.

A further trend concerns the existence of multiple different communications systems such as 2G, 3G, WLAN, DECT and others. These will lead to a merger of the applications for the end user, and thus for end user devices. The token containing the authentication data and performing the trusted operations in the network for the end user will contain different authentication and network access applications. These applications may share some of the information stored on the smart card. This puts the smart card in a role of providing a smooth roaming from one access technology to another. The smart card acts as the medium that keeps the subscriber connected and that provides the means of interworking between

the different networks. Smart card ownership in such a scenario is crucial as it means that the churn of subscribers could be reduced: the subscriber could be more easily added as a customer for a new access technology by simply putting the required information on the smart card to access the new network. The network operator issuing the SIM and also operating WiFi hotspots could very easily enable the subscriber to access the WLAN at the airport by simply re-using the SIM card for the authentication. This makes it more difficult for new providers to offer such a service.

The pressure in the industry to generate additional revenues is extremely high. Companies have invested massively in the purchase of licenses and the setting up of new generation networks. Further enhancements to the network infrastructure and the introduction of further generations of communication systems will be equally expensive, so even more revenue has to be generated in order to be prepared for those future systems. This revenue will be generated by those companies who succeed in providing the appropriate services that are accepted by the consumers. Including the power of the smart card in the concept of such services may well be one major step towards achieving that goal.

Chapter 3.22
Unobtrusive Movement Interaction for Mobile Devices

ABSTRACT

Gesture control of mobile devices is an emerging user interaction modality. Large-scale deployment has been delayed by two main technical challenges: detecting gestures reliably and power consumption. There have also been user-experience-related challenges, such as indicating the start of a gesture, social acceptance, and feedback on the gesture detection status. This chapter evaluates a solution for the main challenges: an event-based movement interaction modality, tapping, that emphasizes minimal user effort in interacting with a mobile device. The technical feasibility of the interaction method is examined with a smartphone equipped with a sensor interaction cover, utilizing an enabling software framework. The reliability of detecting tapping is evaluated by analyzing a dataset collected with the smartphone prototype. Overall, the results suggest that detecting tapping is reliable enough for practical applications in mobile computing when the interaction is performed in a stationary situation.

INTRODUCTION

The source of innovations in a mobile device user interface lies in combinations of input and

output technologies that match the user's needs. In the mobile context, movement sensing, and haptic feedback as its counterpart, offers a new dimension to multimodal interactions. There are use cases where traditional interaction modalities are insufficient, for example, when the device is placed in a pocket or a holster, or if the user is wearing gloves. In these situations the user cannot press or see buttons to interact with the device. Instead, small motion gestures can be used as a limited, but convenient, control modality. The movement of the device can be captured with a 3-axis accelerometer, and the resulting acceleration signal can be used to detect the movement patterns for controlling the device.

One of the main questions in the application of a movement-based interface is how to distinguish gesture movements the user performs from those movements that are produced by various other activities while carrying and using the device. Reliability can be argued to be the most important challenge in developing a mobile device gesture interface. This chapter presents a reliability evaluation of an unobtrusive event-based gesture interface by analyzing a multiuser dataset collected with a smartphone prototype. Another main challenge has been the relatively high power consumption from the continuous measurement of acceleration, which is not acceptable in mobile devices. Novel accelerometers are capable of producing interrupts based on exceeded thresholds; therefore, the detection, initiated by a hardware interrupt, can be implemented as event based and low power. The technical feasibility of event-based tapping detection is examined with a smartphone equipped with a sensor interaction cover, Figure 1, and an enabling software framework. Furthermore, the chapter addresses the issue of flexibly customizing the gesture interface and feedback modalities relevant to aiding the user.

There are various ways of implementing a gesture interface. This chapter focuses on analyzing the tapping interaction, which shows potential as a significant application of accelerometers in future mobile devices. More specifically, the chapter addresses the movement pattern where the

Figure 1. Smartphone prototype equipped with the sensor interaction cover

user taps the device twice consecutively, which is called a double tap. With an implementation based on abstractions initiated by sensor-driven interrupts, the aim is a low-power, reliable, and customizable user interaction modality.

Gestures can be detected either from a continuous stream or discrete segments of sensor data. In detection from discrete segments, gesture start and end are explicitly marked with a button instead of a continuous flow of device movements. From the usability perspective, interaction without explicit marking is preferred, in general, since it requires less attention from the user. However, continuous data streaming and execution of the gesture detection algorithm requires continuous data processing, which normally consumes battery power.

The development in digital acceleration sensor technology enables the integration of programmable interrupt-based solutions that can operate with low current consumption. Such sensors generate interrupts when acceleration on a spatial axis is over or below a set threshold level. Hence, movement detection algorithms, initiated by an exceeded threshold, can be implemented as event based instead of continuously processing a stream of data. The processing load at the mobile device side is similarly reduced since the operating system is woken up less frequently. This development opens up new possibilities for practical application of the technology in mass products such as mobile phones.

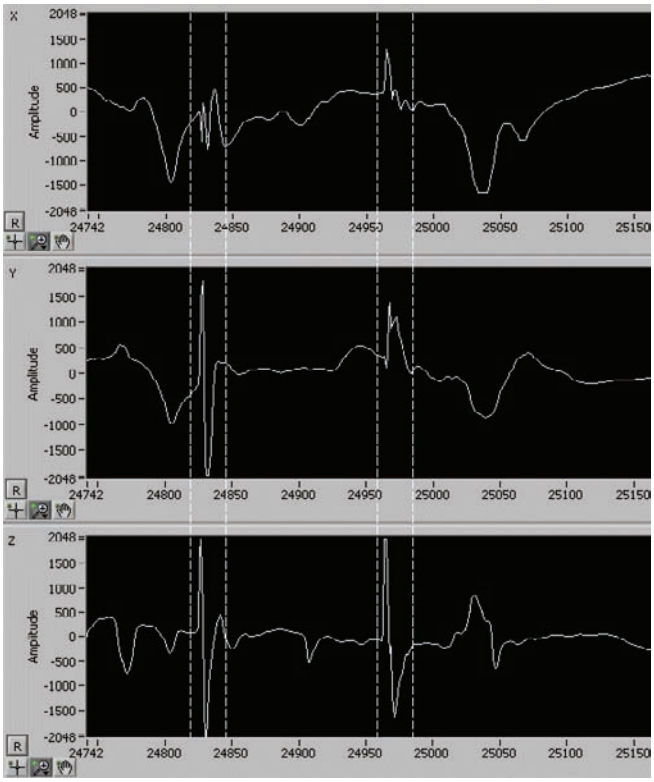
The distinguishable form of the tapping pattern, processed after the event threshold, is the basis for the potential reliability of detecting them, even when the detection process is continuously active, Figure 2. By contrast, free-form gesture recognition has a much wider problem setting, requiring a more complex model of the gesture and thus, heavier processing load, making continuous processing much more challenging, especially in mobile devices.

This chapter publishes the first statistical performance evaluation based on a dataset that characterizes the reliability of user-independent tapping interaction in mobile phones. Moreover, the sensitivity of the method to misrecognitions is evaluated with scenarios consisting of various activities. As an introductory topic, applying a smartphone equipped with sensor interaction cover, customization, and feedback of the addressed interaction modality are discussed.

BACKGROUND

In acceleration sensor-based gesture recognition, gestures are detected either from a continuous stream or from discrete segments of sensor data. While this chapter addresses the detection of movement patterns from a continuous stream, there are a lot of studies in the literature on gesture recognition from discrete segments (Feldman, Tapia, Sadi, Maes, & Schmandt, 2005; Mäntyjärvi, Kela, Korpipää, & Kallio, 2004). Specifically, acceleration sensors have been applied in user-trainable and pretrained machine-learning-based gesture recognition systems (Kallio, Kela, Korpipää, & Mäntyjärvi, 2006; Kela, Korpipää, Mäntyjärvi, Kallio, Savino, Jozzo, & Di Marca, 2006). Free-form gesture recognition still has a limitation; it requires an explicit marking of the gesture, for example, with a button, and longer duration gestures to increase the recognition accuracy. Hence the interaction requires more user effort, and gesturing can be socially obtrusive. However, despite the possible obtrusiveness when applied in public places, free-form gestures also have a wide range of potential uses in other settings, such as games, home electronics control, and so forth, where social acceptance does not limit the use of the modality. The social aspect, distinctively important in the mobile usage context, has been addressed by Linjama et al. (Linjama, Häkkilä, & Ronkainen, 2005), Rekimoto (2001), and Ronkainen et al. (Ronkainen, Häkkilä, Kaleva, Colley, & Linjama, 2007). Based on the literature, it can be extrapolated that, when

Figure 2. Three channels of acceleration data on a double tap performed while walking. The Z axis has two distinguishable spikes in this double tap.



performed with a mobile device such as a phone, smaller gestures are considered more socially acceptable than large ones.

This chapter especially advocates the unobtrusiveness of the interaction; gestures as small and as unnoticeable as possible are preferred, assuming they are more acceptable by the users (Linjama et al., 2005). Examples of possibly useful small-scale gestures include shaking the device, for example, Levin and Yarin (1999), and swinging it from side to side (Sawada, Uta, & Hashimoto, 1999). However, both of these interaction methods can be considered quite noticeable, regardless of scale. Shaking also raises the question of how many repetitions of the shake movement are required until a shake is recognized. A simple accelerometer-based tilting control has been discussed in the literature in many studies over the years, for example, Rekimoto (1996), but also recently, for example, combining tilt and vibrotactile feedback (Oakley, Ängeslevä, Hughes, & O'Modhrain, 2004), scrolling, and switching between landscape and portrait display orientations (Hinckley, Pierce, Horvitz, & Sinclair, 2005). Tilting is another potentially unobtrusive, and very simple to implement, movement-based interaction modality to be applied in carefully selected use cases in mobile computing.

A minimalist extreme in hand gestures is tapping the mobile device, first introduced in Linjama and Kaaresoja (2004). Tapping only requires a small scale of device movement, and can be performed by finger or palm. The technological benefit is that tapping can be relatively straightforwardly captured with a 3-D accelerometer, since the resulting movement pattern has a distinguishable sharp spike form. The detection problem can be narrowed down by applying a small, predefined fixed set of movement patterns: tap events.

The unique usability benefit of the tap interaction is that it is discreet and can be used if the mobile device is located in a pocket or a backpack, since explicit marking is not needed. Furthermore, the user is not required to hold the device or see the keyboard to interact. A good example of a use case where tapping is useful can be found in the Nokia 5500 phone (Nokia, 2006): when a text message arrives, the user has 30 seconds to tap the phone twice and the message will be read aloud to the user. It is useful when the phone is in a pocket or on a belt, or the user is wearing gloves; the message can be read without first taking the phone into the hand and opening the keypad lock. Furthermore, tapping can be used as an additional modality. For instance, phone music player commands, such as play next or previous song, can be controlled by tapping on either side of the phone, which is convenient when the device is worn on a belt or in a pocket. Again, the user does not have to take the phone, open keypad lock, and press a button to perform the control action.

SENSOR INTERACTION COVER

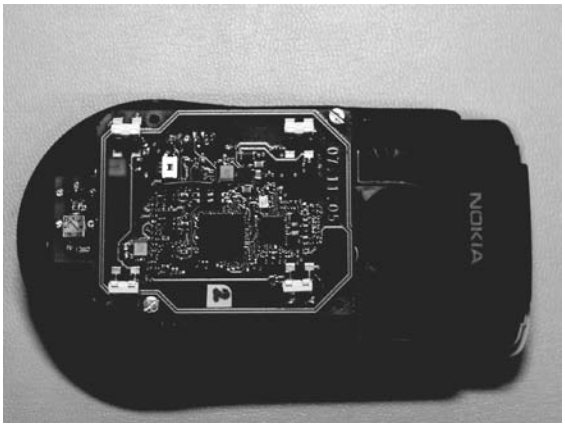
Interrupt-initiated abstracting of movement patterns can be performed using a separate microcontroller, or, ideally, it can be directly integrated in the sensor chip. A sensor interaction test platform was developed to experiment with the interaction concept. The platform consists of a Symbian S60 phone (Nokia 6630) equipped with a sensor and feedback cover attached to the back of the smartphone, Figure 3.

Inside the cover, the hardware includes a 3-D acceleration sensor (STMicroelectronics LIS3LV02DL), a microcontroller (Atmel), an NFC reader, blue LEDs, a buzzer, and a vibra motor, Figure 2. The board is two sided. Tap detection parameters and feedback configuration can be set to the microcontroller from the phone software. The tap detection algorithm and the feedback processing are performed in the cover microcontroller, and the cover transmits recognized tap events to the phone through USB. Thus, the communication between the cover and the phone, as well as power consumption, is minimized.

INTERACTION CUSTOMIZATION

Once sensor events are abstracted by the microcontroller and sent to the phone through the USB, they should activate the desired actions

Figure 3. Sensor interaction cover hardware

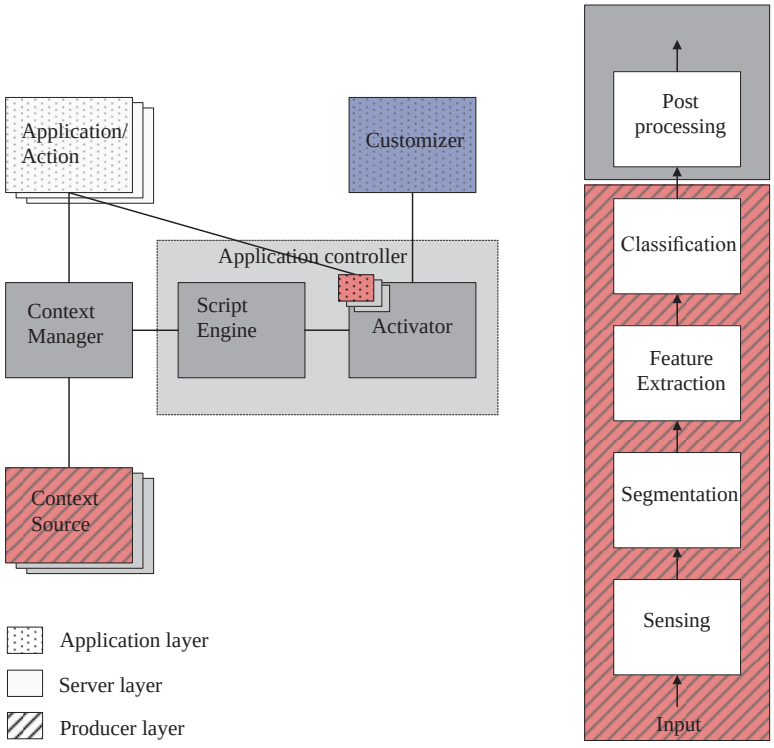


in the mobile phone. Flexibly connecting the abstracted sensor events to various application actions requires supporting middleware on the phone side. Instead of connecting an application directly to a device driver, the data is abstracted into a uniform representation applied through Context Framework.

Context Framework (CF) is a blackboard-based software framework for enabling and customizing situation-aware and sensor-based mobile applications (Korpipää 2005; Korpipää, Mäntyjärvi, Kela, Keränen, & Malm 2003). All interaction-related information, including implicit and explicit sensor-based inputs, is treated as context objects within the framework, expressed with a uniform vocabulary. An implemented instantiation of the framework is illustrated in Figure 4 (left-hand side). In this case, the sensor signal abstracting process functionality is on the microcontroller side, illustrated in Figure 4 (right-hand side flow diagram). Sensing, feature extraction, and classification are performed at the cover's microcontroller. Classified movement (context) events are sent over the USB to the phone side, where CF enables controlling any available application action based on the events.

The user can create desired context-action behavior with a mobile phone by creating

Figure 4. Context Framework (CF) architecture example instantiation (left), and pattern recognition flow (right)



XML-based rule scripts with the graphical UI of the Customizer. CF handles the background monitoring of context events and the triggering of actions according to the rules. The Application Controller facilitates the application control inference on behalf of the user or application, in other words, provides an inversion of control. The framework completely separates the management of sensor-based context events from application code and the hardware. Hence, by applying CF, no changes need to be made to existing mobile phone applications when they are augmented with sensor-based features.

In the case of tapping input, the events are abstracted into context objects by the sensor cover of the phone and delivered to CF. The application developer or the user interface designer can use the Customizer tool to define which application actions are executed by which abstracted sensor events. The definable actions include available feedback modalities, such as tactile, auditory, and visual indications. By creating rules with the Customizer tool, the user can define actions on an operating system level, or for a specific application, by setting a condition part of a rule to include a specific foreground application. For instance, the following accelerometer-based features were defined and executed simply as XML-based rule scripts:

- Playing the next or previous song in music player using double tap
- Activating display illumination using tap
- Unlocking the keypad using double tap

Figure 5 presents a series of screenshots from the Customizer tool, illustrating the definition of a rule that enables the user to unlock the keypad by double tapping the phone.

In Figure 5a, the user selects an action for the rule by navigating through the action type Phone. Keypad and selecting the action value KeypadUnlock. In Figure 5b, the user selects a trigger for the rule by navigating through context type Gesture and selecting context value DoubleTap. The first screenshot in Figure 5c shows the complete rule after the user has selected the elements. After the user selects the option Done, the rule script is generated, and the rule is activated and functional in the context framework. The second screenshot in Figure 5c shows the main rule view with the list of active rules. When the rule conditions are met, the Context Framework automatically performs the action.

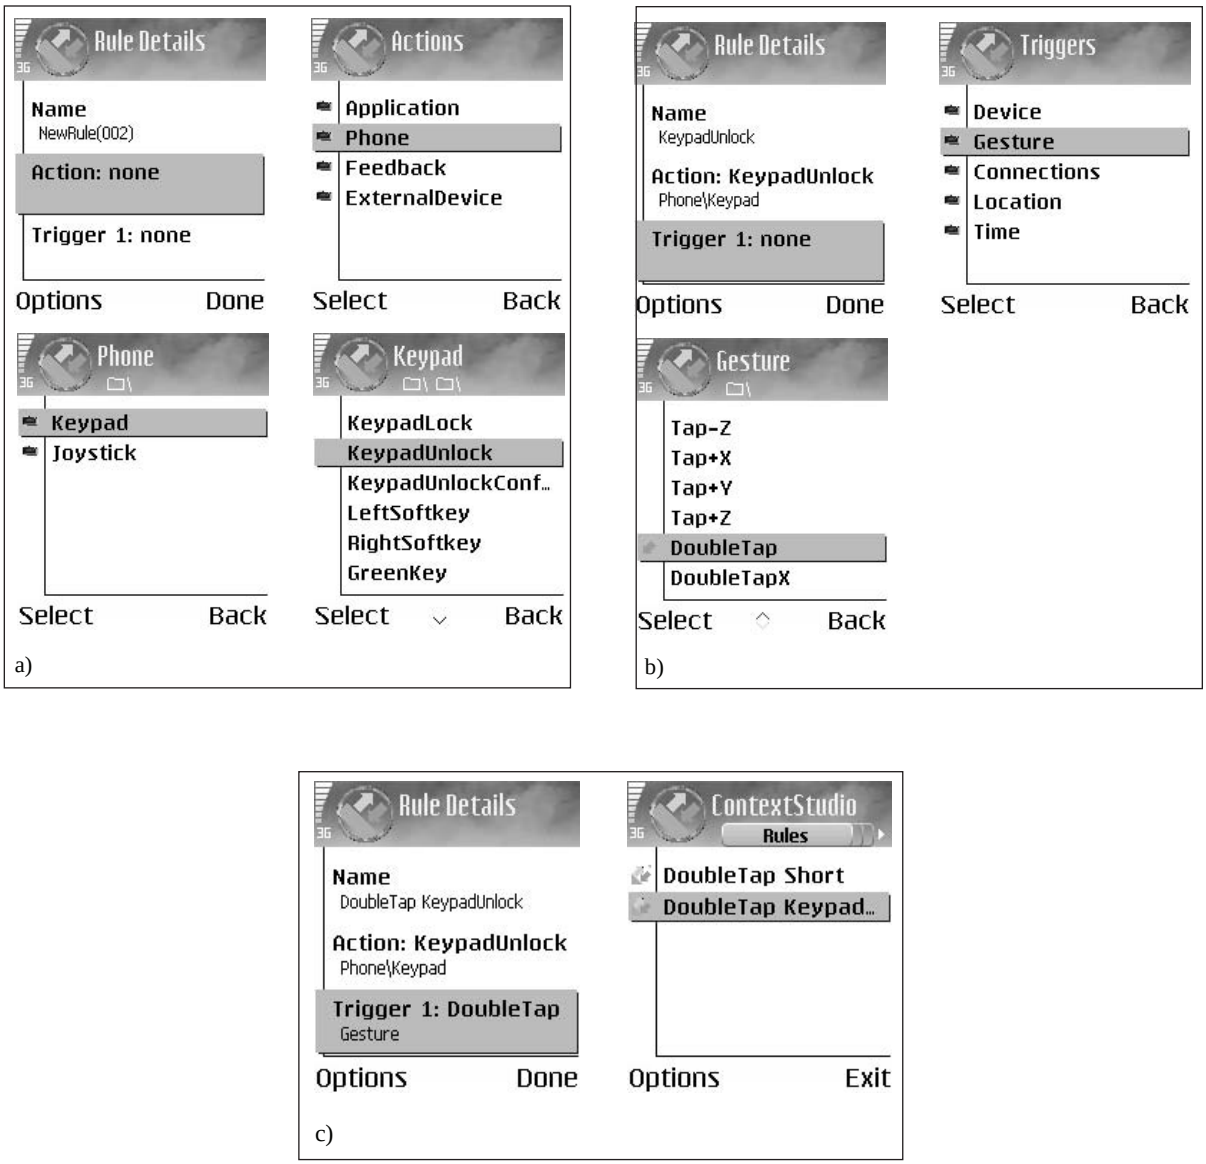
USE CASES AND USABILITY

Evaluating the general usability is an essential aspect in developing tapping interaction, in addition to evaluating the reliability and technical feasibility. As an extensive topic, however, it cannot fit within the scope of this chapter. The purpose of this section is to briefly discuss a few usability-related points as an overview of the experiments studying the usability of the novel interaction modality.

New interaction modalities, like tapping, have certain application areas where they add value, both in terms of utility (usability) and joy (fun of use). The only way of evaluating these aspects is to try the interaction elements in practice, with real hardware and applications. The smartphone sensor interaction cover serves this purpose. It enables the rapid prototyping and iterative development of interaction concepts and demonstrations. User experiences and feedback can be collected during various stages of development, early concept tests, peer evaluations, and end user tests in the lab and in the field.

A number of formal user tests, to be published separately, have been conducted with the smartphone prototype. The tests measure the potential usefulness of tap interaction with a standard Symbian Series 60 phone user interface. For instance, controlling a phone music player with tapping commands, in addition to existing keypad controls, has been studied. The results

Figure 5. Series of screenshots illustrating how to program the phone to open the keypad lock with a double tap.



from the studies indicate that it is very important to maintain consistency in case there are multiple different uses of tap interaction in several applications of the same device. Users may get confused if tapping is used for too many different purposes, such as muting the phone audio in one application and selecting the next or previous music track in another application. Furthermore, using different

tap directions, for example, tapping on the device top or the side for activating different controls in different applications, requires delivering specific instructions to the users.

User satisfaction, joy of use, has also been addressed in the usability tests. The enjoyability of the user experience is largely determined by the very details of the interaction; what kind of feedback elements support the user interaction. What is the metaphor behind the observed device behavior that the user learns when using new interaction modalities? All sense modalities in multimodal interaction must be addressed together.

CONTINUOUS DETECTION RELIABILITY: EXPERIMENTS

This study focuses on analyzing the reliability of detecting double taps in various usage situations. The experiments to be presented next aim to answer how accurately double taps can be detected in a general mobile usage setting and how many misrecognitions occur. The results should reflect an essential part of how feasible this interaction method could become, from the reliability viewpoint, when used in mobile phone applications. Detection accuracy is quantitatively analyzed based on acceleration data collected from users performing the interaction, and the results are discussed.

There were 11 users performing the interaction and the scenarios; 7 of the users were male and 4 were female, aged from 25 to 36 years. The subjects were selected randomly from acquaintances of the authors. The subjects were not interviewed and no subjective opinions were collected, only acceleration signals. Therefore, the limited variability of the subjects in the user group was assumed not to bias the results significantly.

There are two categories of use cases for continuous detection of movement events. In the first category, the detection process is initiated by a specific application or a situation, and is active for a certain time. In the other category, the detection process is always active. In the first category, the use cases can be designed such that misrecognitions, false positives, have a minimal effect. In the latter category, false positives usually have a more negative effect since they may result in incorrect operation. In both cases, the sensitivity of detection should yield enough correct recognitions, true positives, to be acceptable for the users.

This section describes the experiments aiming at evaluating how well the tapping interface performs from a statistical point of view, based on collected data. Detecting tapping events is a type of pattern recognition problem (Duda, Hart, & Stork, 2001), although not a very complex one. The aim of the data analysis during the development process was to reach optimal recognition of a double tap pattern, that is, to find detection algorithm parameters that produce a minimal number of false positives while maintaining a high percentage of true positives. The primary goal was to minimize misrecognitions. The algorithm should give the best results as an average when performed by multiple users, not just one specific user. In other words, the aim is to reach optimal user-independent detection accuracy. The experiment involved collecting a dataset on the target patterns performed by several users in controlled stationary conditions. Furthermore, data from several real-world scenarios containing various daily activities was collected to find out how often misrecognitions occurred.

Data Collecting

In order to evaluate the tapping detection reliability statistically, a sufficiently large dataset is required. Dataset size and the variation it contains are in direct relation to the evidence to support generalization. Data was collected in three stages with the sensor cover-equipped smartphone prototypes. The first stage involved exploring a wide set of activities by a user carrying 1-2 proto-

types to find out whether there were any specific activities that produced a lot of false positives. The dataset was collected by one user, and the total duration of the activities in the dataset was 5 hours 8 minutes.

The second stage involved having several users perform the target patterns in stationary controlled conditions involving no other activities. This dataset consisted of 11 users performing double-tap patterns. Data was collected in three categories, arranged by the user's skill level and the given advice. The user groups were beginner, people who had never heard about tapping, and advanced, people who knew or were informed about how the tapping user interaction works. There were six users in the beginner group. In the beginner group, the users were only given one piece of advice: to perform the tapping with their hand(s), not by tapping the phone on the table. The second group, five advanced users, were first told to use one hand for tapping and next to use both hands, that is, hold the phone with one hand and tap with the other. Figure 6 shows an example of both ways of tapping interaction.

There were five users, the same ones, in both of the advanced groups. In the three categories, each user performed a double tap 18 times, resulting in total target of 288 repetitions in the dataset. Repetitions were performed in phases of three repetitions and a break, during which the device was put on the table to avoid a routine speed-up and fixation on a certain way of interaction.

The third stage involved having several users perform scenarios involving real-world activities while carrying the prototype in their pocket. The purpose of this dataset was to find the occurrence of false positives during the scenarios, on average over multiple users. There were four to five users in each of the scenarios. The total length of the activity dataset was approximately 54 minutes. The tapping pattern has a sharp spike-form shape, and proper detection requires a relatively high sampling rate. Hence, the total amount of raw data collected for this experiment was approximately 68 megabytes.

Figure 6. Tapping performed with one hand (a) and with both hands (b)

EXPERIMENT RESULTS

The collected acceleration data was used to analyze the tapping interaction from multiple aspects. The experiments focused on a specific form of tapping, a double tap. Double tap means performing two consecutive taps within a certain short time span, much like a double click with a mouse. Each aspect of this interaction studied with the collected dataset is described in detail in this section. The experiments produced numerical measurements of the system's tapping detection accuracy. The measurements are briefly introduced here before presenting the results and analyzing them.

The first experiment was an initial pilot test, which was designed to count the number of double-tap patterns detected where they should not exist. In other words, the experiment measures the occurrence of false positives, which can be reported as a number per time unit. For example, the aim could be that there is no more than one false double-tap detection per hour.

False positives can also be represented in relation to how many patterns could be falsely detected from a dataset. The relative number of false positives in a dataset can be given by dividing the occurrence of all detected false positive patterns with all segments of data where there should not be a detected pattern. Here a segment is defined as the maximum time span required to detect one pattern. For example, for double tap pattern the maximum allowed duration is 1.1 seconds. This is due to the algorithm wait time for the second tap to appear after the first one. For instance, in a dataset of 110 seconds, there are 100 segments that could potentially contain a double tap. One false double tap in that dataset would result in one percentage of false positives.

True positive means a correctly detected pattern, for example, a double tap is detected correctly when it is performed by the user. The relative occurrence of true positives can be given by dividing all detected true positive patterns by all actually performed true patterns in a dataset.

Pilot Test

The goal of the pilot test was to explore whether some of the randomly selected ordinary daily activities would produce a high occurrence of false positives. This experiment did not contain any actual double taps performed by the user. The user was assigned to carry one or two prototypes in a pocket during various daily activities, for example, random outdoor activities (cleaning the yard, commuting, driving a car, walking, jogging, biking, cross-country skiing, and roller-skating). The users were free to select which clothes to wear and which pockets to carry the devices in. The tasks were given as, for example, "take the phone with you and go jogging." Table 1 summarizes the results of this test.

There were several activities that did not produce any false positives, such as jogging, various outdoor activities, biking, going for lunch, and roller-skating. The activity that produced the most false positives was cross-country skiing.

Overall, the test indicated that potential problem areas are accidental tapping by hand, ski stick, backpack, and so forth, and when the phone is laying freely on a moving and trembling surface such as a car dashboard. After the pilot test, the detection algorithm and parameters were adjusted to reduce the misrecognitions.

Stationary Conditions

Next, an experiment was performed in controlled stationary conditions. The purpose of the experiment was firstly to gain validation of how well the target patterns are recognized in a stationary situation when there are no external disturbances. Secondly, it is important to know whether there are differences between two groups of users when one has no idea what a tapping interface is and the other has prior knowledge of how to interact with

Table 1. Occurrences of double-tap false positives during random daily activities

Activity	**Phone numbers, placement**	**Duration (min)**	**False positives**
Commuting (dressing, driving, walking, stairs up, stairs down, office)	2, left and right lower jacket pocket	28	2
Travel by car, tarmac road	1, dashboard	70	1
Travel by car, rough gravel road	1, dashboard	20	2
Jogging	2, left and right jacket chest pocket	5	0
Cross-country skiing (walking, changing, skiing, walking, undressing)	2, jacket pocket, backpack	75	7
Outdoor activities (removing snow, walking, putting bike in storage)	2, left and right jacket chest pocket	5	0
Biking (gravel road and tarmac road)	2, jacket pockets	10	0
Going for lunch (stairs down, lunch, walking, stairs up)	1, jeans pocket	25	0
Roller skating	1, loose short trousers front pocket	35	0
Roller skating with sticks	1, pants front pocket	35	1
Total		**5 hours 8 min**	**13**

tapping. The results indicate different variations in the first-time use of tapping in terms of gesture signal waveform and the detection accuracy. Thirdly, the results show whether there are major differences between individual users, whether the interaction is equally assimilated by all users or if there are some individuals that cannot use the method as well. Finally, the interaction by tapping can be performed by using one hand or both hands, and the results indicate which is preferred from the reliability point of view with the evaluated algorithm.

The results can be calculated in two ways: the interaction can be allowed from any of the three axes, or from one selected axis only. In most single application use cases, the direction of tapping is known in advance and can be restricted. For example, music player next and previous commands can only be initiated with a tap on either side of the phone, by utilizing only the x-axis while disregarding the others. Hence, depending on the use case, it is feasible to filter the data from one or two other axes and apply the signal from one axis only. The results are first presented for 3-axis detection, Table 2.

The results show that double taps can be detected fairly well in stationary conditions, except in the beginner group. The difference between the beginner and advanced user groups is quite large, which suggests that first-time users may

Table 2. Recognition rate in stationary situation for various user groups in 3-axis detection

User group	Users	True positive %
Beginner	6	55.2
Advanced one hand	5	90.6
Advanced both hands	5	90.2

have trouble when starting to apply the method if they are not properly informed. There were also distinct differences between the individual beginner users, Table 3.

The data from the beginner users that produced low accuracies revealed that they performed the taps too lightly. Half of the beginner users chose to perform the tapping with one hand, and half with both hands. One beginner user tapped the top of the device and one the bottom, others from the side. The two beginner users that tapped with one hand had the zero results. The recollection from the actual test situation and data visualization confirm that the two one-hand users having a zero result only touched the device very lightly instead of properly tapping it. In other words, the first-time users' low performance is partly an algorithm sensitivity issue, but most importantly it is due to the lack of information the user has on how to do the tapping in the first place. The results can be improved by modifying the parameters to be more sensitive, but then the false positives

Table 3. Recognition rate in a stationary situation for each individual user in 3-axis detection

User group	User1	User2	User3	User4	User5	User6	Total
Beginner	94.4	0	77.8	88.9	0	73.3	**55.2**

User group	User1	User2	User3	User4	User5	Total
Advanced one hand	88.2	73.3	100	88.2	100	**90.6**
Advanced both hands	100	50.0	100	100	100	**90.2**
Total	**94.1**	**61.7**	**100**	**94.3**	**100**	**90.4**

tend to increase. The most straightforward way to improve the result is simply to advise the beginner users to tap with the correct intensity. Feedback is one way of giving immediate information to the user.

It must be noted that this experiment produced no information on the learning curve; it simply provides data on how differently first-time users may perform the gesture. There was no feedback or interaction in the test to guide the user on how to improve. In this sense it was a "blind" blank test to examine different users' approaches to performing a double tap, as interpreted from the signal waveform and the resulting detection accuracy. In a normal usage situation, the user would learn that too light taps do not cause the desired operation, and would likely either modify their behavior or abandon the method. In this test the users did not know that they tapped too lightly and thus, could not know how to change their tapping style.

The results in Tables 2 and 3 present the results for a setting where double taps from any direction are allowed. Table 4 presents results where only one predetermined axis signal is applied to detect a double tap. A significant increase in detection accuracy is evident. Furthermore, it is likely to reduce the occurrence of false positives, although it was not tested in this study. In light of the results, it is preferable to restrict the detection axis whenever is possible.

The results indicate that tapping is detected slightly more accurately when performed with one hand in 3-axis detection. In 1-axis detection, the accuracy is slightly better when performed with both hands. However, statistically, a conclusion cannot yet be drawn with this dataset on which way of tapping is more reliable.

Table 4. Advanced user recognition rate in a stationary situation in 1-axis detection

User group	Users	True positive %
Advanced one hand	5	95.3
Advanced both hands	5	98.8
Total	**5**	**97.0**

False Positives - Multiple Users

The purpose of the experiment with mobile scenarios was to find the occurrence of false positives during the selected common daily activities: walking, walking up stairs, jogging, and roller-skating. Furthermore, the scenarios were performed by multiple users in order to address the issue independent of the user. The scenarios in the experiment were designed to address a usage situation where the phone is in the user's pocket and the user could tap the phone from any direction. The users wore their own clothes and were free to select where to put the phone during the test. No other hard objects were allowed in the same pocket.

The results show that the number of double tap false positives was zero during the total of 54 minutes of activity data. By adjusting the algorithm parameters to more sensitive (which also increased true positives in the stationary test), false positives started to occur. The most false positives occurred on stairs. However, the parameter set that produced zero misrecognitions was generally perceived as sensitive enough, even though there were beginner users who would have benefited from increased sensitivity.

Summary of Results

Overall, the results based on the collected data, Table 5, indicate that detection is reliable enough for practical applications in mobile computing when the user performs the interaction in a

Table 5. Overview of the test results

Test	Users	True positive %
Beginner	6	55.2
Advanced one hand 3 axis	5	90.6
Advanced both hands 3 axis	5	90.2
Advanced one hand 1 axis	5	95.3
Advanced both hands 1 axis	5	98.8

stationary situation. Moreover, the number of false positives is low enough for types of mobile applications with at least a restricted scope. The results have significance for commercial applications built on use cases that have a clear usability advantage from the tapping interaction.

The results also show that there is room for improvement. This especially concerns the usability aspect of first-time use. An important question is how to give instruction on using the interface. This experiment took a worst-case scenario where the user was given almost no information, much like when the user does not even read the manual before starting to use the device. In a real learning situation, however, the user may sometimes even look for instructions in the manual, or someone will demonstrate how to use the feature. Thus, the results could be different. Furthermore, unlike in this test, the user would get feedback if the device did not respond to the interaction. Analyzing the learning curve, which is another relevant topic, requires a different experiment setup.

Having zero misrecognitions from four activities performed by four to five users with a total of 54 minutes of data does not yet statistically allow a strong generalization statement, although it is a good result, and shows that practical application is certainly feasible. To gain even wider evaluation, the next phase is to perform longer tests by equipping the users with prototypes for use in their normal daily lives.

FUTURE TRENDS

Although this study did not specifically discuss the user experience side of movement-based interaction, there is one aspect we would like to briefly address when viewing future trends: feedback. This aspect is still often found insufficient in novel user interfaces. While the presented experiments evaluated the reliability of the double-tap detection, future work includes analyzing the learning curve, the best type of feedback, and its effect on the user experience.

The user experience and learning curve for new interaction modalities can potentially be improved with suitable feedback. For example, if the beginner user makes too light taps in a tutorial mode, the device can indicate this with feedback. In general, feedback gives an indication of the state of the system and guides the users in how to use it. As suggested by O'Modhrain (2004), a key to the design of successful touch and haptic-based mobile applications is in ensuring a good mapping between the tasks, the required sensory cues, and the capabilities of the system on which the application is to be implemented. With the Customizer tool, introduced earlier, developers and user interface designers can easily experiment with different multimodal input and output combinations to find the most suitable and enjoyable solution for their application needs.

Different combinations of the feedback patterns (vibration, LED, sound) available in the interaction cover were implemented in this study. The option of using direct cover feedback in addition to phone vibra in the interaction had the benefit of avoiding possible latencies in feedback generation on the phone side. The vibra feedback was thus precisely adjustable to the desired parameters. Even though experiments on feedback supporting usability were not presented in this chapter, it

can be predicted that utilizing minimalist gesture control, together with related haptic feedback elements, has great potential in a mobile device usage and technology context. Haptic content fidelity can be rather low if it is designed to be multimodal; visual and haptic content are applied synchronously to support each other. The interaction and content design are used to promote the adoption of the technology among users.

Continuous detection of small sharp movement events also facilitates forms of gestures other than double tap. As an analogy to mouse control, there is a click and a double click. Obviously, single taps can be utilized for many purposes. However, single taps are more sensitive to various disturbances, such as accidental knocking, dropping, quick swings, turning, and so forth, that can produce a similar sharp pattern to the data and thus, a false positive. Another interesting gesture that feels natural is to swing the device. There are many other possible movement patterns to utilize in the future.

Several research questions remain, such as how to inform the user about the correct intensity of the tapping, and what kind of learning curve the tapping has. Many of the misrecognitions in the beginner group, as well as in the group that used only one hand, were due to too light a touch when tapping the device. In the beginner group, the gestures were even confused with touching in a user's approach. From the detection algorithm point of view, there is a trade-off: the parameters cannot be set too sensitively to avoid increasing the occurrence of false positives. Even though a lighter tap is viewed as more satisfying by some users, this usability increase cannot cost the reliability too much.

Yet another relevant research problem is to examine the recognition accuracy of target patterns during various activities in mobile usage. This study addressed the stationary situation and false positives during scenarios. A relevant question is what happens if the user performs the interaction while jogging, for example, without stopping to do it. Future work includes examining whether and how the continuous gesture interaction algorithms should adapt to the movement situation of the device.

CONCLUSION

Gesture control is increasingly being applied in mobile interaction. Widespread movement interaction application in mobile devices has been delayed by research challenges such as reliably detecting gestures, power consumption, and user experience-related issues such as obtrusiveness and increased effort. This chapter has focused on analyzing and evaluating the reliability of an event-based gesture interaction modality that emphasizes minimal user effort in interacting with a mobile device. The technical feasibility of the interaction modality was examined with an implementation in a smartphone environment. The reliability of continuous detection of sharp movement events produced by the user by lightly tapping the phone was evaluated by analyzing a dataset collected with the prototype.

The results show that for five informed users performing 36 repetitions of double taps in controlled stationary conditions, the target pattern was recognized with 90.4% accuracy for 3-axis detection and 97.0% for 1-axis detection. In four mobile scenarios containing 54 minutes of daily activities, each performed by four to five users carrying the prototype, there were no false positive detections of the pattern. Overall, the results based on a statistical analysis of the collected acceleration data suggested that double-tap detection is reliable enough for practical applications in mobile computing when the user performs the interaction in a stationary situation. Furthermore, it was found that the occurrence of false positives is low enough for application, presuming carefully selected usage situations where possible misrecognitions are not critical.

The contribution of this work has significance for commercial utilization.

Several research questions remain to be addressed as future work. These include how to inform the user about the correct intensity of tapping; there were users with too light a touch in the experiments. From the detection algorithm point of view, a balance needs to be found as the parameters cannot be set too sensitive to avoid increasing the occurrence of false positives. Another important research problem is to examine the recognition accuracy of target patterns during various activities in mobile usage. This study addressed the stationary situation and false positives during scenarios.

As to the movement interaction detection performance in general, the trend of development firmly aims toward increased reliability. As a result, the restricted application-specific use cases are likely to be followed by more general platform-level operations, where movement can be used as an additional interaction modality complementary to the existing ones. With emerging commercial utilization, it is easy to see the beginnings of wider adoption of the new interaction modality in mobile computing, while not forgetting that there is still further work to be done.

ACKNOWLEDGMENT

We would like to acknowledge the work of Arto Ylisaukko-oja in the hardware development, Hannu Vasama for designing the cover casing, and other contributors at Finwe, Nokia, and VTT for their kind collaboration.

KEY TERMS

Accelerometer: 3-D accelerometer is a sensor capable of measuring object acceleration along three spatial axes.

Double Tap: Double tap is a form of movement interaction where the user performs two consecutive taps on a mobile device with a finger or palm, each producing a sharp spike waveform in an accelerometer signal measured with a high sampling rate.

Gesture Interaction: Gesture interaction here refers to explicit movements made with a mobile device while holding it in a hand in order to perform any tasks with the device.

False Positive %: False positive percentage is the relative number of falsely detected patterns, given by dividing the occurrence of all detected false positive patterns by all segments of data where a detected pattern in a dataset should not exist.

Pattern Recognition: Pattern recognition is the scientific discipline whose goal is the classification of objects into a number of categories or classes. Objects can be, for example, signal waveforms or any type of measurement that needs to be classified. These objects are here referred to using the generic term "patterns."

Smartphone: A smartphone is an advanced multifunctional mobile phone with a platform open to third-party software.

True Positive %: True positive percentage is the relative number of correctly detected patterns, given by dividing all detected true positive patterns by all actually performed true patterns in a dataset.

Chapter 3.23
Positioning Technologies for Mobile Computing

Michael J. O'Grady
University College Dublin, Ireland

Gregory M. P. O'Hare
University College Dublin, Ireland

INTRODUCTION

Mobility is, as the name suggests, the defining characteristic of mobile computing and the primary differentiator between it and other computer usage paradigms. Traditionally, computers were used in what may be termed a static context. However, when computers are used in a mobile context, a number of difficulties that challenge traditional assumptions emerge. Not least amongst these are those difficulties that arise in delivering a service that is relevant and consistent with the situation in which the end-user find themselves. Should a person be waiting at a bus stop, he or she does not wish to go online and browse a bus timetable. Rather, he or she wishes to know when the next bus will stop at his or her particular stop. Thus location and time would be fundamental to the provision of such a service. Capturing time provides no major difficulties. However, identifying the physical location of a service subscriber may prove problematic.

In this review, we summarize some of the key technologies that enable the position of a mobile computer user to be determined.

BACKGROUND

Research in mobile computing and associated disciplines (Vasilakos, 2006) began in earnest the 1990s as the feasibility of the paradigm became increasingly clear. As the various research issues began to crystallize, researchers became aware of the desirability of using additional known facts of the end user's prevailing circumstances as a basis for customizing or personalizing the service for the individual end user. The term *context-aware computing* was coined to conceptualize these ideas. Pioneering research in this area was conducted at Xerox Parc in California by Schilit Adams,

and Want (1996). The Oxford Concise dictionary defines context as "the interrelated conditions in which something exists or occurs." Intuitively, everybody understands what context is. Almost paradoxically, this has made the derivation of an agreed definition almost impossible, leading some researchers to reconsider its philosophical roots (Dourish, 2004) and inherently dynamic nature (Greenberg, 2001). One issue commonly agreed is that a person's location or physical position forms an indispensable aspect of his or her context—so much so that Schmidt, Beigl, and Gellerson (1999) almost remind researchers that there are other aspects of context that should be considered. The reasons for researchers' enthusiasm are understandable. In the mid-1990s, the global positioning system (GPS) was deployed, making it possible to determine position to within 100 meters for those people equipped with a GPS receiver. Thus the technological issues were being addressed in a meaningful way. However, it was developments in wireless telecommunications that provided the spur for the upsurge in business interest in what would be termed location-aware computing (Patterson, Muntz, & Pancake, 2003).

In 1996, the Federal Communications Commission (FCC) in the United States announced the E-911 directive. In brief: this obliged public telecommunication network operators to provide the position of those people making emergency calls, thus enabling police, medical, and other personnel to react quicker. It soon became clear that this facility could have other uses for commercial purposes as, in principle at least, the location of any subscriber could be identified. Thus an era of location-aware services was anticipated. This era has yet to materialize, but as outstanding technological issues are continually being addressed, it is only a matter of time before a suite of location-aware services are available for subscribers.

To deliver location-aware services, it is necessary that an appropriate technology be selected that will provide a subscriber's position within a certain range. In the next section, some of the principal technologies for determining position are described.

TECHNOLOGIES

Various technologies and techniques are described in the academic literature for determining user position. Naturally, each has its respective advantages and disadvantages. For the purposes of this discussion, it is useful to classify them as satellite techniques, cellular network techniques, and hybrid. Each classification is now considered briefly.

Satellites Technologies

Trilateration is the basic principle for determining position using satellites. In short, the time taken for a signal to travel from a satellite at a known position to a receiver is calculated. This process is repeated for three satellites and a solution can be generated. In practice, a fourth measurement is necessary to account for the lack of synchronization between the atomic clocks on the satellite and the receiver's internal clock. The accuracy of the resultant calculation may vary due to a number of factors, including atmospheric conditions and the satellite constellation configuration. However, a reading within 20 meters of the receiver's exact geographic position may be realistically expected.

At present, there are two satellite systems in operation that broadcast signals:

1. *Global positioning system* was deployed in 1996, covers the entire earth, and is freely available. It remains under the control of the United States military. It is currently the de facto standard with specialized receivers on the market for all kinds of purposes including aviation, maritime, and leisure. To use GPS, a mobile computer user would

acquire a receiver, usually in the form of a Compact Flash (CF) card. More recently, receivers are sold as separate devices that can interface with any device that supports the Bluetooth protocol stack. Interestingly, a significant number of mobile phones on the market support Bluetooth, thus offering one scenario for providing location-aware services to mobile phone users.

2. *GLONASS* was developed and deployed by the former USSR in competition to GPS. For a number of years, it was not adequately maintained. However, this situation has changed recently, and GLONASS is currently being overhauled and restored to its former state. There are very few commercial products available that use GLONASS at present.

A third satellite navigation system is scheduled for launch in 2008. *GALILEO* is an initiative by the European Union (EU) that seeks to deliver a similar service to GPS and GLONASS, but with adequate guarantees regarding signal reliability. It is designed for purely civilian and commercial use, and unlike GPS and GLONASS, it is not controlled by defense or military groups. However, the signal broadcast will be compatible with GPS and GLONASS, and it is hoped that receivers that can utilize all three systems will developed.

Cellular Network Techniques

E-911 obligated network operators and, implicitly, telecommunications equipment manufacturers to facilitate the determination of a subscriber's position within an emergency call context. A number of *cellular network techniques* were proposed as a result of ongoing research, and Zhao (2002) provides a useful overview of these. The Third Generation Partnership Project (3GPP) proceeded to standardize on four different techniques for third-generation (3G) UMTS (Universal Mobile Telephone Networks) networks (3GPP, 2005):

1. In *cell-ID*, the geographic coordinates of the base station serving the subscriber are identified. The position of the subscriber must be within the radius of this cell. Though this method is easy to implement, its principle limitation concerns the variability in cell size. Thus the precision with which the subscriber's position is calculated may range from tens to hundreds of meters.
2. *Observed time difference of arrival (OTDOA)* requires the handset to measure the time taken for a signal to arrive from three separate base stations. Hyperbolic curves must be constructed, and their intersection indicates the position of the subscriber. Though computationally expensive, a particular difficulty involves guaranteeing that the subscriber can see three base stations simultaneously. OTDOA is highly susceptible to fading and interference.
3. *Assisted GPS (A-GPS)* involves the handset measuring GPS signals from satellites. Initially, the handset is informed as to where to look for the signals, thus minimizing delay in signal acquisition. The signal measurements are then returned to the appropriate component on the network where the position is calculated. Though increasing power consumption on the device, users can expect position readings comparable with GPS.
4. *Uplink time difference of arrival (UTDOA)* is similar in principle to OTDOA, but in this case, the signals are generated at the handset and measured at a number of base stations. As the geographic positions of the base stations are known, the position of the subscriber can be calculated using hyperbolic trilateration.

With the exception of A-GPS, the accuracy of a position obtained using these techniques is variable and unpredictable. In the case of the cell-ID method, urban areas will have a concentration of base stations so the method may work well. In

contrast, the diameter of cells in rural areas may be several kilometers, thus rendering the method ineffective. In the case of OTDOA and UTDOA, accurately measuring the time it takes the signal to travel between the subscriber's handset and surrounding base stations, and vice versa, is essential. Yet the signal may be subject to interference and fading, depending on the vagrancies of the immediate physical environment.

Hybrid Techniques

A scenario can be envisaged where a number of techniques may be combined, with each remedying their respective deficiencies in certain situations. For example, in an urban area, base stations are relatively plentiful, and in certain cases, a number may be deployed in individual streets. Thus techniques like cell-ID, OTDOA, and UTDOA will function reasonably well. In contrast, GPS—and implicitly, A-GPS—may not perform satisfactory, as the high nature of the surrounding buildings, so-called urban canyons, can result in satellites being obscured. In rural areas, the sparsity of base stations may render techniques based on the topology of the cellular network redundant. However, a clear view of the sky is likely, thus GPS and A-GPS should both function satisfactorily.

It should be noted that A-GPS itself could be arguably considered a hybrid technology. However, its close association with and standardization in the telecommunications world result in it being generally considered as a cellular network technique.

The Indoor Scenario

Determining the position of people in an indoor scenario raises particular issues and difficulties. Traditionally, satellite technologies have not operated indoors, as the signal is weak and is subject to additional reflection and fading problems when tracked indoors. A new generation of receivers promises to address this deficiency, with each succeeding generation being incrementally more sensitive. However, the key issues of accuracy and precision remain. This continues to be the case when cellular network techniques are considered, thus making the provision of guarantees concerning the quality of the calculated position exceedingly difficult.

If it is necessary to track a person in an indoor environment with confidence; it is almost essential to consider deploying a dedicated infrastructure, expensive and time-consuming as this may be. However, the required accuracy is a significant determinant. For example, it may be only necessary to track a person to room level. Alternatively, in a museum or art gallery setting, it may be necessary to determine the visitor's position to within one meter so as to determine which artifact is nearest to him or her.

Hightower and Borriello (2001) and Pahlavan, Xinrong, and Makela (2002) provide useful overviews of the issues involved in indoor tracking and positioning. A common approach is to tag the person and place a network of sensors throughout a building. This approach was adopted by Want, Hopper, Falco, and Gibbons (1992) in the pioneering active badge project, and the feasibility of the approach was verified. Systems that use a similar approach today include Cricket (Priyantha, Chakraborty, & Padmanabhan, 2000) and Ubisense (Cadman, 2003). Indeed, given the increased interest in Radio Frequency IDentification (RFID), one can easily envisage a solution involving a fixed network of RFID readers and RFID-tagged personnel.

FUTURE TRENDS

One of the key developments currently taking place concerns the deployment of *satellite-based augmentation systems (SBAS).* Such systems are a satellite-based implementation of the well-known differential GPS (DGPS) method of improving

GPS positions to within a few meters. A number of SBAS systems are being deployed, including the European Ground Navigation Overlay Service (EGNOS) and the Wide Area Augmentation System (WAAS) in the United States. More SBAS satellites are expected to be launched for other areas of the world in the coming years. Two methods for accessing SBAS are of interest. The easiest way is to incorporate an appropriate chip in a GPS receiver. In this way, the position is augmented seamlessly and transparently to the user. A second method involves the Internet, via which SBAS signals can also be broadcast. SISNet (Chen, Toran-Marti, & Ventura-Traveset, 2003) is one example of such a system. Indeed, when A-GPS is reconsidered, it can be seen that integrating this approach with a system such as SISNet is relatively straightforward.

Indoors, the situation is more complex. One approach receiving increasing attention by the research community concerns pseudolites (Wang, 2002). Pseudolites (pseudo-satellites) are placed throughout a building and mimic the GPS signal. Naturally, the pseudolite network should be calibrated for the building in question. However, the important issues of interoperability and standardization—issues that have so far been neglected—must also be addressed.

CONCLUSION

A significant choice of technologies is available for aspiring providers of location-aware services. The required accuracy and precision of the resultant subscriber position is a key determinant of the choice of technology. Attitudes of network operators toward independent small businesses seeking to deploy new services are also of critical importance. It is essential that such operators provide an open and transparent mechanism for accessing subscriber position information. Should the operator adopt an attitude of restricting access or charging excess fees for such information, the potential of location-aware services will be compromised. Overtime, it can be anticipated that a number of mobile phones with integrated GPS and SBAS technologies will be launched on the market. Ultimately, however, it beholds those people designing for mobile users to judiciously consider the merits of the respective positioning technologies in the context of both the application domain and target audience. Only in this way can they be reassured that the needs and expectations of their customers will be addressed.

KEY TERMS

GPS: Global positioning system.

OTDOA: Observed time difference of arrival.

Pseudolite: Pseudo satellite.

SBAS: Satellite-based augmentation system.

SISNet (Signal In Space through the Internet): An initiative by the European Space Agency (ESA) to broadcast corrections to the standard GPS signal through the Internet and in real time.

3GPP: Third Generation Partnership Project.

Trilateration: A method of determining the position of an object using the known position of at least three reference points.

UMTS: Universal mobile telephone system.

UTDOA: Uplink time difference of arrival.

Chapter 3.24
Emerging Mobile Technology and Supply Chain Integration:
Using RFID to Streamline the Integrated Supply Chain

Richard Schilhavy
University of North Carolina at Greensboro, USA

A. F. Salam
University of North Carolina at Greensboro, USA

ABSTRACT

This chapter explores how a mobile tracking technology is able to further streamline the integrated supply chain. Previous technologies which have attempted to integrate suppliers, manufactures, distributors and retailers have lacked the flexibility and efficiency necessary to justify the prohibiting costs. Radio frequency identification (RFID) technology however enables various organizations along the supply chain to share information regarding specific products and easily remotely manage internal inventory levels. These applications are only a sample of what RFID is able to accomplish for the integrated supply chain, and this chapter seeks to explore those applications.

INTRODUCTION

This chapter sets forth to provide a holistic view of how a recently adopted wireless identification technology, specifically radio frequency identification (RFID) tags, could potentially revolutionize the integrated supply chain. Companies are able to become more flexible and efficient by using a combination of mobile technologies and RFID to provide for remote inventory control and real-time, information-rich tracking of shipments in the distribution channel (Lapide, 2004). Although this technology has several hindrances currently blocking it from mass usage (Thompson, 2003), recent advancements in the technology have increased the viability of RFID for widespread organizational use, increasing the capacity and

strength while decreasing the size and cost. RFID now rests in a unique position wherein large organizations are strongly considering its viability in a variety of applications to streamline the supply chain.

Organizations have already begun considering its application in the realm of supply chain management, attempting to further streamline the process. However, while many authors have discussed the benefits of RFID tags for parts of the supply chain, this insight has only focused on a localized level, such as inventory management in retail outlets (Atkinson, 2004; Lapide, 2004; Kinsella, 2003; Schindler, 2003). Much of this discussion is centered on reducing costs for those isolated parts of the supply chain. For example, several large manufacturers are pushing the technology by actively conducting trials in manufacturing, distribution, and even retail. These companies include Proctor and Gamble, Gillette, Unilever, and retail giant, Wal-Mart (Kinsella, 2003). These RFID trials have been limited to single stages of the supply chain, focusing on the reduction of costs as the ultimate goal. Although cost reduction is commendable, true improvements in value for industry and consumers come through a unified effort to improve the entire supply chain network, reducing costs and improving accuracy and efficiency for all companies integrated into the network.

This chapter will first provide an overview of the technical aspects of RFID. Following this, an analysis of two perspectives of the integrated supply chain will be framed in light of the current and possible future applications of RFID in each area and the relationships between those areas. Finally, RFID will be framed in a holistic view of both the integrated supply chain as well as the demand chain, addressing some inter-organizational issues.

BACKGROUND

The RFID Tag and Reader

The core of RFID technology consists of two components, the identification tag and the tag reader. The identification tag itself is composed of a small antenna and a microchip, which stores a small amount of information pertinent to the object tagged (Rappold, 2003). Although the information stored may take a wide variety of forms, for many objects a simple code would be sufficient to identify the item. Asif and Mandviwalla (2005) identified five types of RFID tags in their RFID Applications Framework, including active, semi-passive, passive, chipless, and sensor. Tag readers may also be stationary or mobile, depending on the application. Of those tags which contain chips, RFID tags may either be active, passive, or a combination of the two. Active tags are powered by some external power source, such as a small battery. Passive tags, on the other hand, have no individual power source and receive power from the electromagnetic waves the tag reader uses to access the information from the tag. Some tags may use a combination of the two strategies, where an active tag containing a battery is recharged by the transmission used to read it. Chipless tags have the lowest power consumption, range, as well as cost of all the types of RFID tags since they do not contain either a battery or a silicon chip. Information storage is also significantly less, often only enough to store a simple product code.

The tag reader uses electromagnetic waves in the radio frequency band to transmit the data stored on the identification tags to the reader and, in some cases, power the identification tags. The reader may be a mobile or stationary unit depending on the application, and an organization could easily employ both. Mobile readers naturally benefit from being able to change location; however, power limitations have a severe impact on the range and may even become an issue if passive

RFID tags are used extensively. The effective range of a tag reader is a function of the frequency the tag reader is operating on and the power output available. At lower frequencies, range is severely diminished; however, power output is minimal. At higher frequencies, identification tags are able to be accessed from further away, but require significantly more power. Here, active RFID tags may need to be utilized to increase the range along with increasing the power output of the tag reader. Finally, sensor tags combine a small sensor targeted at a particular purpose, such as measuring temperature, viscosity, movement, and so forth, with an antenna, chip, and battery to store and transmit information from the sensor to a reader or network.

Not unlike any other wireless technology, RFID comes with a few limitations or issues affecting communication reliability (Angeles, 2005). The use of radio frequencies becomes a significant issue since these bands are often open to a multitude of other devices, such as wireless phones, computes, radios, and other office equipment. These common workplace devices may cause interference with reading a RFID tag and should not be overlooked when problems arise. Another problem common among mobile technologies is the increased collision of packets when more senders and receivers (in this case, more tags) are present. Since the reader is not limited to line of sight, a reader may pick up a multitude of tags in any direction of the reader, and if a large amount is present surrounding the reader, the transmissions between identification tag and reader may become interrupted due to such collisions. Anti-collision technologies are currently being developed to confront this problem with collisions (Angeles, 2005).

The RFID Network

Thanks to the Auto-ID Center at MIT, recent developments in RFID technologies have expanded RFID technology to create a holistic product identification system that consists of four components (Rappold, 2003; Smith & Konsynski, 2003; Asif & Mandviwalla, 2005). The identification tag and tag reader, again, transmit and read the information stored on the identification tag attached to the particular physical object. Stored on the identification tag is an electronic product code (EPC), which identifies the particular object or the state of that object. The EPC is a 96-bit identification code similar to conventional bar codes which uniquely identifies a product. The object name server (ONS) is a local or remote server that acts as a directory service, mapping the EPC to additional information about the physical object. This additional information in Physical Markup Language (PML) provides a standard format for describing products and storing other information about them (Smith & Konsynski, 2003). For example, the PML documents may contain information about the product manufacturer, source, and destination, or simply more detailed information about the product itself (Rappold, 2003). By mapping the EPC code to the PML documents containing information about the product, the tag may be significantly smaller since all the information is not required to be stored on the tag itself.

RFID Applications

Companies are able to become more flexible and efficient by using a combination of mobile technologies and RFID to provide for remote inventory control and real-time, information-rich tracking of shipments in the distribution channel (Lapide, 2004). Although this technology has several hindrances currently blocking it from mass usage (Thompson, 2003), the potential long-term benefits are astounding for both the integrated supply chain and other mobile technology applications as well. RFID technology is able to provide item- and product-specific information which remains with the physical object. Since no line-of-sight is required to read a tag and multiple tags may be

read simultaneously, inventories may be tabulated quickly with little manual labor and items may be tracked regardless of their location in the range of the readers. Rich information can be stored on the tags themselves, or simply mapped to the tags via an EPC, allowing this new technology to be easily mapped into current systems. PML provides additional information through a standardized markup language, providing additional interoperability between existing systems and the systems of other organizations. The technology is small, flexible, and relatively inexpensive. In the following sections, we will look more closely at the applications of RFID—specifically in the supply chain—and analyze the relative costs and benefits for each.

RFID AND THE SUPPLY CHAIN

One of the problems of current implementations of RFID tags and readers in the supply chain is that they have largely been efforts of a single company operating independently in their area of the supply chain. Technology improvements in the supply chain which are isolated to a single stage, such as manufacturing or retail, are limited to minor improvements in costs. To further illustrate this point, the following paragraphs will explain potential implementations of RFID in each stage of the supply chain considered entirely in isolation. Therefore, suppliers will be considered apart from manufacturers, retailers apart from distributors and consumers, and so on. Relative costs and benefits will be weighed with each implementation, as well as the possible risks and rewards in undertaking the endeavor.

Table 1.

	Costs	***Benefits***
Supplier	Moderate.	Improved inventory management and control.
	High for complex systems, such as monitoring devices.	Improve demand forecasting.
Manufacturer	Moderate, increasing with the complexity of the product or equipment.	Improved inventory management and control.
		Improve demand forecasting.
Distributor	Moderate. Package-level tagging.	More accurate tracking information.
	High costs when integrating with tracking systems.	En-route location tracking of packages.
Retailer	High. Item-level tagging required for pervasive implementation.	Improved inventory management and control.
		Reduce stock-outs.
Consumer	Variable. Low for luxury items to extremely high for low priced goods.	Improved shopping experience.
		Reducing in price.

Suppliers

A common theme among many of the stages of the supply chain is inventory management, even when considered in isolation. Technology improvements in inventory management allow for significant improvements in labor and capital costs, and accuracy over traditional inventory systems which require manual operation. Suppliers are no different, requiring the maintenance of large amounts of raw and processed materials in various forms. However, there are unique considerations for each stage of the supply chain in regards to inventory management which needs to be addressed. In particular to suppliers, some materials and parts require significant specialization and complexity, such as composition requirements or well-defined specifications, which can be maintained through the information stored in RFID tags or using EPCs to map the product to the information stored in a database.

Materials which require constant monitoring of temperature, viscosity, or other physical qualities could also benefit. This also applies to those materials which are heavily time dependent in regards to time-to-disposal, time-to-shipment, and so forth. RFID tags could wirelessly transmit updated information of the state of the material in real time, without human interaction or the costs of installing and/or maintaining an infrastructure based upon a physical connection. While the wireless monitoring devices would require maintenance in case of failure, the overall complexity of the system and of the maintenance would significantly decrease.

Naturally, there are significant costs involved with such implementations of RFID technology in the supplier's world. Compared with manufacturing or distribution, the information necessary to store is uniquely different. The cost of identification tags and tag readers are a common theme among all of the stages in the supply chain—an unavoidable cost. The supplier does have a slight advantage in this regard, in that relatively few tags are necessary in comparison to the other stages in the supply chain. However, if the materials required highly precise specifications or other physical properties, the complexity of the system required to maintain the information could increase the cost exponentially. Monitoring the state of the materials poses even more problems, requiring specialized identification tags attached to sensors. Additionally, simple EPC codes may no longer be sufficient to monitor the possible states of the materials and therefore require a more specialized system for each individual monitoring tag. In this regard, semantic mark-up languages similar to PML may become incredibly useful in such applications.

Manufacturers

Similar to suppliers, manufactures have much to gain in regards to simplifying inventory management and increasing the robustness and richness of the inventory system on the whole. However, what is unique to manufactures is the need to maintain large amounts of data on highly specialized or customized parts or products. RFID tags will provide item-level information unique to the particular part or product, which remains with the individual part of product. Manufacturers will find a significant reduction in the effort necessary to manage the inventory of parts or products on hand and find an increase in the accuracy of that inventory.

Manufacturers often require many complex pieces of equipment for specific applications which, in a large bustling factory, may become lost or simply difficult to find. TransAlta found that tagging pieces of equipment across the 600-foot plants made finding and maintaining the equipment easier and more flexible (Malykhina, 2005). Using Wi-Fi and Bluetooth wireless technologies in conjunction with RFID to blanket the entire facility, TransAlta was able to locate equipment regardless of its location in the company's large facilities. Active RFID tags were used to elimi-

nate the need for manual operation and provide real-time information about the location of the equipment and specific metrics from temperature gauges, vibration probes, and a variety of other peripherals (Malykhina, 2005).

If suppliers could have a problem due to complexities in inventory management, manufacturers have an overabundance of them. Implementing RFID throughout the manufacturing process requires that the individual raw materials and parts from other manufacturers be tagged, and the ultimate product to be shipped out the door also be tagged, either individually or as a package. The system becomes exorbitantly more complex when the manufacturing process requires multiple steps where information of the part or product at each stage is required.

Here, at the manufacturing stage, managers will be first posed with a difficult question when considering implementing RFID technology at their site. The question is whether package level or item level will be more economical for the specific application. For larger products or specialized equipment, tagging individual items is an economical choice. However, if the factory produces millions of widgets per month with little or no variation in those widgets, tagging them on an individual level would be a foolish choice. In most cases, manufacturers have little need for individual tagging of parts and products that come off the assembly lines, leaving package-level tagging a more prudent choice.

Distribution

In isolation, distributors are able to see significant benefits. One of the most significant proposed implementations of the technology in distribution channels is the ability to locate in real time each individual shipment, regardless of its location, and to provide information about its shipment location, destination, content, and so forth. This can be accomplished through combining several other mobile technologies. One implementation suggested the use of GPS technology to locate and identify individual vehicles, then remotely transmit the information obtained by scanning the individual shipment tags, thus providing remote access to the current contents of the vehicle, regardless of its location. Such a system could provide some value to the business and consumers alike. Richer tracking information allows interested parties to know exactly where a highly important package was last scanned, even if the package or shipment is "en route."

Wireless mobile technologies are used throughout distribution channels for varieties of business benefits, such as geographic positioning systems (GPS), for tracking and monitoring vehicles in distribution channels (Faber, 2001; Schindler, 2003). However, one issue distributors have with current mobile tracking technologies is that en-route information of vehicle contents is almost impossible to monitor, which is where RFID technology has significant promise.

However, several obstacles hinder the practical feasibility of such a system. First, current tracking systems are easily able to provide similar information, but nevertheless lack the remote, real-time tracking such a system would offer. The practical issue comes with the fact that the cost involved with implementing such a system still surpasses any benefit, even considering how the cost of RFID per tag and per reader has become more reasonable.

Retail and Consumers

Similar to suppliers, if the product retail is selling is dependent upon time—that is, perishable with a limited shelf life—those must be sold, moved, or discarded by a particular date. By outfitting each individual item sold within the store, single, outdated items will not find themselves sitting on then shelves for extended periods of time. A simple system could automatically read the tags and inform the employees which items have or will soon pass the date in question.

There have been several technologies over the years which have been considered as replacement for the aging UPC standard. However, few have provided sufficient benefits over and above UPC labels. Electronic tags were considered as a replacement, but the benefits over the current standard were so minimal that the small cost associated with each tag was too great to justify the switch. On the other hand, RFID tags provide richer information about the product over and above the current UPC standard, which simply identifies the product. Since the RFID tag can be read via a wireless connection, many items can be scanned and identified in seconds, whereas the present UPC standard requires line-of-sight reading through an optical scanner. This application could further be extended into the often-dreamed automatic checkout machines.

Current theft-deterrent technologies are an independent system from the limited UPC standard. The technology is often unreliable, resulting in countless false positives, and requires that the electronic tag passes through a small area before detection. RFID, on the other hand, would be able to provide for both the UPC label functionality discussed previously, as well as a rudimentary theft deterrent system similar to the ones currently used in retail outlets. Through RFID, retailers would be able to know exactly what products are entering and leaving the store, and which have been purchased and which have not. However, cost barriers are significant in this application since item-level tagging is necessary for it to be effective. Until the cost of individual RFID tags drops substantially in comparison to the price or quantity of the product, in the realm of fractions of a cent, it is not likely we will see widespread, item-level application of RFID. However, some retailers have begun tagging larger, higher priced items for this purpose. Both Wal-Mart and Woolworth's in the United Kingdom have begun tagging items considered high risk, such as CDs, mobile phones, computer accessories, and other electronic goods (Smith & Konsynski, 2003).

However, retail has a particularly difficult time when isolated from the rest of the supply chain in the implementation of RFID technology. Although the obstacles from the distribution side of retail are not insurmountable—requiring the contents of palettes and packages to be tagged at the distribution centers, similar to package-level distribution or manufacturing inventory, before being sent to individual retail stores—on the consumer side however, implementation becomes a much more difficult task. To be effective, individual items must be tagged. While other stages could have survived with a small amount of identification tags and tag readers, retailers cannot avoid the substantial costs associated with the thousands upon thousands of tags to cover individual items in some RFID applications. Inventory management and automatic checkouts require each individual item in the entire store to be appropriately tagged, with no assurance that the tags could be reused. Effectively, the costs of tagging individual items would be directly added to the wholesale cost of each item, and at the current five cent-mark—a substantial portion of many items' wholesale costs—further reducing the already meager margins in retail. Some organizations have implemented theft-prevention systems utilizing RFID technologies, but it is a small fraction of merchandise, particularly high-risk or high-cost items. However, retail systems are particularly simple in comparison to those found in the other stages. Since all items already possess UPC labels, mapping EPC to individual items via RFID tags may not be a daunting task and would provide some technological redundancy in case of system failure.

STREAMLINING THE SUPPLY CHAIN

Implementing technologies in the supply chain ultimately creates value when each organization at each stage of the supply chain vertically inte-

grates, standardizing on the single technology. RFID is no different. Using the same technology from the manufacturing of a product to the sale of the product throughout the entire supply chain substantially reduces costs and provides business value for everyone (Poirier, 1999). However, this does not always occur, for example, when an integral part of the supply chain chooses not to implement or share information, or organizations force their supply or demand chain to implement a particular technology, largely at the cost of those implementing (Kinsella, 2003). In the following section, how RFID can provide value to a more integrated supply chain through the implementation of RFID technologies will be discussed, ultimately culminating on a view of the entire supply chain. While many of the applications, costs, and benefits have been covered in previous sections, how their applications tie together in the supply chain and provide value will be the focus.

Suppliers to Manufacturers

The real power and value of RFID technology in supply chain management sadly comes later in the supply chain, although many benefits can be realized between suppliers and manufacturers. Materials are cultivated, packaged, distributed, received, and processed by the respective manufacturers. Throughout this entire process, RFID is able to track the inventories of materials, the source of the materials (the supplier), and the destination (the manufacturer). Manufacturers then benefit by knowing what inventory they have on hand of pre-production materials and from what vendors those materials originated. This improves the production process at manufacturing facilities greatly if such information is already accounted for by the source of the materials. However, because of the transforming nature of the manufacturer, the same RFID tags are not valuable to the remainder of the supply chain. Once the materials are transformed into products and finally head downstream to distributors and retailers, they must be retagged. In fact, after every transformation of the product, the nature of the product changes and tags must be reapplied.

Manufacturers to Distributors

Here, at the manufacturing phase, we begin to see the real potential of implementing RFID technologies and the scope of their effect on the integrated supply chain. Package-level tagging at the manufacturing level before distribution occurs both helps maintain inventories at the manufacturing sites and aids distribution and other inventory management and control systems to be equally as streamlined. Incoming materials from suppliers are able to be logged, and inventories updated and maintained throughout the manufacturing process. However, the beauty occurs when item-level tagging is implemented. As the product is produced, the item may be tagged with manufacturing information and other specifications particular to the product. Other organizations down the supply chain will be able to access this information even when the package it was contained in was dismantled and the contents strewn across retail stores and the consumer population. Additionally, the benefits from improved forecasting comes from information downstream, at the retail level, where manufactures are able to determine which products are sold, at what locations, in specific quantities. For retailers to provide this information, with the RFID network previously discussed in place, would be far from an insurmountable feat, and the value coming downstream from the manufacturers would be to their benefit. While manufacturers ultimately may bear much of the implementation cost, they will receive equally in benefits, with even more significant benefits for organizations downstream from the manufacturer.

Distributors to Retailers

Leaving the distribution centers are countless cases and palettes of merchandise heading to different retail stores with varying quantities of thousands of different products. Managing what products are leaving or being received and where they are going can become a daunting task, even with some of today's technologies. For distributors, RFID technologies provide some of the more impressive benefits, even in isolation with relatively smaller increases in cost. However, having package-level inventories tagged by suppliers and manufacturers before entering the distribution channels improves the efficiency of the logistics systems for both those parties. As the tagged packages move through the distribution channels, retailers ultimately will benefit as well as the packages move through their receiving centers, actively managing the incoming inventory at individual stores. However, between manufacturing and retail, distributors must retag if the packages themselves are repacked. Luckily, if this is not the case, the RFID network system provides separate semantic information for each of the EPCs associated with the packages. Again, the beauty is at the item level. Since each individual product is now tagged, even repackaging the products does not require new tags to be placed on them. In fact, distributors need not retag any items whatsoever, only change the information associated with the corresponding EPC, which is unique for all the items entering and leaving the distribution channel, regardless of the location.

Tesco, a large UK retailer, recently implemented an RFID system of significant size, totaling 20,000 identification tags for their stores and distribution centers, with 4,000 tag readers and 16,000 antennas to receive the identification tag signals (Sullivan, 2005). RFID tags have been installed in order to track the merchandise cases and palettes which grace the docks at the distribution centers and receiving doors at retail stores. Unlike the retail giant Wal-Mart, however, Tesco made the investment in RFID themselves independent of their suppliers, in hopes that they perceive similar cost benefits as Tesco.

In some situations, logistics systems may need to make a sudden re-route of product or material in case of a sudden stock-out. When a product is in demand, having no inventory of a product on hand means lost sales for retailers or lost production time for manufacturers. In conjunction with GPS and cellular technologies (Schindler, 2003), distributors now may locate items en-route between destinations and calculate precise inventories of those vehicles. If a reroute is economically reasonable, the vehicle is able to be informed of where the reroute is located and what products the reroute are for. All in all the distribution system becomes more flexible and capable of providing for the retail and customer base.

Retailers to Consumers

One of the significant benefits from implementing RFID technology at the retail level is the reduction of labor costs from managing inventory, which now can be accounted for and monitored with little or no manual operation. Reduction in labor costs provides for two potential outcomes that benefit consumers. First, the additional labor capacity can be used to improve customer service of the retail establishment for customers. Or, the additional savings in labor costs not rerouted to another activity could be brought directly to the consumer in the form of lower prices, ultimately an increased value for the customers.

Merchandise Security

RFID technologies also move the retail and consumer relationship to the Holy Grail, the market of one. Prada of New York is one of the first retailers to use RFID technologies to revolutionize the shopping experience of its customers. Each item sold in the store is tagged with an RFID tag. Naturally, this provides additional security in the

case of stolen merchandise; however, the interesting aspect of the implementation occurs when the customer re-enters the store. Whether carrying or even wearing the previously purchased garment, the tag readers at the entrance to the store scan for an RFID tag; if found, information pertinent to that garment appear on large flat-panel displays around the store. For example, items matching that garment may appear, in reasonable sizes to the item purchases, directing the customer. In addition, richer marking information is obtained through this system, as item purchases are now tied together with how frequently the customer visits the store, what items are purchased in combination or sequences, and so forth. However, consumer privacy concerns have already arisen in regards to this implementation.

From the information gathered here, at the retail and consumer level, suppliers and manufacturers are now better able to forecast demand and control inventories, sending the business value back upstream (Lapide, 2004). The value invested earlier in the supply chain to tag either packages or items leaving manufacturing facilities returns to them through this improved ability to forecast demand.

CONCLUSION AND FUTURE DIRECTION

RFID technology is a fairly simple wireless technology, composed of a small antenna and microchip, and able to streamline the mobile supply chain. Technologies surrounding the RFID technology, such as EPC and PML, improve the interoperability, transparency, and flexibility of implementing RFID systems with current inventory management and distribution systems. The mobile nature of the technology incorporates additional advantages only found with more complex, higher cost systems. However, important cost considerations must be given, as choosing between the costs and benefits for package level and item level becomes an important decision. While it provides substantial value for organizations downstream, it requires significant investment upstream. As additional implementations appear throughout the supply chain, the cost of the technology will fall and the relative benefits will increase. If standardized on RFID technology, regardless of package- or item-level implementation, the entire supply chain benefits from a standard mechanism to identify objects moving up and down the supply chain, through distribution channels, and off the shelves at retail stores. RFID is poised to revolutionize the supply chain by streamlining operations, providing flexible, transparent communication between organizations.

INTRODUCTION

The contribution of context information to content management is of great importance. The increase of storage capacity in mobile devices gives users the possibility to maintain large amounts of content to their phones. As a result, this amount of content is increasing at a high rate. Users are able to store a huge variety of content such as contacts, text messages, ring tones, logos, calendar events, and textual notes. Furthermore, the development of novel applications has created new types of content, which include images, videos, MMS (multi-media messaging), e-mail, music, play lists, audio clips, bookmarks, news and weather, chat, niche information services, travel and entertainment information, driving instructions, banking, and shopping (Schilit & Theimer, 1994; Schilit, Adams, & Want, 1994; Brown, 1996; Brown, Bovey, & Chen, 1997).

The fact that users should be able to store the content on their mobile phone and find the content they need without much effort results in the requirement of managing the content by organizing and annotating it. The purpose of information management is to aid users by offering a safe and easy way of retrieving the relevant content automatically, to minimize their effort and maximize their benefit (Sorvari et al., 2004).

The increasing amount of stored content in mobile devices and the limitations of physical mobile phone user interfaces introduce a usability challenge in content management. The physical mobile

phone user interface will not change considerably. The physical display sizes will not increase since in the mobile devices the display already covers a large part of the surface area. Text input speed will not change much, as keyboard-based text input methods have been the most efficient way to reduce slowness. While information is necessary for many applications, the human brain is limited in terms of how much information it can process at one time. The problem of information management is more complex in mobile environments (Campbell & Tarasewich, 2004).

One way to reduce information overload and enhance content management is through the use of *context metadata*. Context metadata is information that describes the context in which a content item was created or received and can be used to aid users in searching, retrieving, and organizing the relevant content automatically. Context is any information that can be used to characterize the situation of an entity. An entity is a person, place, or object that is considered relevant to the interaction between a user and an application, including the user and the applications themselves (Dey, 2001). Some types of context are the *physical context*, such as time, location, and date; the *social context*, such as social group, friends, work, and home; and the *mental context*, which includes users' activities and feelings (Ryan, Pascoe, & Morse, 1997; Dey, Abowd, & Wood, 1998; Lucas, 2001).

By organizing and annotating the content, we develop a new way of managing it, while content management features are created to face efficiently the usability challenge. Context metadata helps the user find the content he needs by enabling single and multi-criteria searches (e.g., find photos taken in Paris last year), example-based searches (e.g., find all the video clips recorded in the same location as the selected video clip), and automatic content organization for efficient browsing (e.g., location-based content view, where the content is arranged hierarchically based on the content capture location and information about the hierarchical relationships of different locations).

DATE, TIME, LOCATION, AND PROXIMITY

While context can be characterized by a large number of different types of attributes, the contribution of context attributes to content management is of great importance. We focus on a small number of attributes, which are considered the most important in supporting content management and also have the most practical implementations in real products, such as date, time, location, and proximity (nearby Bluetooth devices). Bluetooth is a short-range wireless technology used to create personal area networks among user mobile devices and with other nearby devices.

The first two attributes, date and time, are the most common in use in a wide range of applications. They are used to organize both digital and analog content, and offer an easy way of searching and retrieving the relevant content automatically. For example, many cameras automatically add the date and time to photographs. Furthermore, the location where content is created is another useful attribute for searching the content (e.g., home, workplace, summer cottage). Mobile devices give users the possibility to create content in many different locations. Users can associate the location with the equivalent content in order to add an attribute to it that will enable them to find it easier. Finally, proximity also plays an important role in content management, as nearby Bluetooth devices can provide information both in social and physical context. While each Bluetooth device can be uniquely identified, information can be provided on nearby people by identifying their mobile phones. An example for physical context is the case of a Bluetooth-based hands-free car kit that can be used to identify that the user is in a car.

USABILITY ISSUES AND PROBLEMS

The expansion of the dimension of context information in order to include location, as well as proximity context, can be of benefit to users while they are able to store, access, and share with others their own location-based information such as videos and photos, and feel the sense of community growing among them (Kasinen, 2003; Cheverist, Smith, Mitchell, Friday, & Davies, 2001). But when it comes to proximity to be included in context information, the problem of *privacy* emerges. It appears that users are willing to accept a loss of privacy when they take into account the benefits of receiving useful information, but they would like to control the release of private information (Ljungstrand, 2001; Ackerman, Darrel, & Weitzner, 2001).

While context metadata is attached to content, when users share content, they have to decide if they share all the metadata with the content or they filter out all or some part of them. The cost for memory and transmission of metadata, as it is textual information, is not an important factor to influence this decision. When the user receives location and proximity information attached to content, he or she may also find out where and with whom the creator of the content was when the content was created. As a result, both the location of the content creator and the location of nearby people are shared along with the content information. If this information is private, the sharing of it could be considered as a privacy violation. This violation may be 'multiplied' if the first recipient forwards the content and the metadata to other users.

However, users seem to be willing to share context metadata attached to content, as it would be convenient if context metadata were automatically available with the content (so that users do not have to add this information manually). Furthermore, it would be very helpful for the recipient if the received content was annotated with context metadata so that the recipient does not have to annotate it manually and be able to manage the content more easily. For example, in the case of image and video content, the filtering of context metadata such as location and people could be useless, since these same items appearing in the image or video can be identified visually from the image content itself.

But what is meaningful information to the end user? It seems that users want meaningful information, but they are not willing to put too much effort in creating it, unless this information is expected to be very useful. In the case of location, it would be difficult for users to type the name of the place and other attributes manually, since it would require their time and effort. Thus it would be important if meaningful context metadata, which include the required information, are automatically generated.

Proximity information also needs to be meaningful. In this way, meaningfulness is important when attaching information on nearby devices in the form of metadata. If the globally unique Bluetooth device address and the real name of the owner of the device could be connected, this functionality would give meaningful information to the user.

It is hard to determine which information is useful, while what is useful information in one situation might be totally useless in another. For example, when looking at photo albums, what is thought to be useful information varies a lot. When one is looking at family pictures taken recently, it is needless to write down the names of the people, since they were well known and discernable. But it is different looking at family pictures taken many years ago: the same people may not be that easily recognizable.

It appears that useful information depends on a user's location, what the information is used for, and in which time span. In order to create meaningful information, users need to put much effort into getting the data, organizing it, and annotating it with context metadata. Ways to

minimize their effort and maximize their benefit should be developed.

CONCLUSION

The increasing amount of stored content in mobile devices and the limitations of physical mobile phone user interfaces introduce a usability challenge in content management. The efficient management of large amounts of data requires developing new ways of managing content. Stored data are used by applications which should express information in a sensible way, and offer users a simple and intuitive way of organizing, searching, and grouping this information. Inadequate design of user interface results in poor usability and makes an otherwise good application useless. Therefore, it is necessary to design and built context-aware applications.

Issues of usefulness and meaningfulness in utilizing context metadata need to be further investigated. Usefulness depends on the type of metadata. As far as location and proximity are concerned, it appears that the more time has passed since the recording of the data, the more accurate the information needs to be. Furthermore, in the case of location information, the closer to one's home or familiar places the data refers to, the more detailed the information needs to be. A main usability challenge is the creation of meaningful context metadata automatically, without users having to add this information manually. There exist many ways for automatic recording of information about a user's context, but the generated information is not always meaningful.

Another field that requires further research is privacy. It seems that users are willing to accept a loss of privacy, provided that the information they receive is useful and they have control over the release of private information. Content management provides users with a safe, easy-to-use, and automated way of organizing and managing their mobile content, as well as retrieving useful information efficiently.

KEY TERMS

Bluetooth: A short-range wireless technology used to create personal area networks among user devices and with other nearby devices.

Content Management: Ways of organizing and annotating content in order to retrieve and search it more efficiently.

Context: Any information that can be used to characterize the situation of an entity.

Context Metadata: Information that describes the context in which a content item was created or received.

Entity: A person, place, or object that is considered relevant to the interaction between a user and an application, including the user and the applications themselves.

Location: The place where content is created by the user.

Usability: The effectiveness, efficiency, and satisfaction with which users can achieve tasks in the environment of mobile devices.

ABSTRACT

The mobile device presented here is designed to offer several services to enhance autonomy, security, and communication for the cognitively impaired people and their caregivers. Two mobile devices are linked through a server; one is dedicated to the patient, the other one to the caregivers. The services fill three functions for patients: a simplified reminder, an assistance request service, and an ecological information gathering service. Three services are available for the caregiver: monitoring patients'ADLs, informing system and colleagues of an intervention, and planning patients' ADLs.

INTRODUCTION

The number of people suffering from cognitive impairments (Alzheimer disease, head injury, schizophrenia, etc.) is growing continually. For one, the aging of the society plays an important role in this trend. The always increasing needs for resources generates a huge stress on human and economical actors. Thus in Canada and United

States, as in most western countries, social and medical policies try to keep people suffering from cognitive deficits at home (Hareven, 2001). Progress in cognitive rehabilitation also augments the number of semi-autonomous people that would be able to stay at home if light assistance is provided. Of course, this results in higher expectations and even more demand on resources. But most of the time, families have to take responsibility for care without access to appropriate resources. Too often, this situation then turns to an exhausting weight. Therefore, natural and professional caregivers urge for help.

Recent advances in mobile technology can provide affordable solutions to lessen the burden and anxiety put on caregivers and to collect reliable information. For many years, numerous devices have been designed to counterbalance physical and sensory deficits. Nowadays progress in technology set high hopes for cognitive orthotics that address cognitive decline (Lange, 2002; Pollack, 2004). Thanks to their small size and their versatility, mobile devices can offer a personalized assistance anytime anywhere. Mobile devices then become portable cognitive prosthesis, for instance acting as pervasive system to remind people activities of daily living (ADL) to perform when needed. They can also foster sense of security by keeping people and caregivers directly in touch. In its simplest form a direct call button may be used to request immediate assistance. Geo referenced data may also be used to detect crisis of schizophrenia or when a patient suffering from Alzheimer disease is lost (Médical Intelligence, 2005). Mobile devices can also provide non-intrusive remote supervision by caregivers. Besides mobile devices can gather ecological data compulsory to adapt or fine-tune diagnosis and treatments. Nevertheless, the design of devices and mobile services must put a very careful attention to user interfaces used to deliver information. Population suffering from cognitive deficits has often severe limitations and constraints.

This chapter discusses features and implementation of mobile services for cognitive assistance and remote supervision. Mobile devices provide practical solutions to the issues presented above. First, we review benefits and limitations of current reminder systems that can assist patients and/or caregivers. Then we present the needs of the population regarding the assistance necessary to stay safely at home. The multiple mobile services, designed especially for that population, are also described. We show how supervision can safely foster autonomy. Next, we describe cognitive assistance to patients and remote supervision by professionals or relatives, and then we go further and gather ecological data to foster better treatments. Finally, outdoors, safety and security of the patients is relying on geo-localization features. Implementation specific details are also sketched.

MOBILE PROSTHETIC SYSTEMS

The management of ADL is a central issue for people suffering from cognitive deficits. In the process of rehabilitation, occupational therapists provide a patient with a paper agenda as a tool he has to master to manage his life and autonomy. A lot of research projects and commercial applications also targeted electronic adaptation of specific functionalities of these agendas. In this section, we review the advantages and limitations of current reminder and/or agenda systems.

Some systems are device specific and are explicitly designed to be used inside the patient home and then could not help outside (Helal et al., 2003; Visions, 2005). Another category of systems is designed specifically for mobile devices in such a way that their use is not restricted to a specific location. These applications are usually running on PDAs or smart phones to either assist for needs specifically related to mobility (Patterson et al., 2004) or as general reminder/agenda systems or electronic organizers (Gorman, Dayle, Hood,

& Rumrell, 2003; Haberman, Jones, & Mueller, 2005; Neuropage; Szymkowiak, Morrison, Prveen Shah, Evans, & Wilson, 2005). They are usually provided with acoustic alert or remote communication.

Activity Compass project intends to provide compensatory aid for outdoor courses for patient suffering from Alzheimer disease (Patterson et al., 2004). It consists basically of a PDA equipped with a GPS. Its role is to guide patient towards their destination by a mean of an arrow indicating the direction to take.

Neuropage is a reminder system that uses radio technology to send reminders of things to do (Neuropage). When the message arrives, the pager beeps (or vibrates), one button is pressed and the message can be read from the screen. Messages can be regular events or single-time message. Messages are added or removed by contacting Neuropage office by phone, e-mail, letter, or fax.

The ISAAC system acts as a cognitive prosthesis used by people experiencing dysfunctions in autonomy due to different kinds of brain injury (Gorman et al., 2003). It provides a checklist reminder to execute safely the ADL. Its hierarchical structure permits to navigate easily throughout the different pieces of advice displayed. Personalization and adaptation of pieces of advice enable ISAAC to evolve according to the patient cognitive evolution.

Providing a reminder helps the cognitively impaired patient to increase his autonomy. But the patient himself and his caregiver express needs for safety. Both want to keep in touch and be confident that activities will be performed in time. So a mean of communication must be added to the current reminders. In the next section, we review the cognitive deficits encountered and the needs that ensue.

NEEDS OF COGNITIVELY IMPAIRED PEOPLE

Cognitive impairments encountered in schizophrenia, head trauma and during the early stages of the Alzheimer disease provoke similar losses in autonomy that justify exploring a common approach to support, assistance and remediation by technology (Pigot, Savary, Metzger, Rochon, & Beaulieu, 2005). Cognitively impaired people present lacks of initiation. For instance, they remain for long periods without undertaking actions. They all call for frequent reminders to remember what to do and sometimes how to do. Alzheimer disease strikes elders and one's situation evolves from relative autonomy to an unrelenting dependence while trauma injury and schizophrenia appear most often during adulthood and one's situation evolves from dependence to relative autonomy.

Unless severely affected, cognitively impaired people are usually quite autonomous in performing basic ADL such as eating, dressing, and washing themselves. But they at times forget to do them and then need continuous recalls in order to initiate ADLs. Taking medication is a critical issue, as it requires a good short-term memory in order to fulfill the prescription correctly: which pills, how many and when. Without a reliable short-term memory, it can be forgotten or taken twice. At home oblivion or bad discernment in the use of domestic appliances often cause bath and sink flooding, fire, burn, cut...Beside these hazardous situations, risk of malnutrition, bad hygiene, and isolation are also real.

Cognitive impairments experienced at home have also manifest effects outside. Moreover, cognitively impaired people exhibit more difficulties in an unusual context. Oblivion leads to problems in finding one's way to a destination, in remembering the shopping list or even the reason of the trip.

Loss of autonomy requires assistance. Caregivers lavish attention to the patients days and

nights long. Frequent recalls and safety are two factors especially important in the overall burden coming from constant supervision and assistance. Therefore, an electronic companion could alleviate the "threatening" recalls and improve the relationship. Safety prevents a caregiver from letting the patient alone.

MOBILE AND PERVASIVE COMPUTING

Although existing services are invaluable for patients and caregivers, overall they suffer from some drawbacks. These services are not integrated in a common portal. They must run on a specific patient device. They are either closely linked to a given location or, if they are location independent, they can not benefit from the casual presence of other devices in the environment, for instance sensors on the kitchen cupboards.

In next sections, we present the first steps of an on-going research project at DOMUS Laboratory. Mobile computing is coupled with pervasive computing (Weiser, 1991). Mobile computing will enable patients and caregivers to use services wherever they are. Pervasive computing will allow them to access services whatever the device is and to benefit from existing devices, sensors, and effectors present in their current environment. This approach then promotes a tighter integration of devices and services to the environment when possible while preserving mobility and independence of the patients.

Currently, a common portal and many services were implemented and are ready to be evaluated in situ. Through this portal, a patient gets access to services with a simplified adapted user interface. Caregivers also have access to their counterpart of services but the interface is more complex. For the moment, devices used are PDAs, but we intend to port them on e-mate, a platform that renders deployment of services independent of devices they are deployed on (Giroux, Carboni, Paddeu, Piras, & Sanna, 2003). So phones, laptops, TVs could be used to access services.

ASSISTANCE AND SUPERVISION SERVICES

A mobile device is designed to offer several services to enhance autonomy, security, and communication to cognitively impaired people and their caregivers. PDAs are linked through a server. Some are dedicated to patients. Others run applications presenting the caregivers point of view on information. Patient services fill four functions: a simplified reminder, a prompter to request immediate assistance, a service to gather ecological information, and a location-based health information service (Boulos & Maged, 2003) to help patient in case of crisis. On the other side, three services are available for the caregiver: monitoring patients' ADLs, informing system and colleagues of an intervention, and planning patient' ADLs. Services also enable patients and caregivers to communicate. The client component running on a patient's PDA is kept very simple. The patient benefits on an auto login procedure in order to reduce the cognitive load.

An Enhanced Agenda as a Mean for Cognitive Assistance

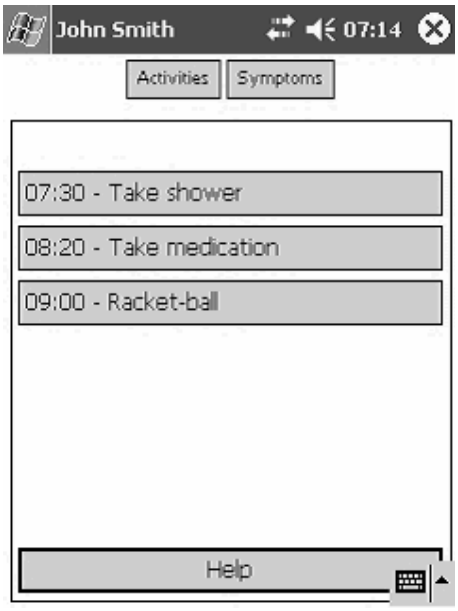
A basic paper agenda is designed to help remembering appointments, to fill a timetable and to prevent time conflicts. Our aim here is quite different. The agenda acts mainly as a cognitive prosthesis. Typically, the home of a patient suffering from head injury is covered with numerous notices, for instance written on a post-it. Each one indicates something to do. On the contrary, the electronic diary can show solely the activities often forgotten, and moreover just when it is necessary. By default, our prototype displays on the PDA single window the next three activities to perform in a three hours time bracket (Figure

1). Depending on the patient's cognitive abilities the number of activities displayed and the time slot can be easily reduced or increased. When an activity is performed the patient clicks on it to indicate its completion to the caregivers. The activities monitored on the agenda are either events occurring just one time, as appointments, or recurring events as ADLs often forgotten.

Keeping in Touch

If help is necessary, the patient clicks on the button "Help" at the bottom of the screen to warn caregivers. This button is always visible and active. This remote supervision ensures permanent contact between them. It provides a sense of safety for both patients and caregivers. Caregivers feel insecure to let patients alone without the opportunity to be reached. For patients, the phone is often too complicated to use. Carrying everywhere a PDA offers permanent assistance at a single click.

Figure 1. Patient agenda



Monitoring ADL

Previous sections described the patient side of the system. In this section and the next two, we depict the caregiver view: how ADLs are monitored, how cooperation can be foster between caregivers, and how to manage a patient list of ADLs.

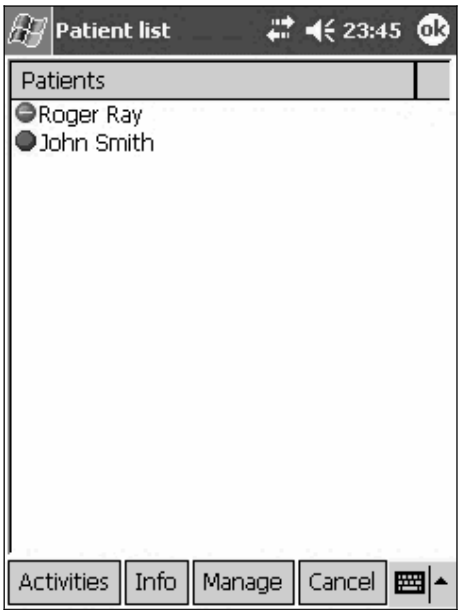
The role of the patient PDA is to foster his or her autonomy. From time to time, he or she does not perform given activities in time which may compromise his or her ability to stay alone. Equilibrium must be maintained between a patient intimacy and his or her safety. For instance, forgetting one day to take a shower does not justify an immediate intervention. However, after several days without showers, caregivers urge him or her to do it. On the other side, forgetting once to take medication could be harmful for the patient's health. Without a tool that helps to monitor ADLs, a caregiver surveys constantly the patients asking for the ADLs completion.

The current prototype supports remote supervision of ADLs to perform (Figure 2). Caregivers then know when an ADL is completed without bothering residents. On his or her mobile device, a caregiver can monitor every patient under his or her responsibility. On his or her patients list, colored icons indicate the status of current ADLs for each patient: green if all is OK, yellow if the patient is near to forgot to perform an ADL, and red if time planned for the ADL is over (Figure 2a). For each patient, a caregiver can know: which activities are under monitoring (Figure 2b) and the time of completion of a given ADL. The same color code prevails.

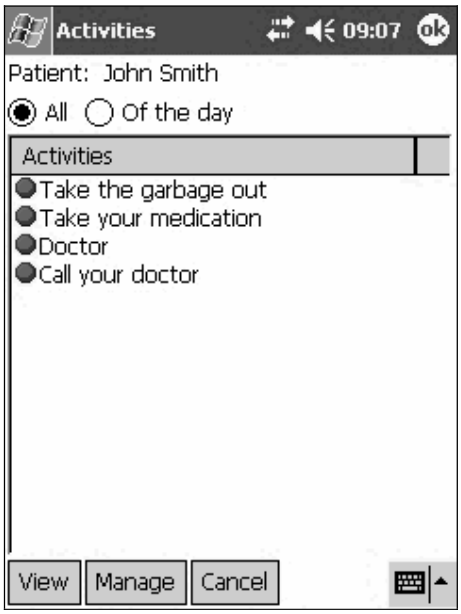
Coordination Between Caregivers

Since many caregivers can be in charge of a patient, coordination is important. Several caregivers can take care of many patients. When a patient does not perform a task in time, all responsible caregivers are informed. It is then essential to

Figure 2. Caregiver's ADL monitoring a) Supervised patients b) One patient ADLs



(a)



(b)

coordinate their actions, for instance in order to avoid all of them going to see the patient. As soon as a caregiver notifies his intervention to the system, this information is sent to all the mobile devices owned by the other caregivers. Caregivers can also exchange responsibility of patients, for instance when a working shift occurs.

Implementation section explains in more details how the information is updated on each PDA.

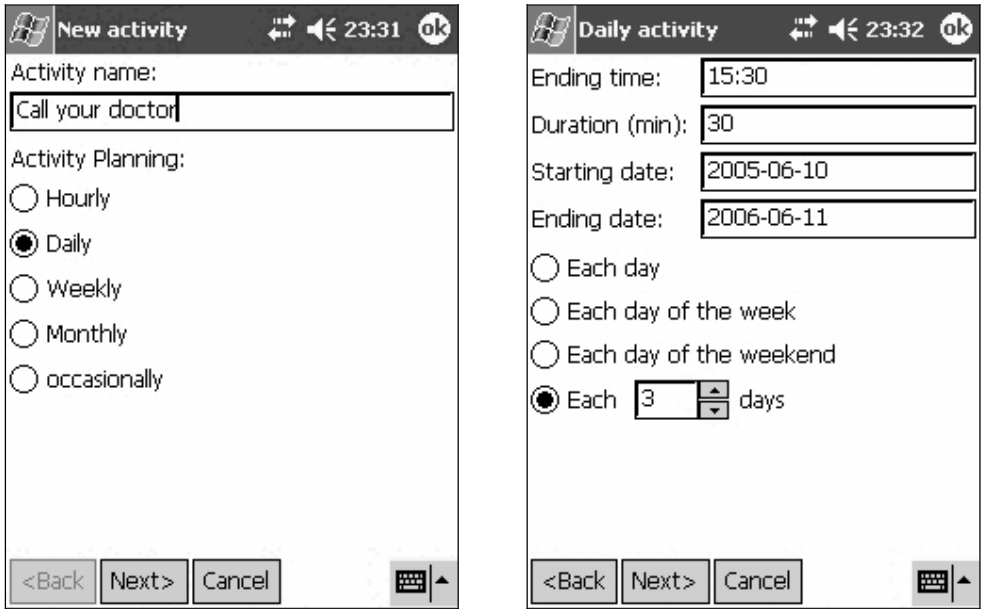
Planning ADL

In addition to ADL monitoring, caregivers must have also simple means to update and change rapidly the ADLs and events that have to be monitored. Like a usual organizer, the caregiver mobile device enables to register an activity occasionally or on a periodic basis ranging from hours to months (Figure 3a). The caregiver has to specify duration and completion time and for how long the activity has to be monitored (Figure 3b). This last information is particularly suitable during the rehabilitation period or to update a medication prescription that is regularly changed by the physician.

Ecological Data: Gathering Information for Better Treatments

Collecting ecological information may be of tremendous value for delivering better treatments. For instance to control the schizophrenic symptoms, a physician prescribes neuroleptics which induce severe side effects (Shriqui & Nasrallah, 1995). The physician has then to adjust medication

Figure 3. Planning activity a) Activity period basis b) Time activity information



(a) (b)

during years to limit side effects and to avoid the recurrence of hallucinations. He or she needs valid information about the patient feelings.

On his or her mobile device, the patient can notify symptoms (or other information) as soon as he or she feels them (Figure 4). An intensity scale permits him or her to estimate the level of severity. The PDA is also equipped with a GPS to register automatically date, time, and position. These geo-referenced data are sent to the server on a batch mode. Data can be analyzed later to improve diagnosis and treatments.

IMPLEMENTATION

The basis of the implementation is a client-server architecture (Figure 5). Patients and supervisors use iPAQs to connect to the server through wireless networks. The system is available both indoors and outdoors. Indoors, the wireless connections to the server use IEEE 802.11b,g. Outdoors, the wireless connection is made through a Sierra Wireless AirCard®. Each PDA connects to the server through TCP sockets. The server allocates a different thread to each connection. If the connection is lost, the mobile device tries to restore it. The PDAs and the server exchange serialized objects through sockets. Outdoors, a GPS gives the patient location. To ensure rapid communication the traffic is kept low. When a patient confirms an ADL has been done or when a caregiver let know about his intervention, a message is sent to the server. The server first updates the database, and then sends a message to each PDA to inform a change happens. At that moment, some PDAs

Figure 4. Patient symptoms

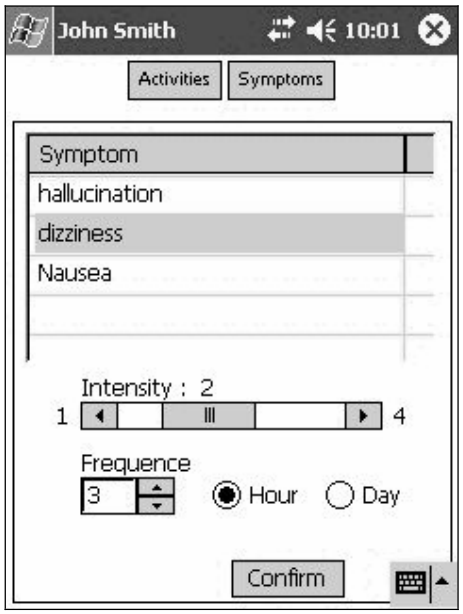


Figure 5. Connection infrastructure

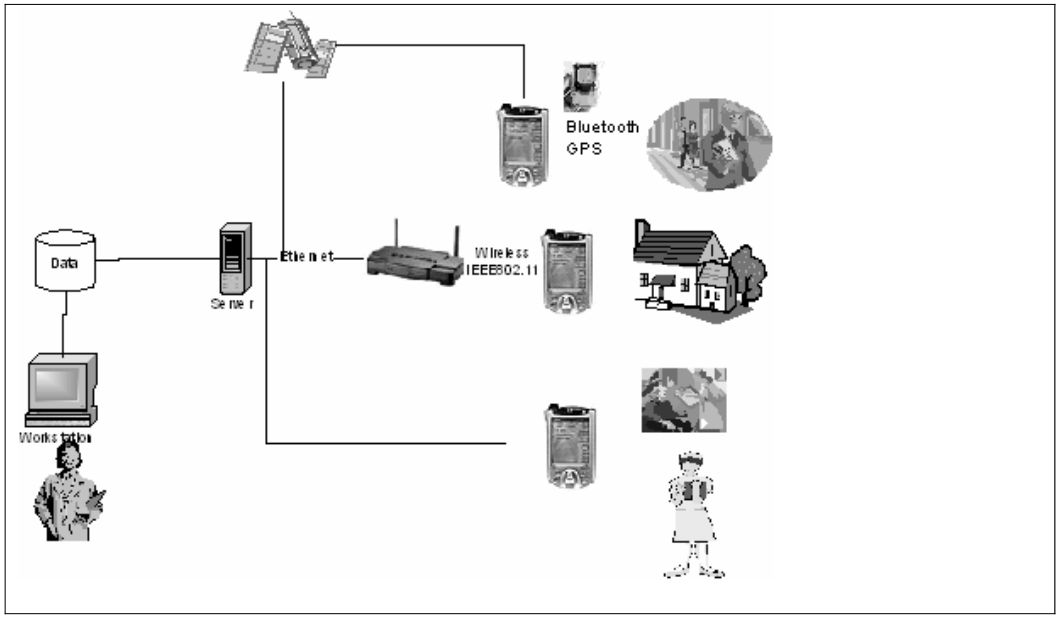

may want to display the information under change. They request all the information needed to update their screen displayed.

Different types of communication are used between the PDAs and the server. Inside, when the connection is established the transmission is in direct mode. Outside or when the connection is out, the communication is in batch mode. Messages are saved in a queue waiting until a connection becomes available. Finally, a configuration file is used to personalize the application: auto-login, font, font size, message strings, icons, and number of activities displayed.

The implementation is in standard Java (J2SE) for the server part. PersonalJava is used for the client part on PDAs. On the PDAs, user interfaces were implemented with SWT. On the PDAs, the virtual machine was J9 for PocketPC. The system was tested on HP iPAQ 4155 and HP iPAQ 1945 running Microsoft PocketPC OS.

DISCUSSION

Specific needs are addressed by our system for cognitively impaired people in order to foster their autonomy. Functions of an electronic agenda are redesigned to limit cognitive load, especially the burden put on memory. Presently only the patient name is displayed. We are evaluating the relevance of adding other information such as the patient address and caregiver phone number. It may be helpful when a patient is lost but it could raise the cognitive load by requiring one more screen.

The help function is germane to a panic button provided by various companies. A panic button is generally linked to a remote controller that intervenes when the button is pressed. The use of such panic systems remains generally difficult especially for elders suffering Alzheimer disease. First, we hope that providing on the PDA a help button they use frequently is more likely to be used in case of emergency. Secondly, making explicit the help button on the PDA by an icon or by writing the function is a guarantee they could understand its use.

Providing geo-referenced data is another critical issue. Knowing a patient position may be worthful and even vital in many situations and for a range of purposes:

- To send directly somebody at the patient location if he is in crisis or in danger
- To forbid specific zones
- To detect crisis states by analyzing paths and detecting pathologic patterns of movement of patients suffering from schizophrenia
- To predict the goal of a patient combining path history and analysis

When a patient is outdoors, a GPS connected to his PDA get his or position. This position is sent at predefined time interval to the server. Path analysis can then be performed. Currently client and server components are under development to specify and manage forbidden zones.

Mobile services are actually designed to offer the activities monitoring by professional caregivers. Families need too a similar system to be informed of difficulties. They feel insecure to let alone the patient. They could exploit geo-referenced data in the timetable information to know if it is conform to the one expected. For instance, a patient suffering from schizophrenia shows disorganization symptoms before experiencing a new crisis. Sending no information about the activity performed is a premonitory sign. Applying it to the Alzheimer disease may help to detect falls or other health problems.

CONCLUSION

In this chapter, we presented a client-server-based mobile system for patients suffering from cognitive deficits and their caregivers. Users will use mobile devices. They help especially to remember the activities a patient have to perform.

We adapted traditional agenda to decrease the cognitive prerequisites and to provide a permanent communication between a patient and his caregiver. All along the development process, attention was paid on the real needs expressed by patients and caregivers. A sociological questionnaire and study had established previously the needs among patients suffering Alzheimer disease, head injury and schizophrenia (Pigot et al., 2005). Periodic meetings with caregivers have ensured conformity of the design of services to the needs expressed. Finally, a clinical validation is under process among people suffering from schizophrenia.

Future works will integrate mobile services to a helpful environment designed for people suffering from cognitive impairments in the spirit of pervasive computing. For instance instead of asking a patient to notify when an activity is completed, the environment will be able to recognize the activities performed by means of sensors (Pigot, 2004). The home will adapt itself to alleviate autonomy, remembering when necessary what needs to be done and how to do it. Such smart homes are an answer to the growing demand of cognitively impaired people to stay safely at home.

KEY TERMS

Batch Mode: The batch mode indicates the transmission mode where the data are sent to the receptor a moment after the transmittor command.

Cognitive Assistance: It is the assistance provided by the environment to compensate the cognitive deficits.

Cognitive Deficits: They are the deficits encountered by a person following a brain lesion. The memory losses and the lacks of planning, initiation, and attention are examples of cognitive deficits.

Direct Mode: The direct mode indicates the transmission mode where the data are sent to the receptor immediately after the transmitter command.

Mobile Services: Mobile services refer to the software applications available on portable devices such as PDA or smart phone.

Pervasive Computing: Pervasive computing is the next generation computing environments with information and communication technology everywhere, for everyone, at all times.

Reminder: A reminder is a prosthetics aid which displays the common agenda functions and information on memories or advices to be followed.

Remote Monitoring: See smart home.

Sensors: The sensors are electrical devices that gather information on the state of the environment and on the localization and the activities performed by the inhabitant. For instance some sensors detect the presence of the inhabited or which door is open.

Smart Home: The smart home is the home equipped with sensors and effectors that could react according to the inhabitant actions. The smart home could warn persons outside by the remote monitoring or give advices to the inhabitant.

ABSTRACT

Video management research has been neglecting the increased attractiveness of using camera-equipped mobile phones for the production of short home video clips. But specific capabilities of modern phones — especially the availability of rich context data — open up new approaches to traditional video management problems, such as the notorious lack of annotated metadata for home video content. In this chapter, we present MobiCon, a mobile, context-aware home video production tool. MobiCon allows users to capture video clips with their camera phones, to semi-automatically create MPEG-7-conformant annotations by exploiting available context data at capture time, to upload both clips and annotations to the users' video collections, and to share these clips with friends using OMA DRM. Thereby, MobiCon enables mobile users to effortlessly create richly annotated home video clips with their camera phones, paving the way to a more effective organization of their home video collections.

INTRODUCTION

With recent advances in integrated camera quality, display quality, memory capacity, and video compression techniques, people are increasingly becoming aware that there mobile phones can be used as handy tools for the spontaneous capture of interesting events in form of small video clips. The characteristics of mobile phones open up new ways of combining traditionally separated home video production and management tasks at the point of video capture: The ability of mobile phones to run applications allows video production tools that combine video capture and video annotation. The classic approach of using video annotation tools to provide metadata for the organization and retrieval of video long after capture lacks user acceptance leading to the characteristic lack of metadata in the home video domain (Kender & Yeo, 2000). Context data about video capture available on mobile phones can be exploited to ease annotation efforts, which users try to avoid even at the point of capture (Wilhelm, Takhteyev, Sarvas, van House, & Davis, 2004). Time, network cell, GPS position, address book, and calendar can all be used to infer events, locations, and persons possibly recorded.

Furthermore, mobile phone-based video production tools can combine video capture with video upload and video sharing. With the ability to access the Internet via 2G and 3G networks from almost anywhere, phone users can directly load their clips to their home video collections stored on their PCs or by service providers disencumbering the limited memory resources of their phones. They also can share clips instantly with their friends via multimedia-messaging services. Digital rights management platforms like OMA DRM give users rigid control over the content they share preventing unwanted viewing or copying of shared clips.

However, video management research so far has mainly regarded mobile devices as additional video consumption channels. There has been considerable work concerning mobile retrieval interfaces (e.g., Kamvar, Chiu, Wilcox, Casi, & Lertsithichai, 2004), the generation of video digests for mobile users (e.g., Tseng, Lin, & Smith, 2004), and adaptive video delivery over mobile networks (e.g., Böszörményi et al., 2002), but a comprehensive view that considers the use of mobile phones as video production tools is still missing.

In this chapter, we present MobiCon: a context-aware mobile video production tool. Forming a cornerstone of the Candela platform, which addresses mobile home video management from production to delivery (Pietarila et al., 2005), MobiCon allows Candela users to record video clips with their camera phones and to semi-automatically annotate them at the point of capture in a personalized fashion. After recording, MobiCon extracts context data from the phone and passes it to an annotation Web service that derives reasonable annotation suggestions. These do not only include time- or position-based suggestions such as the season, city, or nearby points of interest possibly documented by the video; they also include personal calendar- and address book-based suggestions such as likely documented events and known locations like a friend's house. Besides these suggestions, the user can select concepts from a personal ontology with little manual effort or enter keywords for additional annotation.

MobiCon is further capable of uploading clips and their annotations to the users' private video collections in Candela's central video database directly after capture and permits users to immediately share these clips with friends, granting controlled access via OMA DRM.

Thus, MobiCon enables mobile phone users to create and share richly annotated home video clips with little effort, paving the way towards the more effective organization of their home video collections. The extensible architecture of the annotation Web service allows us to embrace and incrementally integrate almost any method for the generation of annotation suggestions based

on context without having to change the MobiCon application.

In the following, we first illustrate the use of MobiCon in an application scenario. We then relate MobiCon to state-of-the-art mobile home video production tools. After a brief coverage of the Candela platform, we provide a technical description of the MobiCon tool. We provide a discussion and outline future developments, before we come to a conclusion.

MOBICON APPLICATION SCENARIO

In this section, we want to provide an intuitive understanding of MobiCon by illustrating its usage for home video clip production and sharing in a typical application scenario.

In the scenario, MobiCon is used to produce two video clips of a birthday barbecue and sauna party. Figure 1 depicts a sequence of screenshots of the basic steps involved when using MobiCon to capture, annotate, and share a video clip showing some guests having a beer outdoors; Figure 2 shows a similar sequence for an indoor clip showing guests leaving the sauna that is created by a different user, who also wants to restrict the playback of the shared clip via DRM protection. After the capture of both video clips (Figure 1(a) and Figure 2(a)), the users can immediately annotate them. MobiCon gathers context data from each phone and passes it to an annotation Web service operated by the Candela platform. Based on this data, the Web service infers possible annotations that are suggested to the users (Figure 1(b) and Figure 2(b)). Suggestions do not only include rather simple ones inferred from the capture time like “April” and “evening” (Figure 2(b)); when a mobile phone is connected to a GPS receiver that MobiCon can access, they also include location annotations like “Oulu” (town) and “Peltokatu” (the street name) the Web service derived from the GPS position of the capture using a reverse-geocoder (Figure 1(b)). The availability of a current

Figure 1. Basic video capture, annotation, and sharing with MobiCon

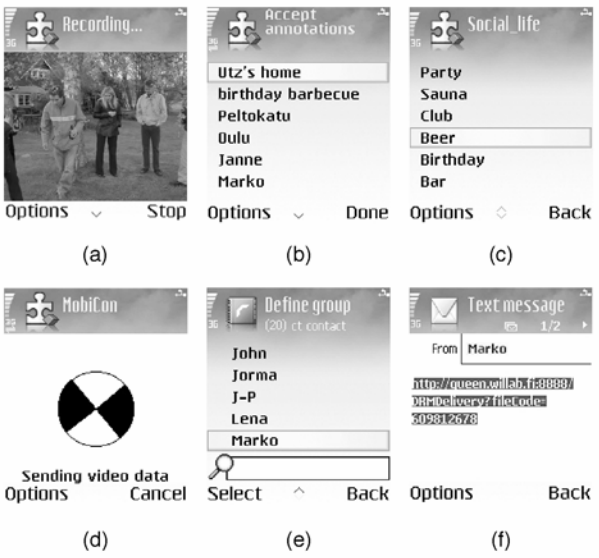

Figure 2. DRM-protected sharing of clips

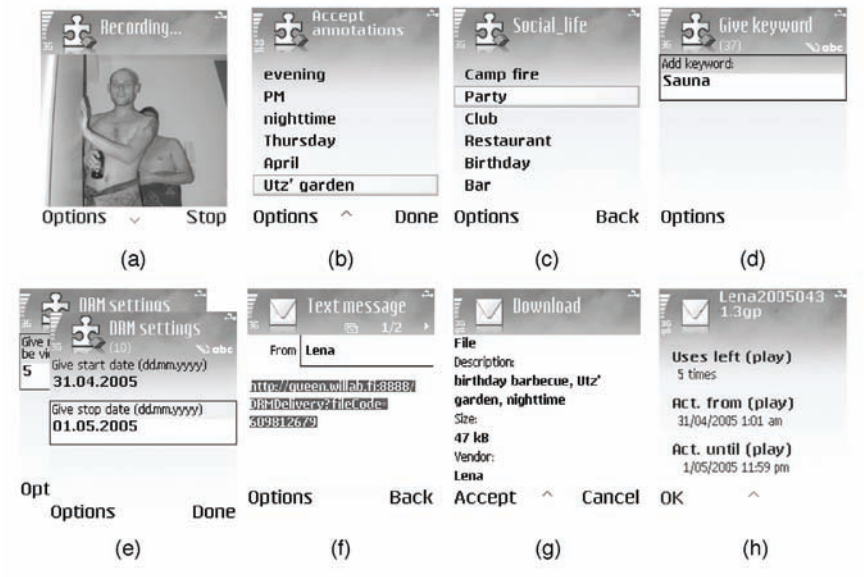


GPS position also suggests that a clip covers an outdoor event (not shown in Figure 1(b)).

There are further highly personalized suggestions derived from phone address books and calendars, which can be synchronized with the Web service. Matching derived location information from the entries in a user's address book, the Web service can suggest known locations like "Utz's home" as annotations (Figure 1(b)); matching the capture time with the entries in a user's calendar, the Web service can suggest documented events like "birthday barbecue" (Figure 1(b)) along with event locations like "Utz's garden" (Figure 2(b)) and participants like "Janne" and "Marko" (Figure 1(b)) provided with the calendar entries. Users can correct the suggestions of the annotation Web service. In Figure 1(b), for instance, the user can remove the name "Marko" because he does not appear in the video.

In addition to the automatically generated annotation suggestions, MobiCon allows users to provide personalized manual clip annotations. Users can select concepts from personal, hierarchically organized home video ontologies that cover the aspects of their daily lives that they frequently document with video clips. The creator of the first video clip likes to have beers with friends, so his personal ontology contains the concept "beer" as a sub concept of "social life" (Figure 1(c)) that he can simply select for the annotation of his clip. The ontology of the creator of the second clip can contain different concepts due to different interests, such as the concept "camp fire" depicted in Figure 2(c). For the annotation of situations not covered by a user's personal ontology, MobiCon permits the entry of arbitrary keywords with the phone's keyboard as a last resort (Figure 2(d)).

After annotation, MobiCon uploads video clips and annotations to the users' personal video collections on the Candela platform (Figure 1(d)). Furthermore, MobiCon allows users to share freshly shot clips with contacts from their phone address books (Figure 1(e)). MobiCon then sends a text message with a link pointing to the shared clip in the user's collection to each selected contact, as depicted by Figure 1(f). When the recipient selects the link, the phone will download and play the clip. The second video clip shows the somewhat delicate situation of two party guests coming out of the sauna. While the creator of this clip still wants to share it with a friend, she wants to impose usage restrictions. Utilizing MobiCon's DRM support, she restricts playback of the shared clip to five times within the next 24 hours on the phone of her friend (Figure 2(e)). MobiCon makes the Candela platform prepare a copy of the clip that encodes these limitations using OMA DRM. The link to the video contained in the text message that is then sent to the friend points to the DRM-protected copy (Figure 2(f)). After selecting the link, the recipient sees a description of the clip and is asked for permission to download Figure 2(g)). If download is accepted, the OMA-DRM-compliant phone recognizes and enforces the restrictions imposed upon the clip and displays the corresponding DRM information before starting playback (Figure 2(h)).

RELATED WORK

The previous section illustrated MobiCon's different functionalities from a user's perspective in a typical application scenario. We now compare MobiCon to existing approaches in the field of mobile video production tools, thereby showing how it exceeds the state-of-the-art. In particular, we relate MobiCon to mobile video capture tools, mobile video editing applications, mobile video annotation tools, and tools for mobile content sharing.

Mobile Video Capture Tools

Probably every modern mobile phone with an integrated camera features a simple video capture tool. MobiCon goes beyond these tools by not only allowing the capture of a video clip but also allowing for immediate annotation for later retrieval, its immediate upload to the user's home video clip collection, as well as its immediate sharing controlled via OMA DRM.

Mobile Video Editing Tools

Mobile video editing tools like Movie Director (n.d.) or mProducer (Teng, Chu, & Wu, 2004) facilitate simple and spontaneous authoring of video clips at the point of capture on the mobile phone. Unlike MobiCon, the focus of these tools lies on content creation and not on content annotation, uploading, and sharing.

Mobile Video Annotation Tools

While there are many PC-based tools for video annotation as a post-capturing processing step (e.g., Abowd, Gauger, & Lachenmann, 2003; Naphade, Lin, Smith, Tseng, & Basu, 2002), mobile tools like MobiCon permitting the annotation of video clips at the very point of capture, when users are still involved in the action, are rare. M4Note (Goularte, Camancho-Guerrero, Inácio Jr., Cattelan, & Pimentel, 2004) is a tool that allows the parallel annotation of videos on a tablet PC while they are being recorded with a camera. Unlike MobiCon, M4Note does not integrate video capture and annotation on a single device. Annotation is fully manual and not personalized; context data is not taken advantage of for suggesting annotations. M4Note does not deal with video upload and sharing.

Furthermore, mobile phone vendors usually provide rudimentary media management applications for their phones that — compared to MobiCon and its support for annotation sug-

gestions automatically derived out of context data and personalized manual annotation using concepts from user-tailored ontologies and keywords — offer only limited video annotation capabilities. As an example, Nokia Album (n.d.) allows the annotation of freshly shot clips with descriptive titles. As a form of context-awareness, Nokia Album records the time stamps of video captures but does not infer any higher-level annotations out of them.

The lack of sophisticated mobile video annotation tools constitutes a contrast to the domain of digital photography. Here, research has recently been investigating the use of context data such as time and location to automatically cluster photographs likely documenting the same event (Cooper, Foote, Girgensohn, & Wilcox, 2003; Pigeau & Gelgon, 2004) and to automatically infer and suggest higher-level annotations, such as weather data, light conditions, etc. (Naaman, Harada, Wang, Garcia-Molina, & Paepcke, 2004). Compared to MobiCon, these approaches do not present the inferred annotation suggestions to users at the point of capture for immediate acceptance or correction; inference takes place long afterwards when the photographs are imported to the users' collections.

For the annotation of photographs at the point of capture, Davis, King, Good, and Sarvas (2004) have proposed an integrated photo capture and annotation application for mobile phones that consults a central annotation database to automatically suggest common annotations of pictures taken within the same network cell. Apart from its focus on video, MobiCon mainly differs from this approach by offering a different and broader variety of derivation methods for context-based annotation suggestions and by addressing content upload and sharing.

Mobile Content Sharing Tools

Mobile content sharing applications like PhotoBlog (n.d.), Kodak Mobile (n.d.), and MobShare (Sarvas, Viikari, Pesonen, & Nevanlinna, 2004) allow users to immediately share content produced with their mobile phones, in particular photographs. Compared to MobiCon, there are two major differences. Firstly, these applications realize content sharing by uploading content into central Web albums, in which users actively browse for shared content with a Web browser. In contrast, MobiCon users view shared content by following links in notification messages they receive. Also, MobiCon gives users more control over shared content by applying DRM techniques.

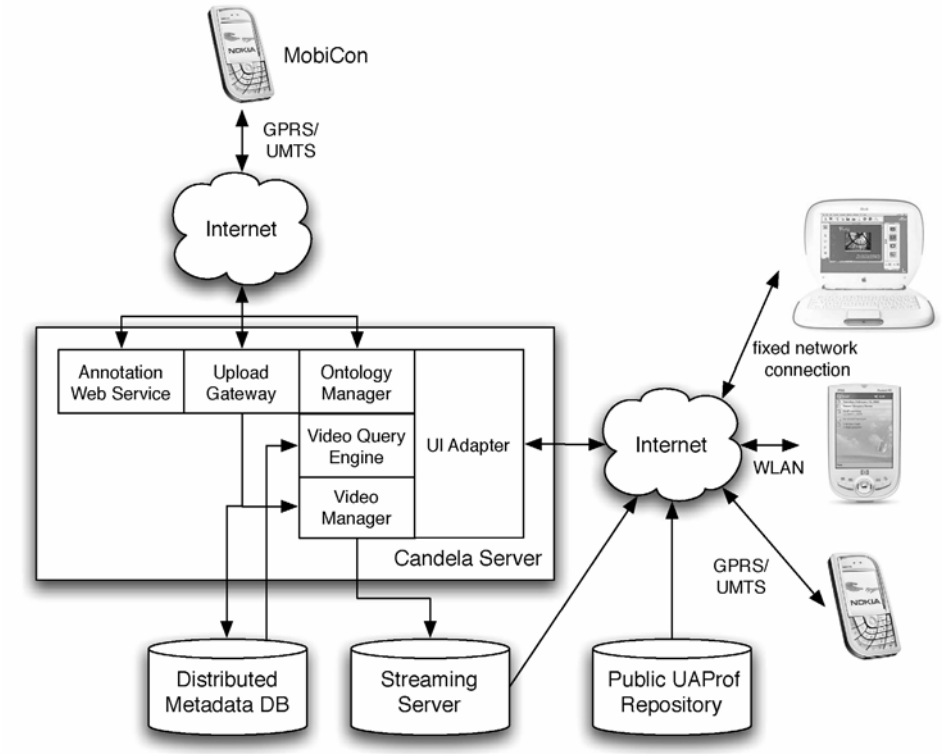
Secondly, current content sharing systems offer rather restricted means for content annotation, mainly allowing content to be manually assigned to (usually flat) folder structures and attaching time stamps for folder- and timeline-based browsing. Nokia Lifeblog (n.d.) goes a bit beyond that by automatically annotating content with the country where it has been created, which is obtained from the mobile network that the phone is currently logged in to. But compared to MobiCon, these still constitute very limited forms of context-based annotations.

THE CANDELA PLATFORM

Facing the increasingly popular use of mobile devices for home video production, we have developed the Candela mobile video management platform. Incorporating MobiCon, it provides support for all major process steps in the mobile home video management chain, ranging from mobile video creation, annotation and sharing to video storage, retrieval, and delivery using various mobile and stationary terminals connected to the Internet via various types of networks like GPRS/EDGE, 3G/UMTS, WLAN, and fixed networks. In the following, we briefly describe the platform's key elements and their relationship to MobiCon.

Figure 3 illustrates the interplay of the different components of the Candela platform. As explained

Figure 3. Candela platform architecture



before, the MobiCon mobile phone-based video production application permits the integrated capture, personalized, context-aware annotation, upload, and DRM-controlled sharing of video clips. To this end, MobiCon interacts closely with the central Candela server, namely with its ontology manager, annotation Web service, and upload gateway components.

The RDF-based ontology manager stores the personal home video ontologies of Candela's users. When MobiCon starts for the first time, it loads the ontology of the current user from the manager so that its concepts can be used for the personalized annotation of videos.

The annotation Web service is called by MobiCon during clip annotation, passing context data such as capture time, GPS position, and user information. The Web service derives annotation suggestions based on this data, which MobiCon then presents to the user.

The upload gateway is used to transfer clips and their annotation after capture from MobiCon to the users' video collections. The gateway receives the clips in 3GP format and clip metadata including user annotations and context data in MPEG-7 format. The clips are passed on to the video manager for storage and transcoding into suitable formats for the video players of different devices and for different network speeds. The

video manager also prepares OMA DRM-enhanced clip variants when MobiCon users define usage restrictions for the video clips that they are about to share. The clip metadata is stored in a database implemented on top of the Solid Boost Engine distributed relational database management system for scalability to large numbers of users and videos.

Via its UI adapter, video query engine, and video manager components, the Candela server also provides rich video retrieval facilities. While MobiCon is a standalone mobile phone application, the video retrieval interfaces of the Candela platform are Web browser-based. Thus, we can apply Web user interface adaptation techniques to give users access to their video collections from a variety of user terminals and networks.

The UI adapter is implemented on top of an Apache Cocoon Web-development framework. Using XSLT stylesheets, it generates an adaptive video browsing and retrieval interface from an abstract XML-MPEG7 content, considering the capabilities of the user devices obtained from public UAProf repositories. For example, when using a PC Web browser, the adapter creates a complex HTML interface combining keyword queries, ontology-based video browsing, as well as the display and selection of query results into a multi-frame page. When using a mobile phone browser, the adapter splits the same interface into several HTML pages.

For performing video browsing and content-based retrieval, the UI adapter interacts with the video query engine, which supports the use of time, location, video creators, and keywords as query parameters. The video query engine translates these parameters into corresponding SQL statements run on the metadata database and returns a personalized ranked result list in MPEG-7 format, which the UI adapter then integrates into the user interface. The engine interacts with the ontology manager for personalized keyword expansion. For example, the search term "animal" will be expanded to all subconcepts of "animal," (e.g., "cat" and "dog") in querying user's personal ontology.

When a video clip is selected for viewing, the video manager takes care of its delivery. It selects the format and compression variant most appropriate to the client device and network, again exploiting the device capability profiles in the public UAProf repositories–especially the information about screen size, and the video manager supports HTTP-based download of a clip as well as streaming delivery via the Helix DNA streaming server.

MOBICON

MobiCon is a Java 2 Micro Edition/MIDP 2.0 application that runs on Symbian OS v8.0 camera phones with support of the Mobile Media, Wireless Messaging, and Bluetooth APIs. We now provide details on the video production and management tasks—video capture, annotation, upload, and sharing—combined by MobiCon.

Video Capture

When MobiCon is started for the first time, the user is authenticated by the Candela platform. Upon successful authentication, MobiCon receives the user's personal ontology from the ontology manager and stores it along with the user's credentials in the phone memory for future use making use of MIDP record management, as it is assumed that the user stays the same. MobiCon still permits re-authentication for a different user.

After successful login, users can start capturing clips. For this purpose, MobiCon accesses the video capture tool of the mobile phone via the Mobile Media API. The captured content is delivered in 3GP format, using AMR for audio encoding and H.263/QCIF at 15 frames per second and 174x144 pixels resolution for video encoding. MobiCon stores the captured video clip in the phone's memory. Users can view the

captured or another stored clip, capture another clip, or start annotating a stored clip as explained in the following.

Video Annotation

For the annotation of video clips, MobiCon provides automatic, context-based annotation suggestions as well as the option to manually annotate clips with concepts of personal home video ontologies or keywords. We now provide more details on the generation of context-based annotation suggestions and the use of personal ontologies for annotation.

Context-Based Annotation Suggestions

For the generation of appropriate annotation suggestions, MobiCon gathers context data that is available about the capture of a video clip on the mobile phone. In particular, MobiCon collects the username, capture time, and duration of the clip. Additionally, MobiCon is able to connect via the Bluetooth API to GPS receivers that support the NMEA protocol. If such a receiver is connected to the phone, MobiCon polls for the current GPS position and stores it along with a timestamp as a measure for its age. Given these context data, MobiCon invokes the annotation Web service running on the Candela server as a Java servlet via an HTTP request, opening a connection to the Internet via UMTS or GPRS if not yet established.

The reasons for outsourcing the derivation of annotation suggestions to a Web service are mainly ease of prototyping and deployment. We can incrementally add new methods for annotation suggestions to the Web service while keeping the MobiCon client unchanged, thus saving on update (re)distribution costs. Also, a Web service allows the reuse of the context-based annotation suggestion functionality on devices other than mobile phones.

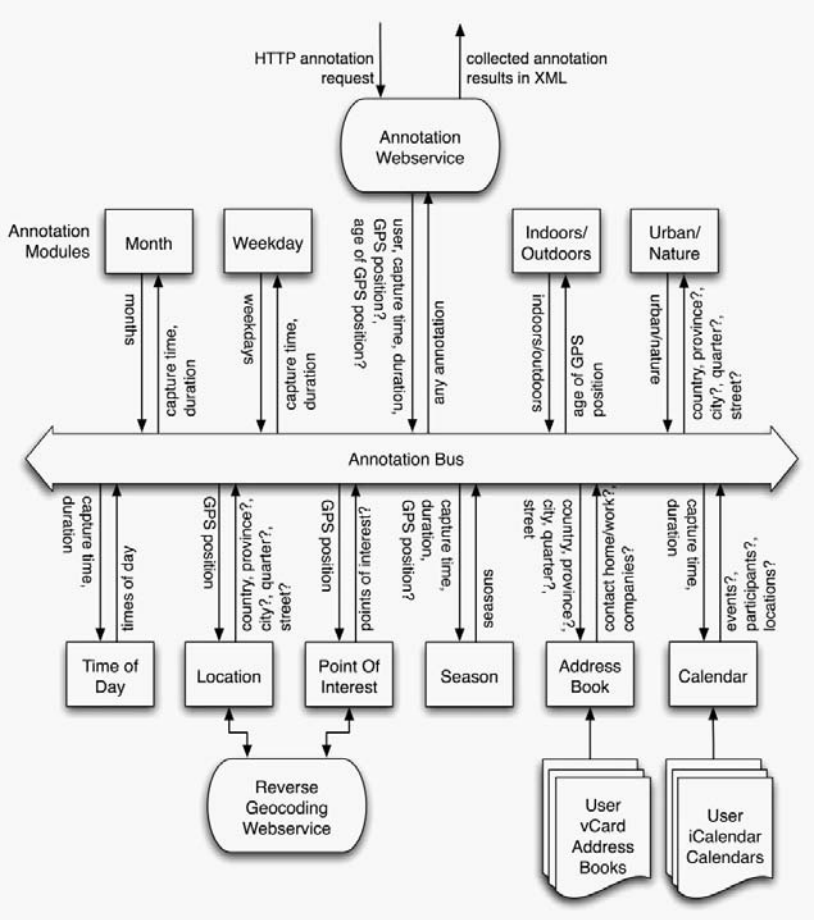
A drawback of this design is the costs incurred by remotely invoking a Web service from a mobile phone. But given the costs accrued anyway by uploading and sharing comparably high-volume video clips, these are negligible. A further problem is how to provide the Web service with access to personal user data for the generation of annotation suggestions, such as phone calendars or address books; passing the whole address book and calendar of a user as parameters to the Web service with each invocation is certainly not feasible. Leaving privacy issues aside, we circumvent this problem by allowing users to upload their calendars and address books to a central directory on the Candela server in iCalendar and vCard formats via a MobiCon menu option. From this directory, this data can be accessed from the Web service with user names as keys.

Figure 4 presents an overview of the design of the annotation Web service. When the Web service receives an annotation request, it publishes the context data carried by the request on the annotation bus. The annotation bus forms a publish/subscribe infrastructure for annotation modules that are in charge of actually deriving annotation suggestions. The annotation modules run concurrently in their own threads, minimizing response times and maximizing the utilization of the Web service's resources when processing multiple annotation requests.

The annotation modules listen to the bus for the data they need for their inferences, generate annotation suggestions once they have received all required data for a given annotation request, and publish their suggestions back to the bus, possibly triggering other annotation modules. The annotation Web service collects all suggestions published to the bus for a request, and, once no more suggestions will be generated, returns the results to MobiCon.

This results in a modular and extensible design: the annotation modules used for the generation of annotation suggestions can be selected to suit the needs of an individual application and new

Figure 4. Annotation Web service design



modules can be dynamically added to the system as they become available without having to reprogram or recompile the Web service.

Figure 4 also provides information about the annotation modules currently implemented, along with the types of data on which they base their inferences and the types of suggestions they publish. In the following, we highlight some of the more interesting ones:

The location and point of interest annotation modules suggest address and points of interests probably captured by the clip being annotated based on GPS position utilizing the commercial ViaMichelin reverse-geocoding Web service. The calendar annotation module searches the user calendar for events that overlap with the capture time, suggesting event names, locations, and participants as annotations. The address book annotation module searches the user address book for the home or work addresses of contacts or company addresses matching the address data derived by any other annotation module, suggesting them

as location annotations. The indoors/outdoors annotation module suggests whether a clip has been shot outdoors or indoors, utilizing the fact that GPS signals cannot be received indoors and thus the age of the GPS position will exceed a threshold in this case. Depending on the level of detail of address data derived by other modules, the urban/nature annotation module suggests whether a clip shows an urban environment or nature. If information about a city or street is missing, it suggests nature, otherwise an urban environment is assumed.

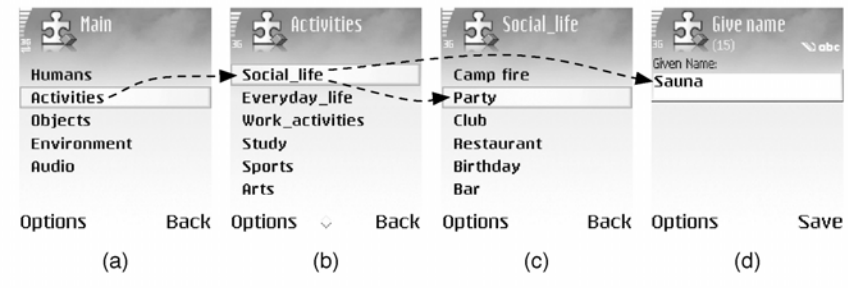
Ontology-Based Annotations

MobiCon permits an inexpensive manual annotation of content using hierarchically structured ontologies with concepts from the daily lives of users. Instead of having to awkwardly type such terms with the phone keyboard over and over again, users can simply select them by navigating through MobiCon's ontology annotation menu as illustrated in Figure 5 (a-c). Without imposing a single common ontology onto every user, MobiCon permits each user to have a personal ontology for home video annotation, merely predefining two upper levels of generic concepts that establish basic dimensions of video annotation (Screenshots (a) and (b) of Figure 5). Below these levels, users are free to define their own concepts, such as those depicted in Screenshot (c). MobiCon's user interface permits the entry of new concepts at any level at any time during the annotation process in Screenshot (d).

The rationale behind this approach is as follows: firstly, it allows users to optimize their ontologies for their individual annotation needs, so that they can reach the concepts important to them in few navigation steps and without having to scroll through many irrelevant concepts on a small phone display on the way. Our experiences from initial user trials indicate that precisely because users want to keep annotation efforts low, they are willing to invest some efforts into such optimization.

The concepts that are important for clip annotation differ very much between people: a person often enjoying and documenting sauna events might introduce "sauna" as a subconcept of "social life" to his or her ontology, whereas an outdoor person might need a subconcept "camp fire", and so on. Differences also occur in the hierarchical organization of concepts: users frequently visiting bars might consider the concept "bar" as a subconcept of "social life" (like in Screenshot (c)),

Figure 5. MobiCon ontology user interface



while a bar's owner might see it as a subconcept of "work activity."

Secondly, by imposing a common set of top-level concepts (used for representation of profiles of users' interests) onto the personal ontologies of the users, we establish a common foundation for the querying and browsing of video collections, making it easier to find interesting clips also in the collections of other users.

MobiCon receives the personal ontology of a user from the ontology manager in RDF format after successful authentication and caches it for successive use in the phone's memory.

Video Upload and Storage

After annotation, MobiCon gives the user an opportunity to upload the video clip and its annotations to his or her video collection on the Candela server via the upload gateway. As already explained, the video clip is handed over to the video manager which transcodes it to different formats at different bit rates in order to provide a scaleable service quality for different devices and network connections: Real Video, H.264, and H.263 encodings are used for delivering video content to mobile devices, as well as MPEG4 for desktop computers. In the future, scalable video codecs will remove the need of transcoding.

The clip metadata is represented in MPEG-7 format that mainly constitutes a profile of the video and video segment description schemes defined by the standard. Figure 6 gives a sample of this format. It incorporates context data about the clip's capture including the creator's name, GPS position, region and country, date and time of day, and length of the video clip, as well as the clip annotations embedded in free text annotation elements. This includes the suggestions generated by the annotation Web service, the concepts selected from the user's personal home video ontology, and the keywords manually provided by the user.

Video Sharing

Users can share uploaded clips with the contacts in their address book, defining usage restrictions according to the OMA DRM standard if desired. The standard offers three approaches to content protection: forward-lock, combined delivery, and separate delivery. Forward-lock thwarts the forwarding of content to a different device, while combined delivery allows one to impose further restrictions, such as a limited number of playbacks or a permissible time interval for playback. In both approaches, the protected content is embedded by the content provider in a DRM packet along with the specification of the usage restrictions. Under separate delivery, the restrictions and the content are delivered separately and integrated on the playback device.

MobiCon supports the protection of video clips via forward-lock and combined delivery. For reasons of implementation, usage complexity, and the requirements imposed onto client devices, we have chosen not to support separate delivery at this stage.

When the user has specified the desired usage restrictions for a clip being shared, MobiCon uses a secure connection to contact the video manager, which employs the Nokia Content Publishing Toolkit to put a copy of the video clip into a DRM packet with the specified restrictions. The video manager also creates a key pair for each recipient of the clip. One key of every pair remains with the DRM packet, while the other is returned to MobiCon.

Using the Wireless Messaging API, MobiCon then sends a text-message to each recipient containing URL-link with a key pointing to the DRM protected clip. When the recipient of the message selects the link, the phone establishes an HTTP connection to the video manager. Using the recipient's key, the video manager checks whether access to the DRM protected clip can be granted by pairing the key with the right clip. If a matching clip is found, a download descrip-

tor with basic information about the clip like creator, length, and description is returned to the recipient's mobile phone and the used key pair is removed, in order to prevent re-usage. After deciding to really download the packet, the user can finally watch the protected video clip, but only on the paired device and within the limits of the usage restrictions.

DISCUSSION

Having given a technical description of the MobiCon application for the combined production, context-aware annotation, and sharing of home video clips with mobile phones at the point of capture, we now provide a critical discussion and outline future developments.

The ways in which the annotation Web service can utilize temporal and spatial context data for the generation of annotation suggestions are not limited to those described in the previous section: weather or light conditions probably documented by a video can be obtained from meteorological databases given capture time and location (Naaman et al., 2004), annotations from other videos shot at the same time and place can be suggested using clustering methods (Davis et al., 2004; Pigeau & Gelgon, 2004), and much more. We want to support these uses for time and location context

data with MobiCon as well. For that purpose, we benefit from the extensible design of the annotation Web service, as it enables us to incrementally develop and integrate modules for these kinds of annotation suggestions without having to modify the MobiCon application itself.

Reasonable annotation suggestions cannot only be derived from context data, from content analysis, or a combination of both. We plan to integrate an audio classifier that is capable of identifying segments of speech, music, and different kinds of environmental noises within videos with high degree of reliability. The results of such an audio classification can be used to enhance our simplistic indoors/outdoors and urban/nature annotation modules, which so far are solely based on the age of the last available GPS position and the level of detail of the address returned by the reverse-geocoder for that position.

Integrating content analysis with the current centralized annotation Web service design is problematic. As an annotation module using content analysis methods needs access to the full video clip being annotated, the clip has to be uploaded to the Web service before any suggestions can be created. The incurring delay will hamper the capture and annotation process. Therefore, we want to distribute the annotation Web service, permitting annotation modules to run on the server and on the mobile phone. This will not only allow us to perform content analysis on the mobile phone avoiding upload delays; we will also be able to perform annotations based on sensitive personal data like address books and calendars directly on the phone, avoiding the privacy issues raised by moving such data to a central server as done currently.

Beyond improving the generation of annotation suggestions, MobiCon's user interface for annotating video clips on the basis of personal ontologies will also require some improvement. So far, users only have very limited means of modifying their ontologies in the middle of the video capture and annotation process, merely being able to add new subconcepts. Larger modifications must be performed outside of MobiCon using Candela's Web front-end. Moreover, MobiCon's DRM-based video sharing functionality is limited, allowing the sharing of clips only right after capture. We are currently investigating the integration of a user interface into MobiCon that allows users to share any clip existing in their collections.

Finally, we want to improve the video capturing and editing functionalities of MobiCon by integrating it with a mobile video editing application.

CONCLUSION

This chapter has introduced MobiCon, a video production tool for mobile camera phones that exploits specific characteristics of mobile phones— in particular the ability to run applications, the availability of context data, and access to the Internet from almost anywhere — to integrate traditionally separated home video production and management tasks at the point of video capture. MobiCon assists mobile phone users in capturing home video clips, uses context data after capture to suggest reasonable annotations via an extensible annotation Web service, supports personalized manual annotations with user-specific home video ontologies and keywords, uploads video clips to the users' video collections in Candela's central video database, and facilitates the controlled sharing of clips using OMA.

Initial experiences we have been able to gain so far from our personal use of MobiCon are encouraging. With MobiCon, the provision of useful annotations for home video clips is largely automatic and not overly intrusive to the general video capturing process, effectively resulting in the better organization of home video clips without much additional overhead. We are in the process of subjecting this personal experience towards a user study.

This work was done in the European ITEA project "Candela", funded by VTT Technical Research Centre of Finland and TEKES (National Technology Agency of Finland). Support of Finnish partners Solid Information Technology and Hantro Products is greatly acknowledged.

KEY TERMS

3GP Format: Mobile phone video file format produced by mobile phone video recording applications.

Annotation: Extra information or note associated with a particular object.

Candela: A two-year EUREKA/ITEA project researching content analysis, delivery, and architectures.

DRM: Digital rights management is a method for licensing and protecting digital media.

GPS (Global Positioning System): A global satellite-based navigation system.

Metadata: Metadata is the value-added information of data, for example, describing a content of picture, video, or document.

MIDP 2.0 (Mobile Information Device Profile Version 2.0): A Java runtime environment for mobile devices.

MPEG-7 (Multimedia Content Description Interface): MPEG-7 is an ISO/IEC standard developed by MPEG (Moving Picture Experts Group) to describe multimedia content.

OMA DRM (Open Mobile Alliance's Digital Rights Management): A standard developed by the OMA organization for the management of digital rights in mobile phones.

Ontology: A description of the concepts and relationships of objects in a formal way using a controlled vocabulary.

Chapter 3.28
From CCTV to Biometrics through Mobile Surveillance

Jason Gallo
Northwestern University, USA

INTRODUCTION

Surveillance is the act or process of observing, tracking, or recording personal details for the purpose of exercising control over the individual or population being watched. Control in this context can mean many things, from directly influencing the behavior of the observed to the use of gathered information for the purpose of management or governance.

Mobile surveillance can be defined as two distinct, yet related, practices. The first is the ability to observe the physical movement of an individual through space. This is most often accomplished through documenting their interaction with a surveillance network. The object of surveillance is tracked from one node of the network to another, providing a record of behavior. The second practice is often referred to as dataveillance, or the ability to monitor an individual's behavior through studying a trail of personally identifiable data, including credit card purchases, mobile phone calls, and health records.

Mobile surveillance employs an array of technologies including video and photography cameras, visual recognition software, radio frequency identification (RFID), global positioning receivers (GPS), information and communication technologies (ICTs), and biometrics. Examples of mobile surveillance networks include the dense deployment of closed-circuit television (CCTV), video, and photographic technologies in a distinct geographic space to monitor activity, the tracking of automobiles and mobile phones via GPS, and radio frequency sensing that records motion as identity chips pass through a distributed network of receivers. As these networks proliferate, individuals are the exposed to overlapping layers of surveillance. Although many of these surveillance networks are deployed for limited purposes, the increasing ability to save and store personally identifiable information in searchable databases, and the ability to mine information from multiple sources raises privacy concerns for the individual. This is especially true in advanced capitalist societies that rely on sophisticated data gathering

to track, model, and predict consumer behavior, as well as for citizen management.

BACKGROUND: SURVEILLANCE, BUREAUCRACY, AND THE STATE

Surveillance has been an integral part of human social interaction since the need for oversight and management of collective endeavors was first realized. As the scope and complexity of these endeavors grew, the need for more reliable information increased accordingly. Surveillance has long been an important method for dealing with risk (Lyon, 1994, 2002, 2003a, 2003b), as the advanced knowledge of aberrant behavior can help minimize the threat or upheaval caused by the unusual events or actions. Therefore, surveillance is often a positive feature of governance, allowing those in power to manage against risk in order to protect public welfare. Nevertheless, surveillance regimes are also employed by the state out of a "desire to more completely manage populations (Lyon, 2003b, p. 20)," identifying and sorting out individuals who's behavior is deemed threatening to the majority. It is of little surprise that the fields of law enforcement and national security and intelligence gathering are the sites of some of the most sophisticated surveillance practices as well as the targets of social concern over privacy and the power of the state.

In Discipline and Punish, Foucault (1977) examines the rise of the surveillance society by utilizing Jeremy Bentham's Panopticon prison as a model for the exercise of power in modern society. The architecture of the Panopticon exerts power over the incarcerated body by making it constantly visible to an invisible central observer. The prospect of persistent observation is used to ensure compliance with the disciplinary rules of the institution, therefore making the simple awareness of surveillance a means of exerting power over the watched individual.

Foucault (1977) notes the historic extension of surveillance architecture from the prison to other social institutions such as schools, hospitals, mental institutions, and the workplace, which increasingly relied on the specter of persistent observation in order to exert control over their subjects. In addition to the direct surveillance enabled by panoptic architecture, the rise of bureaucratic organizations, especially in the West, lead to an institutionalization of mechanisms for the capture, retention, and processing of personally identifiable data.

The direct and indirect surveillance employed by public libraries in Victorian Britain (Black, 2001) serves as a historical example of this phenomenon. Libraries have been at the forefront of efforts to manage, catalogue, and retrieve information since the sorting, and storing of information is central to their mission. To this end, libraries have employed increasingly sophisticated surveillance mechanisms to track, record, and monitor the habits of their users and their interaction with the library's collections. While the hierarchical systems of knowledge and the tracking of library users' habits employed in Victorian libraries did not necessarily originate as a means of coercive control but often as an effort to provide enhanced service, their existence often placed the librarian in a position of social power over those observed (Black, 2001, p. 74).

Surveillance is a central feature of the rational bureaucratic organization in modern society, and the explosion of surveillance is intertwined with the historical development and growth of bureaucratic organizations (Beniger, 1986; Dandeker, 1990; Foucault, 1977; Giddens, 1987; Lyon, 1994; Weber, 1968). Dandeker describes the symbiotic relationship between capitalist organizations and the modern state, declaring that their activities are focused on both the internal exigencies of managing a system of administrative control over subject populations and the problems attendant upon monitoring and managing external relations with other organizations. This theme has been central

in providing a framework in terms of which the growth of bureaucratic surveillance in modern societies can be explained. (p. 195)

In Control Revolution, Beniger (1986) writes that "bureaucratic organization serves as the generalized means to control all large social systems, tending to develop whenever collective activities need to be coordinated toward some explicit and impersonal goal, that is, to be controlled" (p. 390). As the complexity of operations required to control the functioning of a bureaucratic organization increases, so to does the need for advanced technologies to manage information throughput (Beniger, 1986, p. 424). Historically, bureaucratic organizations have utilized technological advances to exert control over the volume of information vital to the functioning of their operation, often to automate data gathering, record keeping, and record retrieval.

Dandeker (1990, p. 40) provides an excellent four point schema for evaluating the surveillance capacity of organizations. This model evaluates the size of the files held in a surveillance system, the centralization of those files, the speed of information flows, and the points of contact between the system and its subject population. The escalating use of automated surveillance technologies, sorting software, and searchable computer databases has lead to increases in all four of these areas and has greatly enhanced the surveillance capacity of organizations, making the practice of mobile surveillance possible. The ability of organizations to utilize information and computer technologies in order to search and cross-reference personally identifiable information from a variety of independently established databases has greatly expanded the scope of their surveillance, and has enabled the tracking of individual through digital data profiles compiled from records stored in computer databases.

MOBILE SURVEILLANCE

As social relationships have become more fluid and individual mobility increases, surveillance technologies have developed to keep up with the mobile subject. They are increasingly capable of tracking subjects on the move, and across various media, and through a variety of environments, casting a continual and inescapable gaze upon their subject (Lyon, 2003b). This is accomplished in a variety of ways. Perhaps the surveillance regime that most clearly illustrates the capabilities of mobile surveillance, and embodies the extension of Foucault's panopticism into society at large is CCTV. A CCTV system consists of a network of cameras that provide optical surveillance of a specific geographic area and transmits the visual data to a central location for analysis.

CCTV is most often employed by law enforcement in high-crime areas as a method for identifying criminal behavior, as well as a deterrent factor. Additionally, Norris and Armstrong (pp. 43-51) note the use of CCTV surveillance in residential areas, schools, banks, shops, workplaces, hospitals, schools, and train stations, as well as to regulate automobile traffic and police football stadia. The ubiquity of CCTV in Britain has lead to authors to conjecture that for a British urban dweller it is nearly impossible to move through public and, to some extent, private space without being photographed and recorded (Norris & Armstrong, 1999, p. 2). Increasingly these systems are being automated to work with face recognition software to look for "known" individuals and track their movement from camera to camera throughout the network.

While CCTV surveillance is directly concerned with the local observation of movement, the rise of dataveillance is critical for the observation of what Lyon refers to as "disappearing bodies" (Lyon, 2002). As transactions occur over longer distances, often with the aid of information and communication technologies, the physical body "disappears" and is replaced with personally

identifiable data that represents the individual (Gandy, 1993). Mechanisms such as security numbers, banking codes, and telephone numbers are recorded to provide a record of the interaction, which is often stored in computer databases. This information can be mined and analyzed by software using sophisticated algorithms to detect information patterns and assign a relative value to an individual, or what Gandy refers to as the "panoptic sort."

Automation through the employment of information and communications technologies and advances in surveillance hardware and software have expand the scope and speed of surveillance systems, enabling these systems to increasingly observe and record real-time activity and physical mobility at often exceptional distances. The growing reliance on information and communications technologies to conduct and coordinate surveillance has lead to the increasing importance of codes in the surveillance process (Lyon, 2003b). Codes are not only critical for the efficient operation of computerized systems, but they are also embedded with politics (Lessig, 1999). Programming establishes the rules that guide the functioning of computer codes, determining what information is stored and sorted, which individuals are tracked, and whose data-profile is flagged for review. To this end, the choices that are made during the programming and implementation of surveillance systems generate the set of laws that govern the operation of those systems.

In the wake of the September 11th attacks on New York and Washington, DC, the U.S. government has been on the forefront of bureaucratic uses of mobile surveillance technology and systems. Examples include the recently discontinued Terrorism Information Awareness (TIA) program (formerly Total Information Awareness) that was under development by the Defense Advanced Research Projects Agency (DARPA). The goal of the program was to preempt terrorist attacks by examining a variety of independently collected data sources in order to build comprehensive data profiles of potential terrorists. To accomplish this goal, DARPA was developing software that would have enabled intelligence officials to mine a virtual database that would consist of government, financial, education, medical and housing records from around the globe (Swartz, 2003, p. 6). Although the program was later abandoned, extensive data collection and data mining operations will almost certainly continue to be developed by national governments wishing to hedge against the risks inherent in an increasingly globalized world characterized by global flows of information, finance, and population (Castells, 1996).

FUTURE TRENDS

In Surveillance After September 11, David Lyon (2003a) provides us with three key issues that have emerged during the U.S.-lead "war on terror," namely suspicion, secrecy, and the mobilization of citizens as spies. He asserts that suspicion has been harnessed by local and national governments to broaden the scope of who may legitimately become a target of state-sponsored surveillance, while also being used to justify the secrecy of new or enhanced surveillance regimes under the rubric of "national security." Finally, the culture of suspicion that has arisen in the U.S. and to varying degrees in other societies around the world has increased acceptance for enhanced surveillance activities.

Mobile surveillance must be viewed through the prism of Lyon's three-part schema. If the culture of suspicion persists as a major motivating factor in bureaucratic implementation of enhanced surveillance capabilities, we can expect that new mobile surveillance technologies will be at the forefront of research, development and implementation, as they provide authorities with the ability to track and sort individuals and populations in real time. In the wake of the September 11 attacks, and the subsequent string of attacks around the globe including the bombings in Madrid and

Bali, a number of national governments have made upgrading their surveillance capabilities a priority. Additionally, technological advances will decrease the need for the human supervision of surveillance systems, creating a fully automated surveillance apparatus.

Three technologies in particular will enhance the surveillance capacity of the bureaucratic organization in the future: GPS, RFID, and biometrics. The inclusion of GPS receivers in mobile phones, often at lawmakers' request to provide assistance in locating missing individuals, allows for monitoring the precise location of the phone in real time, whether a call is being made or not. RFID tagging, a bonus for merchandisers keen to increase logistical efficiency, is also an ideal technology for bureaucratic management. It will likely become a permanent feature of future identification cards, as the miniaturized tags are capable of storing personally identifiable information and transmitting it wirelessly to strategically placed receivers in airports, and other access-restricted locales. Finally, biometrics, the practice of identifying an individual based on physiological characteristics, seems poised to be the next big field of personally identity. Coupled with optical surveillance, biometrics can be used to further automate CCTV systems, providing a reliable method for identifying individuals.

Serious questions must be asked about the architecture of current and future systems and the codes that govern them. Who is being tracked, how they are being tracked, and why they are being tracked are important design questions that will influence human outcomes. While it is hard to argue against the use of efficient systems that enable authorities to prevent a small handful of individuals from doing great harm to large number of innocent people, a balance must be struck between the rights of the individual and the safety of the majority. Many nations have a legal and legislative framework in place to wrestle with balancing these two responsibilities. However, the push for secrecy inspired by a climate of suspicion may be the single greatest variable to consider when examining the future of surveillance. A move toward greater state secrecy serves to obscure the existence and operation of the surveillance apparatus, limiting transparency, and diminishing the possibility of legislative and public oversight.

Looking forward, it is important to remember that technological development must be coupled with legislative action and social awareness. State sponsored surveillance that is designed to protect the public from harm should be at least minimally transparent and ideally subjected to oversight in order to protect against abuses. Technological advances in data gathering, sorting, storage, and retrieval, coupled with complimentary advances in computing and mobile ICTs will enhance the surveillance capacity of large organizations. They will be increasingly able to tap into vast stores of personally identifiable information from multiple sources through refined data-mining practices.

CONCLUSION

The regulatory framework in which these organizations operate will help determine which surveillance practices are available to the state and which are not. Legislative bodies will need to set guidelines that simultaneously encourage technological growth and positive uses of surveillance, while demanding state accountability and balancing the rights of the citizen and individual to privacy. Despite increasing globalization and surveillance regimes aimed at minimizing the risks that arise from global population flows, it is import to remember that concept of privacy and privacy regulations vary greatly from state to state. A patchwork of laws governs the surveillance of globally mobile bodies, as individuals pass borders and therefore into and out of the gaze of the state surveillance apparatus. Post-September 11th agreements between nations have lead to greater international security cooperation and informa-

tion sharing, subjecting the actions of citizens of one nation to the gaze of another. What right to privacy does the global citizen have from the government of a foreign nation, for whom he or she cannot vote?

The ability of the citizenry and legislatures in democratic nations to oppose, alter, and eliminate surveillance regimes should not be underestimated. Despite an intense "culture of suspicion" following the September 11, U.S. citizens and lawmakers were able to halt two of the more controversial government programs designed to enhance the nation's surveillance capacity. A key surveillance passage of the USA PATRIOT Act, which granted federal authorities almost unchecked power to collect personally identifiable data, was struck down as unconstitutional by the courts, and the Terrorist Information Awareness (TIA) program, which was attempting to build highly advanced data-mining software to cull vast amount data in order to build predictive models of terrorist behavior, had its funding denied by the Congressional committee charged with its oversight after intense public scrutiny. These two local successes do not signal a victory for transparency and oversight, but rather point to a possible trend of ad hoc coalitions formed to resist specific instances of particularly intrusive state surveillance.

KEY TERMS

Biometrics: Biometrics is the science and practice of verifying individual identity based on the analysis of unique physiological or behavioral characteristics. Examples include the analysis of fingerprints, retinas scanning, voice pattern analysis, facial patterns, and analysis of an individual's walking gait.

CCTV: Closed Circuit Television is a technological system of video surveillance that employs a closed network of cameras to provide a visual observation of a targeted area. CCTV has been used extensively in high crime areas not only as a means of fighting crime but also as a deterrent. The use of CCTV is increasingly being combined with face recognition software to create automated video surveillance networks that can operate with limited human interaction.

Data Mining: Data mining, also known as knowledge discovery in databases, is the practice of extracting targeted information from large databases through the use software technology utilizing algorithms to detect patters.

Face Recognition Software: A software package that is designed to identify individuals in crowds based on distinguishing facial characteristics. This software must be used in conjunction with visual surveillance systems such as CCTV. The facial characteristics of target individuals are loaded into computer systems that analyze the visual data captured by the visual surveillance apparatus and alter system users when a target individual is spotted.

GPS: Global positioning system is a satellite navigation system that is able to provide extremely accurate time and position data through the tracking of user-held receivers. The system was developed and maintained by the United States Department of Defense and is available free of charge to nonmilitary users. The system operates through transmissions between user-held and earthbound receivers to a network of satellites, whereby a receiver's exact location is determined through the process of trilateration and time is determined by the coordinated atomic clocks of the satellites.

Identity Documents: Identity documents take many forms from drivers licenses to passports to national identity cards. These cards are government issued documents that contain personally identifiable information often including a photograph, date of birth, place of residence, gender, physical characteristics such as height, weight, and eye and hair color, and include a unique identifier number specific to the card holder. Increasingly identity documents include personal information encoded in magnetic strips that can be read through the use of a scanner.

RFID: Radio frequency identification technology is a type of wireless automatic identification system that collects data and transmits it directly to a computer database using radio waves. A typical RFID system consists of a radio frequency tag that transmits identifiable data when in proximity of a reader that is then recorded to a database.

Hend Koubaa
Norwegian University of Science and Technology (NTNU), Norway

ABSTRACT

Accessing multimedia services from portable devices in nomadic environments is of increasing interest for mobile users. Service discovery mechanisms help mobile users freely and efficiently locating multimedia services they want. The chapter first provides an introduction to the topic service discovery and content location in mobile environments, including background and problems to be solved. Then, the chapter presents typical architectures and technologies of service discovery in infrastructure-based mobile environments, covering both emerging industry standards and advances in the research world. Their advantages and limitations, as well as open issues are discussed, too. Finally, the approaches for content location in mobile ad hoc networks are described in detail. The strengths and limitations of these approaches with regard to mobile multimedia services are analyzed.

INTRODUCTION

Recently, the advances in mobile networks and increased use of portable devices deeply influenced the development of multimedia services. Mobile multimedia services enable users to access multimedia services and contents from portable devices, such as laptops, PDAs, and even mobile phones, at anytime from anywhere. Various new applications, that would use multimedia services on portable devices from both the fixed network backbone and peer mobile devices in its proximity, are being developed, ranging from entertainment

and information services to business applications for M-Commerce, fleet management, and disaster management.

However, to make mobile multimedia services become an everyday reality, some kinds of service infrastructures have to be provided or enhanced, in order to let multimedia services and contents on the network be discovered and utilized, and simultaneously allow mobile users to search and request services according to their own needs, independently of the physical places they are visiting and the underlying host platforms they are using. Particularly, with the explosive growth of multimedia services available in the Internet, automatic service discovery is gaining more and more significance for mobile users. In this chapter we focus on the issue of discovering and locating multimedia services and contents in mobile environments. After outlining necessary background knowledge, we will take an insight into mobile multimedia service discovery. Major service discovery architectures and approaches in infrastructure-based networks and in mobile ad hoc networks will be investigated. We present also a detailed analysis of their strengths and limitations with regard to mobile multimedia services.

DISCOVERING MOBILE MULTIMEDIA SERVICES AND CONTENTS IN INFRASTRUCTURE-BASED ENVIRONMENTS

Overview

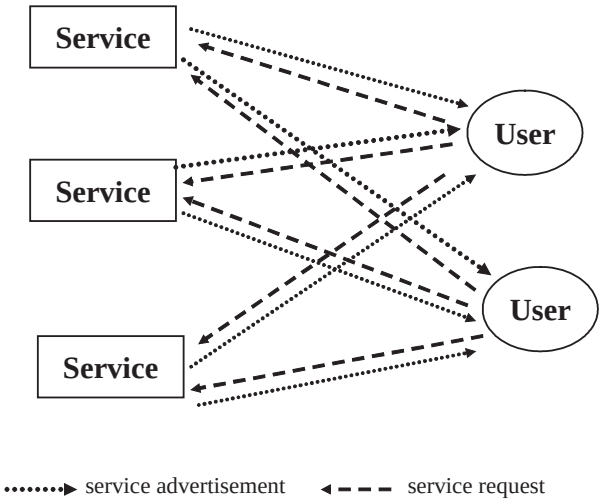
In order to use various multimedia services on the network, the first necessary step is to find the exact address of service providers that implement the service. In most cases, end users might only know what kind of service (service type) and some service characteristics (e.g., data format, cost) they want, but without having the server address. Currently, browsing is one often-used method to locate relevant information. As the number and diversities of services on the network grow, mobile users may be overwhelmed by the sheer volume of available information, particularly in an unacquainted environment. On the other side, user mobility presents new challenges for service access. Mobility means that users probably change their geographic locations frequently. Consequently, services available to users will appear or disappear dynamically while users move here and there. Moreover, mobile users are often interested in the services, (e.g., malls, restaurants) in the close proximity of his or her current place. Therefore, unlike classical distributed environments where location is often kept transparent, applications often need to dynamically obtain information that is relevant to their current location. The service search procedure should be customized according to user's context, (e.g., in terms of when (i.e., time) and where (i.e., location) a user is visiting).

Since most current multimedia services are designed for stationary environments, they do not address these issues. Recently, a number of service discovery solutions are developed. These solutions range from hardware-based technologies such as Bluetooth SDP, to single protocols, (e.g., SLP and SDS) to frameworks such as UPnP and Jini. From architectural point of view, we observed three models are used to discover services in different network environments (Wang, 2003): the broadcast model, the centralized service directory model, and the distributed service directories model. Next, we will investigate these paradigms in detail.

Broadcast Model

The simplest architecture for service discovery is using broadcast to locate services and contents. The conceptual scheme of the broadcast model

Figure 1. Broadcast model



is depicted in Figure 1. In this model, clients and servers talk directly with each other through broadcast or multicast.

According to who initiates the announcement and who listens, two strategies are differentiated. The first strategy is the *pull strategy* where a client announces his requests, while all servers keep listening to requests. The servers that match the search criteria will send responses (using either unicast or multicast) to the client. The other strategy is the *push strategy.* The servers advertise themselves periodically. Clients who are interested in certain types of services listen to the service advertisements, and extract the appropriate information from service advertisements. Of course, hybrid strategies are applied by some approaches.

The **simple service discovery protocol** (**SSDP**) is one typical approach based on the broadcast model (Goland, Cai, Leach, Gu, & Albright, 1999). The SSDP builds upon HTTP and UDP-multicasting protocols, and employs a hybrid structure combining client announcement and service announcement. When a device is newly added to the network, it multicasts an "ssdp:alive" message to advertise its presence. Similarly, when a client wants to discover services, it multicasts a discovery message and awaits responses.

The broadcast model works well in small simple networks, such as home and small office. The primary advantage of such systems is that they need "zero" or little configuration and administration. Besides, they accommodate well to frequent service join/leave actions in a dynamic environment. However, they usually generate heavy network traffic due to broadcast, and thus have only minimal scalability.

In order to improve scalability and performance, an additional entity, service directory, is introduced. Two different models use the service directory: the centralized service discovery model and the distributed service directories model. Both models will be presented in the following sections.

Centralized Service Directory Model

The conceptual scheme of the centralized directory model is shown in Figure 2. The service directory becomes the key component in the search discovery architecture, because it stores information about all available services.

The service discovery procedure consists usually of the following steps:

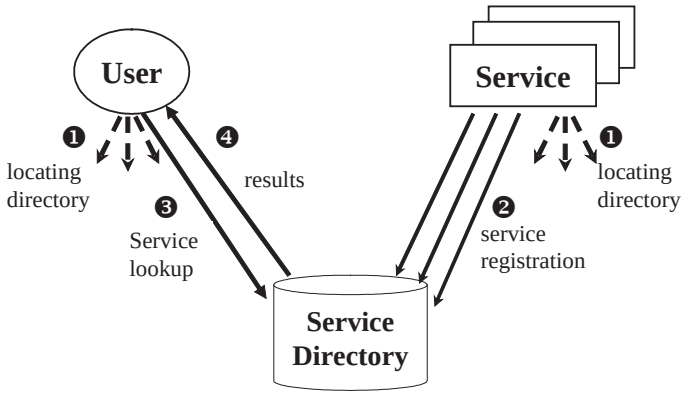
1. **Locating directory:** Either clients or servers should determine the address of the service directory before they utilize or advertise services. The directory could be located by manual configuration, by querying a well-known server, or through broadcast/multicast requests/replies.
2. **Service registration:** Before a service can be found by clients, it must be registered in the appropriate directory. A service provider explicitly initiates a registration request to the directory, and the directory stores the service data in its database. The service description data include service type, service attributes, server address, etc.
3. **Service lookup:** As a client searches for a particular service, he describes his requirements, e.g. service type and desired characteristics, in a query request, and sends it to the directory.
4. **Searching:** The directory searches services in its database according to the criteria provided by the client. When services are found, the server addresses and other information of qualified services are sent back to the client.

The centralized directory model has been used by several service discovery approaches. In this section we will examine some of them.

Service Location Protocol (SLP)

The service location protocol (SLP) is an example of centralized directory-based solution, and is now an IETF standard (Guttman, Perkins, Veizades, & Day, 1999). The current version is SLP Version 2 (SLPv2). The SLP uses DHCP options, or UDP-based multicasting to locate the service directory (known as directory agent (DA)), without manual

Figure 2. Centralized directory model



configuration on individual clients and services (known as user agents (UAs), service agents (SAs) respectively). A multicast convergence algorithm is adopted in SLP to enhance multicast reliability.

Service registration and lookup are performed through UDP-based unicast communication between UAs/SAs and DAs. In addition, SLP can operate without DAs. In this mode, SLP works in the same way as the broadcast model. A service in SLP is described with service type in the form of a character string, the version, the URL as server address, and a set of attribute definitions in the form of key-value pairs.

To improve performance and scalability, more DAs can be deployed in network. However, SLPv2 does not provide any synchronization mechanisms to keep DAs consistent, but leaves this responsibility to SAs which should register with each DA they detect. Recently, (Zhao & Guttman, 2000) proposed a mesh enhancement for DAs to share known services between one another. Each SA needs to register only with a single DA, and its registration is automatically propagated among DAs.

Generally, SLP is a flexible IP-based service discovery protocol which can operate in networks ranging from a single LAN to an enterprise network. However, it is intended to function within networks under cooperative administrative control, and thus does not scale for the Internet.

JINI

Sun's JINI provides a similar architecture as SLP for delivering services in a network (Sun Microsystems Inc., 2003), but it is tightly bound to the Java environment and needs Java Virtual Machine (JVM) support. The protocols in JINI are implemented as Java APIs. For this reason, the JINI client is not as lightweight as the SLP client. However, JINI is more than a discovery protocol. It provides further facilities for service invocation, for transaction, and for distributed events.

INS

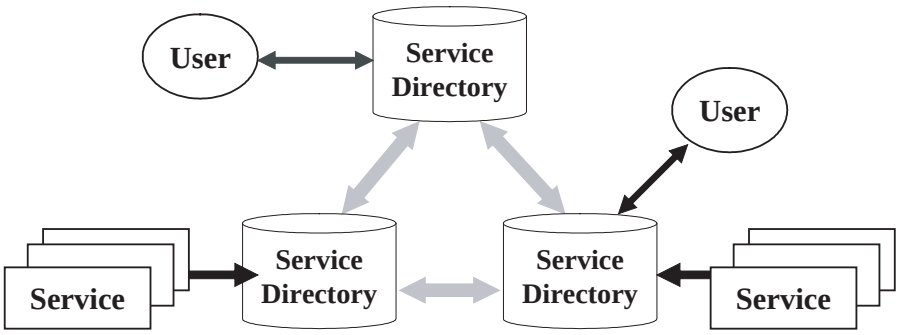
Adjie-Winoto, Schwartz, Balakrishnan, and Lilley, (1999) proposes a resource discovery system named *intentional naming system* (INS). The main idea is that resources or services are named using an ordered list of attribute-value pairs. Since service characteristics can be described by the service name itself, the service discovery procedure is equal to name resolving which is accompanied by the *intentional name resolver* (INR). The INR is actually a service directory that holds the global knowledge about names in the whole network. INS is different from other naming services (e.g., DNS), in that the name describes service attributes and values, rather than simple network locations of objects.

In conclusion, most centralized directory-based architectures have been designed for local networks or enterprise-wide networks which are under a common administration. The primary issue for these systems is scalability. As the number of services and clients increases, a centralized directory, even replicated, will not be feasible to accommodate a large number of registrations and lookups. In this context, the distributed repositories model has been suggested.

Distributed Service Directories Model

In the distributed directories model, the whole service domain is split into partitions, possibly according to organizational boundary, network topology, geographic locations etc. In each partition, there are one or more directories. The conceptual scheme of the distributed directories model is shown in Figure 3. The distributed directories model is different from the centralized directory model in that no directory has a complete global view of services available in the entire domain. Each directory holds only a collection of services in its partition, and is responsible for interaction with clients and services in the partition.

Figure 3. Distributed directories model



The service registration and query submission in the distributed model remain similar to that in the centralized directory model. But the service search operation becomes more complicated. If required services can be found by local directories, the discovery procedure is akin to that in the centralized directory model. But if not, the directories in other partitions should be asked, to ensure that a client can discover any service offers in the entire domain.

The directories in this model are organized in some way to achieve cooperation. As stated in (Wang, 2003), the directories can be organized in a hierarchy structure or in a mesh structure. While in the hierarchy structure there is a "belong to" relationship between directly connected directories, directories in the mesh architecture are organized in a flat interconnected form without hierarchy. The interconnection structure might have strong implications on query routing. In the hierarchy structure queries are passed along the hierarchy, either upward or downward, thus the routing path is inherently loop free. But the rigid hierarchy obstructs to shortcut the routing path in some cases. On the other hand, the mesh structure is advantageous for optimizing the routing path, but might rely on some mechanisms to avoid loop circles or repeated queries.

A typical example of distributed directories-based architecture is **service discovery service (SDS)**, developed in Berkeley (Hodes, Czerwinski, Zhao, Joseph, & Katz, 2002). The SDS is based on the hierarchy model which is maintained by periodic "heartbeat" messages between parent and child nodes. Each SDS server pushes service announcements to its parent. By this means, each SDS server gathers a complete view of all services present in its underlying tree. The significant feature of SDS is the hierarchical structure with lossy aggregation to achieve better scalability and reachability. The SDS server applies multiple hash functions (e.g., MD5), to various subsets of tags in the service description and uses the results to set bits in a fixed-size bit vector. The parent node ORs all bit vectors from its children to summarize available services in the underlying tree.

The hierarchical structure with lossy aggregation helps SDS to reach better scalability, while ensuring users to be able to discover all services on all servers. However, the SDS is more favorable

for applying in stationary network environments since it requires additional overheads to maintain the hierarchical structure and to propagate index updates. If services change attributes rapidly or join/leave frequently, it will generate too much communication burden. Moreover, the OR-operation during aggregation may cause "false positive" answers in query routing. Although it does not sacrifice correctness, it will lead to unneeded additional query forwarding.

The media gateway discovery protocol (MEGADIP) is developed especially for discovering media gateways that act as proxy for transforming or caching data between media source and end users (Xu, Nahrstedt, & Wichadakul, 2000). In MEGADIP the discovery procedure starts from the local directory, and forwards the query to directories along the routing path of the network layer between media source and destination. This idea is driven by the heuristics that a media gateway on or close to the end-to-end path is likely to find more bandwidth and/or to incur smaller end-to-end delay.

Other Issues in Service Discovery

The architectural models and various approaches presented above solved the service discovery problem to some extent. However, in order to let users comfortably and effectively locate mobile multimedia services and contents, there are still some issues to be addressed. From our point of view, interoperability, asynchronous service discovery, and semantic service discovery are the most important.

Interoperability

As previously stated, a number of service discovery approaches have been proposed. Despite that most of them provide similar functionality, namely automatically discovering services based on service characteristics, they have different features and are not compatible with each other. This incompatibility is one of the biggest obstacles for mobile users to really benefit from service discovery. From our point of view, it is more useful to make different approaches interoperable, than to design a new protocol to cover functionalities of existing protocols. So far, some solutions have been proposed to bridge service discovery mechanisms, but they are limited to pair-wise bridges, such as JINI to SLP (Guttman & Kempf, 1999). Authors in Friday, Davies, and Catterall (2001) proposed a general solution on a modified form of the Structured Query Language (SQL). However, no implementation details are presented in the paper. More generally, Wang and Seitz (2002) addressed this issue by providing an intermediary layer between mobile users and underlying service discovery protocols. The intermediary layer on the one hand provides clients with a general consistent view of service configuration and a universal means to formulate search requests, on the other hand is capable of talking with various types of service discovery protocols and handling service requests from users.

Asynchronous Service Discovery

Apart from the heterogeneous environments, most of the existing approaches rarely take the issues of thin client and poor wireless link into consideration. For example, synchronous operation is one of the intrinsic natures of most existing service discovery approaches, such as SLP, Jini, and SDS. Although synchronous operation simplifies protocol and application design, it is fastidious for mobile environments. The unexpected but frequent disconnections and possible long delay of wireless link greatly influence the usefulness and efficiency of synchronous calls. To relax the communication restrains in wireless environments, (Wang & Seitz, 2002) proposed in their CHAPLET system an approach to achieve asynchronous service discovery by adopting mo-

bile agents. The asynchronous service discovery allows mobile users to submit a service request, without having to wait for results, nor continuously keeping the permanently active connection in the process of service discovery.

Semantic Service Discovery

Most existing service discovery approaches support only syntactic-level searching (i.e., based on attribute comparison and exact value matching). However, it is often insufficient to represent a broad range of multimedia services in real world, and lacks of capability to apply inexact matching rules. Therefore, there is need to discover services in a semantic manner. Chakraborty, Perich, Avancha, and Joshi (2001) proposes in the DReggie project to use the features of DAML to reason about the capabilities and functionality of different services. They designed a DAML-based language to describe service functionality and capability, enhanced the Jini Lookup Service to enable semantic matching process, and provided a reasoning engine based on Prolog. Yang (2001) presents a centralized directory-based framework for semantic service discovery. However, the semantic-based service discovery is still in its infancy. To promote wide development of semantic service discovery, more research efforts should be devoted.

DISCOVERING MULTIMEDIA SERVICES AND CONTENTS IN AD HOC ENVIRONMENTS

Overview

There are two well-known basic variants of mobile communication networks: infrastructure-based networks and ad hoc networks. Mobility support described in the previous sections relies on the existence of some infrastructure. A mobile node in the infrastructure-based networks communicates with other nodes through the access points which act as bridge to other mobile nodes or wired networks. Normally, there is no direct communication between mobile nodes. Compared to infrastructure-based networks, ad hoc networks do not need any infrastructure to work. Nodes in ad hoc networks can communicate if they can reach each other directly or if intermediate nodes can forward the message. In recent years, mobile ad hoc networks are gaining more and more interest both in research and industry. In this section we will present some typical approaches that enable discover and locate mobile multimedia services and contents in ad hoc environments. First we present broadcast-based approaches, and then the geographic service location approach is discussed. Next, a cluster-based approach is introduced. Finally, we present a new service or content location solution that addresses the scalability problem in multi-hop ad hoc networks.

Broadcast-Based Approaches

Considering the fact that no infrastructure is available in ad hoc environments, service directory-based solutions are unusable for service discovery in ad hoc networks. Instead, assuming that network supports broadcasting, service discovery through broadcast is one of most widely adopted solutions. Two broadcast-based approaches are possible: (1) broadcasting client requests and (2) broadcasting service announcements. In the first approach, clients broadcast their requests to all the nodes in the ad hoc network. Servers hosting requested services reply back to the clients. In the second approach, servers broadcast their services to all the nodes in the network. Each client is thus informed about the location of every service in the ad hoc network. Since these both approaches are mainly based on broadcasting, their efficiency strongly depends on the broadcast efficiency. The service location problem in that context can be reduced to the broadcast problem in ad hoc networks. For this

reason, in the following, we present a summary of proposed approaches for broadcasting in ad hoc networks. These broadcast approaches are not designed specifically for service location but we believe that a broadcast-based service location protocol has to be informed about how broadcast is carried out. This will help in deploying a cross layer-based service location protocol.

The broadcast techniques can be categorized into four families: Williams and Camp (2002), simple flooding, Jetcheva, Hu, Maltz, and Johnson (2001), probabilistic broadcast, Tseng, Ni, Chen, and Sheu (1999), location-based broadcast, and neighbor information broadcast, Lim and Kim (2000) and Peng and Lu (2000). Flooding represents a simple mechanism that can be deployed in mobile ad hoc networks. Using flooding, a node having a packet to be broadcasted sends this packet to his neighbors who have to retransmit it to their own neighbors. Every node receiving the packet for the first time has to retransmit it. To reduce the number of transmissions used in broadcasting, other broadcast approaches are proposed. The probabilistic broadcast is similar to flooding except that nodes have to retransmit the broadcast packet with a predetermined probability. Randomly choosing the nodes that have to retransmit can improve the bandwidth use without influencing the reachability. In the case of location-based broadcast techniques, a node x retransmits the broadcast packet received from a node y only if the distance between x and y exceeds a specific threshold.

The information on the neighborhood can also be used to minimize the number of nodes participating in the broadcast packet retransmission. Lim and Kim (2000) uses the information about the one hop neighborhoods. Node A, receiving a broadcast packet from node B, compares its neighbors to those of B. It retransmits the broadcast packet only if there are new neighbors that will be covered and that will receive the broadcast packet. Other broadcast protocols are based on the 2 hop neighborhood information. The protocol used in Peng and Lu (2000) is similar to the one proposed in Lim and Kim (2000). The difference is that in Lim and Kim (2000) the neighborhood information is sent within HELLO packets, whereas in Peng and Lu (2000), the neighborhood information is enclosed within the broadcast packet.

The study carried out in Williams and Camp (2002) showed that the probabilistic and location broadcast protocols are not scalable in terms of the number of broadcast packet retransmissions. The neighborhood-based broadcast techniques perform better by minimizing the number of nodes participating to the broadcast packet retransmission. The most significant disadvantage of these protocols is that they are sensitive to mobility.

Geographic Service Location Approaches

A more interesting service location approach than broadcasting the whole network is to restrict broadcasting to certain regions. These regions can be delimited on the basis of predefined trajectories. In fact, recently, geometric trajectories are proposed to be used for routing (Nath & Niculeson, 2003) and content location in location-aware ad hoc networks (Aydin & Shen, 2002; Tchakarov & Vaidya, 2004). Aydin and Shen (2002) and Tchakarov and Vaidya (2004) are closely related where content advertisements and queries are propagated along four geographical directions based on the physical location information of the nodes. At the intersection point of the advertising and query trajectories the queries will be resolved. Moreover, Tchakarov and Vaidya (2004) improves the performance by suppressing update messages from duplicate resources. However, basically they still rely on propagating advertisements and queries through the network.

Cluster-Based Solutions

Besides enhancements in broadcast, clustering can also be used to improve the performance of

service discovery in mobile ad hoc networks. An interesting cluster-based service location approach designed for ad hoc networks is proposed in Koubaa and Fleury (2001) and Koubaa (2003). The proposed approach involves four phases: (1) the servers providing services are organized within clusters by using a clustering protocol. The cluster-heads, elected on the basis of an election protocol, have the role of registering the addresses of the servers in their neighborhoods (clusters). (2) A reactive multicast structure gathering the cluster-heads to which participate the cluster-heads of the created clusters is formed at the application layer. Each client or a server in the network is either a part of this structure or one hop away from at least one of the multicast structure members. (3) Clients send their request inside this multicast structure. (4) An aggregation protocol is used to send the replies of the cluster-heads within the multicast structure. The aim of the aggregation protocol is to avoid using different unicast paths for reply transmission by using the shared paths of the multicast structure.

A study comparing broadcast approaches to the cluster-based approach is carried out in Koubaa and Fleury (2002). This comparison study showed that clustering reduces the overhead needed for clients to send their requests and for servers to send back their replies. This reduction is noticeable when we increase the number of clients, the number of servers, and the number of nodes in the ad hoc network. The multicast structure used in Koubaa (2003) consists of a mesh structure which is more robust than a tree structure. The density of the mesh structure is dynamically adapted to the number of clients using it. The key idea of this dynamic density mesh structure is that the maintaining of the mesh is restricted to some clients called effective clients. Indeed, when the network is dense or the number of clients is high there is no need that all clients participate the multicast structure maintaining. This new mesh structuring approach is compared to ODMRP (Koubaa, 2003) where all the multicast users participate in the mesh maintaining. The comparison study showed that the proposed dynamic density mesh is more efficient than ODMRP. Compared to the tree-based multicast structure, the mesh-based multicast structure shows better server reply reachability performance but using more bandwidth.

Scalability Issue in Service Location

Currently it is well known that ad hoc networks are not scalable due to their limited capacity. The scalability problem is mainly related to the specific characteristics of the radio medium limiting the effective ad hoc network capacity. Even though, we think that designing specific solutions for scalable networks can help us at defining how much scalable is an ad hoc network. In the context of service location, authors in Koubaa and Wang (2004) state the problem of scalable service location in ad hoc networks and propose a new solution inspired by peer-to-peer networks called HCLP (hybrid content location protocol). The main technical highlights in approaching this goal include: (1) the hash function for relating content to zone, (2) recursive network decomposition and recomposition, and (3) content dissemination and location-based on geographical properties.

The hashing technique is used in HCLP both for disseminating and locating contents. But unlike the approaches in peer-to-peer systems where the content is mapped to a unique node, the hash function in HCLP maps the content to a certain zone of the network. A zone means in HCLP a certain geographical area in the network. The first reason for mapping content into zone, i.e. a subset of nodes, instead of an individual node, is mainly due to the fact that it could be expensive in radio mobile environments to maintain a predefined rigid structure between nodes for routing advertisements and queries. For example, in Stoica, Morris, Karger, Kaashoek, and Balakrishnan (2001), each joining and leaving of nodes has to lead to an adjustment of the Chord ring. More-

over, the fact that the routing in ad hoc networks is far less efficient and less robust than in fixed networks makes the adjustments more costly if there is node movement. The second reason for relating content to zone is that it is more robust to host a content within many nodes inside a zone than to host it within an individual node.

The underlying idea of network decomposition in HCLP is to achieve load distribution by maintaining the zone structure. It is well known that if the number of the nodes and contents in an unstructured and decentralized zone is beyond a certain limit, the network overhead related to content advertisement/location would become unsatisfactory. Therefore, to ensure a favorable performance and to achieve a better load distribution in HCLP, a zone could be divided into sub-zones recursively if the cost related to content advertisement/location using unstructured approaches in the zone exceeds a certain threshold.

To enable network decomposition in different zones a protocol is deployed to make it possible to nodes on the perimeter of the network exchanging their geographical locations. This will help estimating the position of the centre of the network. Knowing the locations of the nodes on the perimeter and the location of the network centre, a simple decomposition of the network into four zones is used. Each of these zones can also be decomposed again into four zones, etc.

In HCLP, for disseminating or locating a content in the network, a user first sends out its announcement or query request along one of four geographical directions (north, south, east, and west) based on geographic routing. In a dense network, the announcement or the request will then be caught on the routing path by a node that knows the central region of the network, in the worst case by a perimeter node on the network boundary. This node will then redirect the request into the direction of the central region, again by geographic routing. The node that belongs to the central region and receives this query message has the responsibility to decide whether to resolve the request directly within the zone or whether to redirect the request to the next level of the zone hierarchy, until the content is discovered.

Such a content dissemination and location scheme works completely decentralized. Moreover, only a small portion of nodes is involved in routing and resolving advertisement or query messages. Because not all nodes are necessary for maintaining routing information nor a global knowledge of the whole network is required, HCLP can be expected to be well scalable to large ad hoc networks.

CONCLUSION

The prevalence of portable devices and wide deployment of easily accessible mobile networks promote the usage of mobile multimedia services. In order to facilitate effectively and efficiently discovering desirable mobile multimedia services and contents, many research efforts have been done. In this chapter, we discussed existing and ongoing research work in the service discovery field both for infrastructure-based mobile networks and mobile ad hoc networks. We introduced three main architectural models and related approaches for service discovery in infrastructure networks, and pointed out some emerging trends. For discovering services and contents in ad hoc networks, we presented and compared proposed approaches based on either broadcast or cluster, and discussed the scalability issue in detail. We believe that service discovery will play an important role for successful development and deployment of mobile multimedia services.

KEY TERMS

Aggregation: A process of grouping distinct data. Two different packets containing different data can be aggregated into a single packet holding the aggregated data.

Broadcast: A communication method that sends a packet to all other connected nodes on the network. With broadcast, data comes from one source and goes to all other connected sources at the same time.

Clustering: Identifying a subset of nodes within the network and vest them with the responsibility of being a cluster-head of certain nodes in their proximity.

Hash: Computing an address to look for an item by applying a mathematical function to a key for that item.

Mobile Ad Hoc Network: A kind of self-configuring mobile network connected by wireless links where stations or devices communicate directly and not via an access point. The nodes are free to move randomly and organize themselves arbitrarily, thus, the network's topology may change rapidly and unpredictably.

Multicast: A communication method that sends a packet to a specific group of hosts. With multicast, a message is sent to multiple destinations simultaneously using the most efficient strategy that delivers the messages over each link of the network only once and only creates copies when the links to the destinations split.

Scalability: The ability to expand a computing solution to support large numbers of components without impacting performance.

Service: An abstraction function unit with clearly defined interfaces that performs a specific functionality. Users, applications, or other services can use the service functionality through well-known service interfaces without having to know how it is implemented.

Service Directory: An entity in service discovery architecture that collects and stores information about a set of services within a certain scope, which is used for searching and/or comparing services during the service discovery procedure. Service directory is also known as service repository or directory agent. Service directory can be organized in central or distributed manner.

Service Discovery: The activity to automatically find out servers in the network based on the given service type and service attributes. The service discovery is, therefore, a mapping from service type and attributes to the set of servers.

Chapter 3.30
DRM Technology for Mobile Multimedia

Sai Ho Kwok
California State University, Long Beach, USA

INTRODUCTION

Mobile multimedia has been promoted as a promising service and application in mobile e-commerce (m-commerce) by many mobile operators and mobile service providers, when high-speed mobile networks are expected to take off in the near future. However, at present, mobile multimedia is still in its infancy, accessed by relatively low-end mobile devices with limited bandwidth and resources. A typical example is Orange in Hong Kong which launched a low-grade multimedia service in 2000 to test the market with current mobile technologies. Due to the physical constraints of a 2.5G mobile network, audio broadcast is the best service that the network can offer up to date. However, in the near future, when advanced mobile networks and technologies become available, higher demands will be placed on the quality of mobile multimedia services. Such services support both audio and video data, for example, video conferencing, music video, video-on-demand and so on. Rights management deserves more serious concern because intellectual property of distributed multimedia content is as valuable as a company's physical assets (Doherty, 2002). This will become even more important when mobile multimedia services become marketable and an essential part of the business. The purpose of a digital rights management (DRM) system is to allow owners of digital assets (movies, songs) to distribute their products/services/contents electronically in a controlled way (Peinado, 2002). DRM technology makes various online payment schemes possible, such as pay-per-view, pay-per-download, pay-per-game and so on. Hence, mobile service providers are able to control end users' use of, and accessibility to, their products, and stand to gain huge profits from this capability with the DRM technology (Foroughi, Albin, & Gillard, 2002). A successful DRM system should address both business and technical issues (Grab, 2002), but this chapter only addresses and presents issues in the technical side due to the nature of this book. We present some critical issues of mobile DRM for mobile multimedia. A proposal of mobile DRM framework is presented to meet the urgent DRM needs with the existing 2.5G

mobile technology. This chapter is concluded by presenting future directions of mobile DRM for mobile multimedia.

BACKGROUND

Internet Commerce

In the Internet domain, Vidius Incorporated estimates 450,000 to 580,000 downloads of unprotected full-length films are transferred over the Internet daily (Grab, 2002). Protection of distributed multimedia has been a growing concern to creators, distributors, copyright owners, publishers, and governments. DRM is considered to be one of the desirable solutions to this problem, and it can protect distributed media contents delivered over the Internet.

Several international standard organizations have been developing DRM solutions for various distributed multimedia, for example, digital music and video. The Secure Digital Music Initiative (SDMI) (SDMI, 2003), backed by the Recording Industry Association of America (RIAA) and 200 music and technology companies (as of October 2003), has been proposed to provide a secure environment for music distribution over the Internet. Another standard being developed by the Moving Picture Experts Group (MPEG) is known as MPEG-21 (Bormans & Hill, 2002) dedicated to distributing digital multimedia content. MPEG-21 defines an interoperable framework for Intellectual Property Management and Protection (IPMP). The IPMP can be interoperable with other MPEG standards, for example, MPEG-4. Therefore, the property protection will be also applicable to most of the MPEG video standards in the future. In addition, there are commercial DRM systems especially for the wired Internet business. They include Windows Media Rights Manager by Microsoft, and MetaTrust by InterTrust Technologies (InterTrust, 2000).

The above DRM standards and systems can be classified into two groups, namely, cryptographic-based and watermark-based DRM solutions (Kwok, 2003). Cryptographic systems permit only valid key-holders to access the encrypted data after receiving it from the authenticated senders. However, once such data is decrypted, it is impossible to track its reproduction or retransmission. Therefore, cryptography only provides protection during data transmission. Digital watermarking technology seems to complement the cryptographic process and to protect copyright ownership (Kwok, 2002). Digital watermarks can be visible but they are preferably invisible identification codes that are permanently embedded in the data and present within the data after any decryption process (Doherty, 2002).

In order to manage digital rights effectively and efficiently, many commercial DRM solutions employ license management models (Kwok & Lui, 2002). A license management model consists of a digital license that keeps access and control rights. Corresponding rights enforcement DRM applications determine usage rights based on these digital licenses.

Mobile Commerce

The current 2.5G mobile technologies for mobile multimedia service are fundamentally different from those used for Internet commerce service, and they impose many limitations and constrains upon the sophistication of mobile multimedia service. This explains why existing DRM systems for Internet commerce cannot be applicable to DRM over the mobile environment in a straightforward way. Some of the most important technical and physical obstacles are summarized as follows:

1. *License management:* A mobile device usually has limited resources of both memory and processing power to handle and process license documents and rights-protected contents.

2. *Limited storage and processing power:* Due to the limited resources of the mobile device, it is not possible to download rights-protected contents to the mobile device and play it there.
3. *Rights insertion:* A sophisticated consumer's ID cannot be kept on the consumer's device due to the storage limitation, and it must be provided by another party or uploaded for rights insertion.
4. *Rights enforcement:* An active rights enforcement cannot take place at the mobile device because the device is not capable of intensive computation.
5. *Payment:* Mobile devices cannot support the elaborate computations required for the encryption and de-encryption process of electronic payment, and mobile networks may not be adequately secure to prevent the exposure of personal and credit card information.

CRITICAL ISSUES OF DRM FOR MOBILE MULTIMEDIA

For mobile multimedia, DRM involves specifying and associating rights with the distributed multimedia contents, placing controls on the content to enforce rights, enabling access checks, and tracking permissions usage and payment. For a general mobile service, the required capabilities include:

1. rights specification and rights label management;
2. rights authorization;
3. content protection, rights enforcement, and trusted rendering;
4. rights tracking; and
5. a security and commerce infrastructure.

Business transactions, such as payment, ordering, customer enquiry, and so forth, may occur between the concerned parties during content packaging, distribution, and usage. Managing rights in all these transactions is necessary. To support DRM operations in mobile multimedia, a DRM system needs to perform rights insertion and rights enforcement operations. In addition, a license management mechanism is also needed in managing license documents. A DRM solution for mobile multimedia should possess features stated in Table 1.

There are still many un-resolved technical problems and issues to be addressed before a successful DRM system for mobile multimedia can emerge. Some existing problems and issues are listed in Table 2.

Table 1. Summary of features of DRM solutions

• Media right protection and management
• Secure delivery and distribution of digital contents
• Processing authorization, data authentication and verification for content service
• Data security, integrity check, access control, and management for distributed systems and peer-to-peer (P2P) networks
• Multimedia watermarking for copyright protection, media authentication and integrity checking, finger-printing, and data annotation

Table 2. Problems and issues for mobile DRM

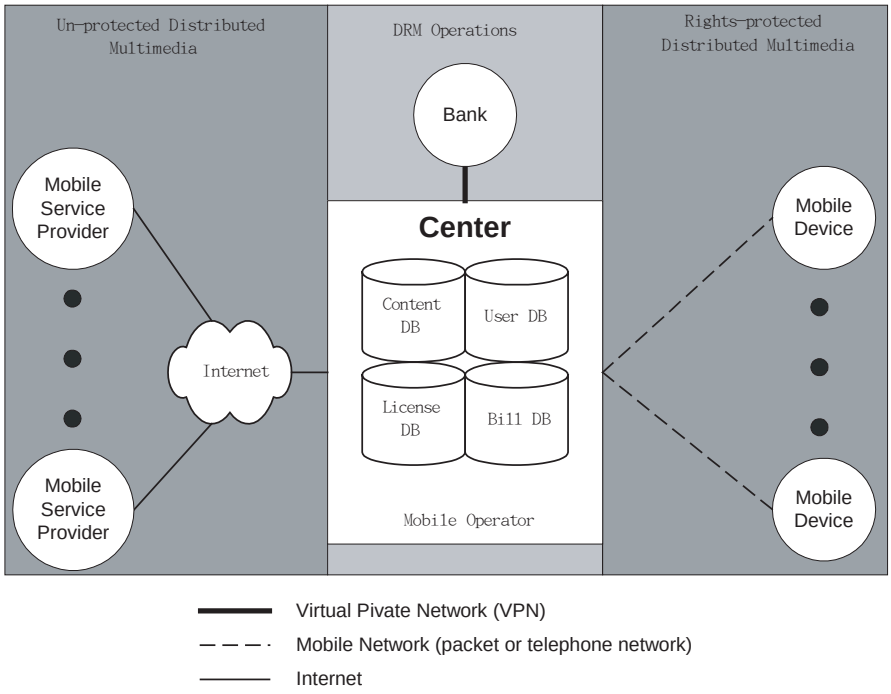
Mobile DRM standard: There is not yet a winner of mobile DRM standard. Open Mobile Alliance (OMA) DRM standard is one of the outstanding mobile DRM standards for mobile phones (Poropudas, 2003). However, other DRM standards, such as Windows Media DRM for Pocket PC (Microsoft, 2003), are highly competitive.
Trustful DRM protocol: Since DRM involves many parties, for example, technology service providers, mobile operators, service providers, creators, distributors and so forth, trust may not exist in all of these parties, for example, in a second-hand market. Hence, a trustful DRM protocol that can deal with DRM but without assuming mutual trust between involved parties is needed. A similar protocol was proposed by Cheung and Curreem (2002).
Robust and secure watermarking: A secure and robust watermarking algorithm is required to protect the distributed multimedia content. Such watermarking algorithm should resist attacks of any kinds. However, it cannot guarantee that a watermarking algorithm can resist all upcoming attacks (Tsang & Au, 2001).
Payment scheme: When trust does not exist, for example, in the second-hand market, a reliable payment scheme becomes an important issue.
Rights expression language: This is a need for a cross-platform rights expression language for all involved parties to specify and utilize their rights.

A MOBILE DRM FRAMEWORK FOR MOBILE MULTIMEDIA

This chapter proposes a mobile DRM framework for mobile multimedia, derived from Kwok (2002). The framework is a closed system that hosts all DRM operations within its center and provides a platform for mobile service providers to conduct business with their customers. Apart from rights insertion and enforcement operations, the center can handle transactions with a highly secure payment scheme. It is assumed that the central party is mutually trusted by both the businesses and consumers. A trustful center can be a mobile operator. The distributed multimedia contents between the center and the mobile users are rights-protected with a digital license and watermarking, while the multimedia contents transferring to the center do not require rights protection.

Figure 1 presents the mobile DRM framework for multimedia distribution in a mobile environment. The center of the framework is a mobile operator that manages information to and from mobile devices, mobile service providers and other concerned parties. The principal components include: (1) a mobile network infrastructure; (2) a DRM system; (3) a payment system; and (4) databases. There are three types of parties

Figure 1. DRM solution for mobile multimedia



involved in this framework: the mobile service providers (both official and unofficial sites), the bank, and the mobile users. The communication channels between different parties and the mobile operator are different from and independent of each other depending on the required security level. For example, a virtual private network (VPN) is used between the bank and the mobile operator, since highly confidential information is transferred through this channel, while the mobile operator relies on the packet network for multimedia content distribution, and the mobile service providers transfer multimedia contents to the mobile operator using the ordinary Internet.

The distinct features of the proposed framework include the following.

1. *DRM operation:* All DRM operations are performed by the center. It shifts all the processing and storage requirements to the center and relieves the burdens of the mobile devices and service providers.
2. *Independence of mobile devices:* The center can tailor the format of the distributed media for a specific mobile device. Besides, streaming technology is used in order to overcome the problems of processing power and storage requirement in the 2.5G mobile devices.
3. *Independence of mobile technology:* The framework can be applicable to 2.5G, 2.75G, 3G, 4G, and even higher because it does not depend on any specific mobile standard.

4. *Standardized rights expression language:* Since all DRM operations are managed by a single party—the mobile operator—the rights expression language can be standardized.
5. *Sharing and trading:* It facilitates media sharing and trading between users. Detail may be referred to Kwok (2002).
6. *Payment:* Transactions and payments are handled centrally through a secured channel.
7. *Ease of use and user satisfaction:* All DRM operations are completely transparent to mobile users and the mobile service providers.

FUTURE TRENDS

Mobile DRM for mobile multimedia is still at its infancy. The direction of mobile DRM is driven by the following factors.

1. *DRM standard:* One key player in mobile DRM standard, OMA mobile DRM has been proven successful in applying to music distribution. The standard is currently supported by some major labels, including Warner Music and BMG. However, the spectrum of mobile multimedia covers more than digital music, but also includes visual-audio data, such as movie, video conferencing, and so forth. It is still uncertain whether the market will accept OMA mobile DRM as the common standard for mobile multimedia.
2. *Mobile network:* Mobile multimedia demands a highly capable mobile network to support its services. An independent and constantly high transmission rate mobile network is the basic requirement for satisfactory mobile multimedia services. Unfortunately, the current mobile network, 2.5G or 2.75G, cannot provide a stable multimedia transmission. This problem will be overcome when 3G or 4G is launched.
3. *Mobile device:* The capabilities of mobile devices will be a major factor affecting the quality of mobile service. Pocket PCs usually perform better than smart phones when viewing mobile movie as their viewing screen and processing power are higher.

CONCLUSION

This chapter presents a mobile DRM framework for mobile multimedia. It is a practical and useful DRM framework when common mobile DRM standard and high bandwidth mobile channel are not available. This temporary but timely DRM solution could meet the urgent needs of DRM in mobile services. The primary objective of the framework is to impose DRM on mobile multimedia services without affecting the service providers and users. This is rather different from the emerging mobile DRM standards that require mobile users and service providers to adopt and apply their DRM technologies to mobile devices and distributed multimedia contents. However, privacy is the major problem of the proposed framework because the mobile operator possesses all of our transactions records. To respond to this problem, a possible solution may be encryption (Torrubia, Mora, & Marti, 2001) and an adapting system (Kenny & Korba, 2002).

KEY TERMS

Digital License: A digital license can be a separate file or message embedded in a media file. The license document states all of the terms and conditions concerning the use of the licensed media file. These terms and conditions can be static or dynamic depending on the payment scheme (Kwok, 2002).

Digital Rights Management (DRM): A set of technologies for content owners to protect their copyrights and stay in closer contact with their customers. In most instances, DRM is a system that encrypts digital media content and limits access to only those users who have acquired a proper license to play the content. That is, DRM is a technology that enables the secure distribution, promotion, and sale of digital media content on the Internet.

Identifiers and Metadata: Identifiers (unique labels for entities) and metadata (structured relationships between identified entities) are prerequisites for DRM. The essence of DRM is the control (licensing, etc.) of copies of entities; the identifiers and metadata are then essential to the management of this process, and to distinguishing and expressing relationships such as replicas and derivations (Paskin, 2003).

License Management: A mechanism to execute the terms and conditions stated in the license. This requires coordination among the media player, the media file, and other supporting modules; for example, the payment module. From the technical perspective, license management refers to issuing, hosting, and verifying the license (Kwok, 2002).

Rights Enforcement (or Verification): There are two types of rights enforcement: namely active enforcement and passive enforcement. The active enforcement takes place within the media player as a built-in function. The passive enforcement is an off-line ownership verification operation to check for the hidden owner identities (Kwok, 2002; Kwok, Cheung, Wong, Tsang, Lui & Tam, 2003; Kwok, Lui, Cheung, & Tam, 2003).

Rights Insertion: An operation to embed the identities of the concerned parties and assign business rules and conditions to the distributed multimedia content (Kwok, 2002; Kwok, Cheung, Wong, Tsang, Lui, & Tam, 2003; Kwok, Lui, Cheung, & Tam, 2003).

Watermarking: A technique for media authentication and forgery prevention. It is also viewed as an enabling technology to protect media from reuse without adequate credit or in an unauthorized way (Trowbridge, 2003). A watermarked media, *M'*, can be mathematically represented as $M'=M+W$ where M is the original media content and W is the embedded watermark. It is common that the extracted watermark, *W'*, could be different from the original watermark W because of the intentional or un-intentional attacks or post processing. To detect the watermark, a watermark detector is used to evaluate the similarity between W and W'.

Chapter 3.31
V-Card:
Mobile Multimedia for Mobile Marketing

Holger Nösekabel
University of Passau, Germany

Wolfgang Röckelein
EMPRISE Consulting Düseldorf, Germany

ABSTRACT

This chapter presents the use of mobile multimedia for marketing purposes. Using V-Card, a service to create personalized multimedia messages, as an example, the advantages of sponsored messaging are illustrated. Benefits of employing multimedia technologies, such as mobile video streaming, include an increased perceived value of the message and the opportunity for companies to enhance their product presentation. Topics of discussion include related projects, as marketing campaigns utilizing SMS and MMS are becoming more popular, the technical infrastructure of the V-card system, and an outline of social and legal issues emerging from mobile marketing. As V-card has already been evaluated in a field test, these results can be implemented to outline future research and development aspects for this area.

INTRODUCTION

The chapter presents the use of mobile multimedia for marketing purposes, specifically focusing on the implementation of streaming technologies. Using V-card, a service for creating personalized multimedia messages, as an example, the advantages of sponsored messaging are illustrated. Topics of discussion include related projects, as marketing campaigns utilizing SMS and MMS are becoming more popular, the technical infrastructure of the V-card system, and an outline of social and legal issues emerging from mobile marketing. As V-card has already been evaluated in a field test, these results can be implemented to outline future research and development aspects for this area.

Euphoria regarding the introduction of the universal mobile telephony system (UMTS)

has evaporated. Expectations about new UMTS services are rather low. A "killer application" for 3rd generation networks is not in sight. Users are primarily interested in entertainment and news, but only few of them are actually willing to spend money on mobile services beyond telephony. However, for marketing campaigns the ability to address specific users with multimedia content holds an interesting perspective.

Advertisement-driven sponsoring models will spread in this area, as they provide benefits to consumers, network providers, and sponsors. Sponsoring encompasses not only a distribution of pre-produced multimedia content (e.g., by offering wallpapers), Java games, or ringtones based on a product, but also mobile multimedia services.

Mobile multimedia poses several problems for the user. First, how can multimedia content of high quality be produced with a mobile device. Cameras in mobile telephones are getting better with each device generation; still the achievable resolutions and framerates are behind the capabilities of current digital cameras. Second, how can multimedia content be stored on or transmitted from a mobile device. Multimedia data, sophisticated compression algorithms notwithstanding, is still large, especially when compared to simple text messages. External media, such as memory cards or the Universal Media Disk (UMD), can be used to a certain degree to archive and distribute data. They do not provide a solution for spreading this data via a wireless network to other users. Third, editing multimedia content on mobile devices is nearly impossible. Tools exist for basic image manipulation, but again their functionality is reduced and handling is complex.

Kindberg, Spasojevic, Fleck, and Sellen (2005) found in their study that camera phones are primarily used to capture still images for sentimental, personal reasons. These pictures are intended to be shared, and sharing mostly takes place in face-to-face meetings. Sending a picture via e-mail or MMS to a remote phone occurred only in 20% of all taken pictures. Therefore, one possible conclusion is that users have a desire to share personal moments with others, but current cost structures prohibit remote sharing and foster transmission of pictures via Bluetooth or infrared.

V-card sets out to address these problems by providing a message-hub for sublimated multimedia messaging. With V-card, users can create personalized, high-quality multimedia messages (MMS) and send those to their friends. Memory constraints are evaded by implementing streaming audio and video where applicable. V-cards can consist of pictures, audio, video, and MIDlets (Java 2 Micro-Edition applications). Experience with mobile greetingcards show that users are interested in high-quality content and tend to forward them to friends and relatives. This viral messaging effect increases utilisation of the V-card system and spreads the information of the sponsor. Haig (2002, p. 35) lists advice for successful viral marketing campaigns, among them:

- Create of a consumer-to-consumer environment
- Surprise the consumers
- Encourage interactivity

A V-card message is sponsored, but originates from one user and is sent to another user. Sponsoring companies therefore are actually not included in the communication process, as they are neither a sender nor a receiver. V-card is thus a true consumer-to-consumer environment. It also can be expected for the near future that high quality content contains an element of surprise, as it exceeds the current state of the art of text messaging. Interactivity is fostered by interesting content, which is passed on, but also by interactive elements like MIDlet games.

Additionally, Lippert (2002) presents a "4P strategy" for mobile advertising, listing four characteristics a marketing campaign must have:

- Permitted
- Polite

- Profiled
- Paid

"Permitted" means a user must agree to receive marketing messages. With V-card, the originator of the MMS is not a marketing company but another user, therefore the communication itself is emphasized, not the marketing proposition. Legal aspects regarding permissions are discussed detailed below. Marketing messages should also be "polite," and not intrusive. Again, the enhanced multimedia communication between the sender and the receiver is in the foreground, not the message from the sponsor.

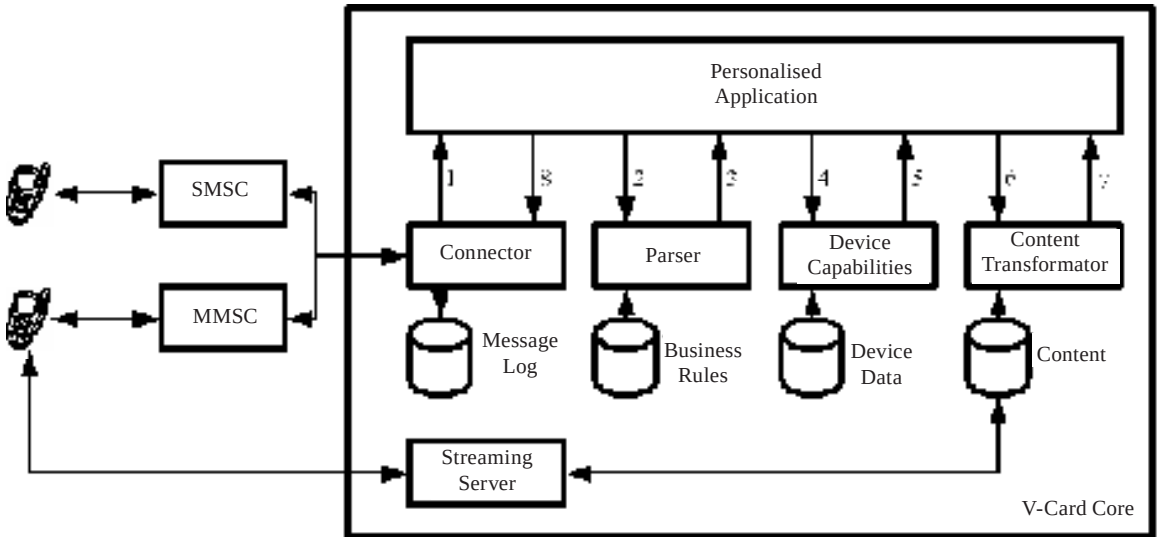
"Profiling" marketing tools enables targeted marketing and avoids losses due to non-selective advertising. Even if V-card itself is unable to match a sponsor to users, since users do not create a profile with detailed personal data, profiling is achieved by a selection process of the sender. As messages can be enhanced by V-card with media related to a specific sponsor, by choosing the desired theme the sender tailors a message to the interests of himself and the receiver. Usually, marketing messages should provide a target group with incentives to use the advertised service; the recipients need to get "paid." With V-card, sponsors "pay" both users by reducing the costs of a message and by providing high quality multimedia content.

V-CARD ARCHITECTURE

V-Card Core Architecture

Figure 1 shows the V-card core architecture and illustrates the workflow. First, the user with a mobile device requests a personalised application via the SMSC or Multimedia Messaging Service Centre (MMSC), which are part of the mobile network infrastructure. The message is passed on to the V-card core, where the connector decides which application has been called.

Figure 1. V-Card core architecture



After the request is passed on to the appropriate application (1), it is logged in the message log. A parser receives the message (2), extracts the relevant data for customisation, and returns this data (3)–this could include the receiver's phone number, the name of the sender or a message. Then, the capabilities of the receiving phone are queried from a database which holds all relevant data (4+5) like display size, number of colours, supported video and audio codecs.

Finally, the application transmits all the data gathered to the content transformator. Here, the pre-produced content is tailored with the input delivered by the user according to the capabilities of the device (6+7). The result is then sent via the connector (8) to the receiving user. Since the personalised applications and the data are separated, new applications can be easily created.

V-Card Streaming Technology

Since video content can not be stored directly on a mobile device due to memory limitations, a streaming server supplies video data to the device where the video is played, but not stored with the exception of buffered data, which is stored temporarily to compensate for varying network throughput. Streaming video and audio to mobile devices can be utilized for various services (e.g., for mobile education) (Lehner, Nösekabel, & Schäfer 2003). In the case of V-card, the MMS contains a link to adapted content stored on the content server. This link can be activated by the user and is valid for a certain amount of time. After the link has expired, the content is removed from the content server to conserve memory.

Currently, there are two streaming server solutions available for mobile devices. RealNetworks offers the HELIX server based on the ReadMedia format. RealPlayer, a client capable of playing back this format, is available for Symbian OS, Palm OS 5, and PocketPC for PDAs. Additionally, it is available on selected handsets, including the Nokia 9200 Series Communicators and Nokia Series 60 phones, including the Nokia 7650 and 3650. The other solution is using a standardized 3GPP-stream based on the MPEG4 format, which can be delivered using Apples Darwin server.

An advantage of implementing streaming technology for mobile multimedia is the fact that only a portion of the entire data needs to be transmitted to the client, and content can be played during transmission. Data buffers ensure smooth playback even during short network interruptions or fluctuations in the available bandwidth. As video and audio are time critical, it is necessary that the technologies used are able to handle loss of data segments, which do not arrive in time (latency) or which are not transmitted at all (network failure). GPRS and HSCSD connections allow about 10 frames per second at a resolution of 176 by 144 pixel (quarter common intermediate format QCIF resolution) when about 10 KBit per second are used for audio. Third generation networks provide a higher bandwidth, leading to a better quality and more stable connectivity.

A drawback of streaming is the bandwidth requirement. For one, the bandwidth should be constant; otherwise the buffered data is unable to compensate irregularities. Next, the available bandwidth directly influences the quality that can be achieved — the higher the bandwidth, the better the quality. Third, a transfer of mobile data can be expensive. A comparison of German network providers in 2003 showed that 10 minutes of data transfer at the speed of 28 KBit per second (a total amount of 19 Megabyte) resulted in costs ranging from 1 Euro (time-based HSCSD tariff) up to 60 Euro (packet-based GPRS by call tariff).

V-Card Examples

Figures 2 demonstrates a picture taken with the camera of a mobile device, rendered into a video clip by the V-card core. Figure 3 combines pictures and text from the user with video and audio content from the V-card hub. Figure 4 shows how simple text messages can be upgraded when a

Figure 2. V-Card with picture in video

Figure 3. V-Card with picture and text in video

Figure 4. V-Card with text in picture and audio

picture and an audio clip are added to create a multimedia message.

Since sponsoring models either influence the choice of media used to enhance a message, or can be included as short trailers before and after the actual message, users and sponsors can choose from a wide variety of options best suited for their needs.

LEGAL ASPECTS

It should be noted that the following discussion focuses on an implementation in Germany and today (2005Q1)–although several EU guidelines are applicable in this area there are differences in their national law implementations and new German and EU laws in relevant areas are pending.

Legal aspects affect V-card in several areas: consumer information laws and rights of withdrawal, protection of minors, spam law, liability, and privacy. A basic topic to those subjects is the classification of V-card among "Broadcast Service" ("Mediendienst"), "Tele Service" ("Teledienst"), and "Tele Communication Service" ("Telekommunikationsdienst"). According to § 2 Abs. 2 Nr. 1 and § 2 Abs. 4 Nr. 3 Teledienstegesetz (TDG) V-card is not a "Broadcast Service" and based on a functional distinction (see e.g., Moritz/Scheffelt in Hoeren/Sieber, 4, II, Rn. 10) V-card is presumed to be a "Tele Service."

Consumer information laws demand that the customer is informed on the identity of the vendor according to Art. 5 EU Council Decision 2000/31/EC, to § 6 TDG and to § 312c Bürgerliches Gesetzbuch (BGB) (e.g., on certain rights he has with regard to withdrawal). The fact that V-card might be free of charge for the consumer does not change applicable customer protection laws as there is still a (one-sided) contract between the costumer and the provider (see e.g., Bundesrat, 1996, p. 23). Some of these information duties have to be fulfilled before contract and some after. The post-contract information could be included

in the result MMS and the general provider information and the pre-contract information could be included in the initial advertisements and/or a referenced WWW- or WAP-site. Art. 6 EU Council Decision 2000/31/EC and § 7 TDG demand a distinction between information and adverts on Web sites and can be applicable, too. A solution could be to clearly communicate the fact that the V-card message contains advert (e.g., in the subject) (analogue to Art. 7(1) EU Council Decision 2000/31/EC, although this article is not relevant in Germany). The consumer might have a withdrawal right based on § 312d (1) BGB on which he has to be informed although the exceptions from § 312c (2) 2nd sentence BGB or § 312d (3) 2 BGB could be applicable. With newest legislation the consumer has to be informed on the status of the withdrawal rights according to § 1 (1) 10 BGB-Informationspflichtenverordnung (BGB-InfoV), whether he has withdrawal rights or not.

§ 6 Abs. 5 Jugendmedienschutzstaatsvertrag (JMStV) bans advertisements for alcohol or tobacco which addresses minors, § 22 Gesetz über den Verkehr mit Lebensmitteln, Tabakerzeugnissen, kosmetischen Mitteln und sonstigen Bedarfsgegenständen (LMBG) bans certain kinds of advertisements for tobacco, Art. 3(2) EU Council Decision 2003/33/EC (still pending German national law implementation) bans advertisements for tobacco in Tele Services. Therefore a sponsor with alcohol or tobacco products will be difficult for V-card. Sponsors with erotic or extreme political content will also be difficult according to § 4, 5 and 6(3) JMStV. § 12(2) 3rd sentence Jugendschutzgesetz (JuSchG) demands a labelling with age rating for content in Tele Services in case it is identical to content available on physical media. Since V-card content will most of the time special-made and therefore not available on physical media, this is not relevant.

The e-mail spam flood has led to several EU and national laws and court decisions trying to limit spam. Some of these laws might be applicable for mobile messaging and V-card, too. In Germany a new § 7 in the Gesetz gegen den unlauteren Wettbewerb (UWG) has been introduced. The question in this area is whether it can be assumed that the sent MMS is ok with the recipient (i.e., if an implied consent can be assumed). Besides the new § 7 UWG if the implied consent cannot be assumed a competitor or a consumer rights protection group could demand to stop the service because of a "Eingriff in den eingerichteten und ausgeübte Gewerbebetrieb" resp. a "Eingriff in das Allgemeine Persönlichkeitsrecht des Empfängers" according to §§ 1004 resp. 823 BGB.

Both the new § 7 UWG and previous court decisions focus on the term of an unacceptable annoyance or damnification which goes along with the reception of the MMS. The highest German civil court has ruled in a comparable case of advert sponsored telephone calls (BGH reference I ZR 227/99) that such an implied consent can be assumed under certain conditions e.g. that the communication starts with a private part (and not with the advertisement) and that the advertisement is not a direct sales pitch putting psychological pressure on the recipient (see e.g., Lange 2002, p. 786). Therefore if a V-card message consists of a private part together with attractive and entertaining content and a logo of the sponsor the implied consent can be assumed. The bigger the advertisement content part is the likelier it is that the level of a minor annoyance is crossed and the message is not allowed according to § 7 UWG (see e.g., Harte-Bavendamm & Henning-Bodewig, 2004, § 7, Rn. 171).

If users use the V-card service to send unwelcome messages to recipients V-card could be held responsible as an alternative to the user from whom the message originated. A Munich court (OLG München reference 8 U 4223/03) ruled in this direction in a similar case of an e-mail news letter service however focusing on the fact that the service allowed the user to stay anonymously. This is not the case with the mobile telephone numbers used in V-card, which are required to be associated with an identified person in Germany.

In addition to this the highest German court has in some recent decisions (BGH I ZR 304/01, p. 19 and I ZR 317/01, p. 10) narrowed the possibilities for a liability as an alternative by limiting the reasonable examination duties.

Manual filtering by the V-card service is a violation of communication secrecy and therefore not allowed (see e.g., Katernberg, 2003). Automatic filtering must not result in message suppression since this would be illegal according to German martial law § 206 (2) 2 Strafgesetzbuch.

The obligation to observe confidentiality has in Germany the primary rule that data recording is not allowed unless explicitly approved (§ 4 Bundesdatenschutzgesetz). Log files would therefore not be allowed with an exception for billing according to § 6 Gesetz über den Datenschutz bei Telediensten (TDDSG). These billing logs must not be handed over to third parties likely also including the sponsor.

As a conclusion, it can be noted that an innovative service like V-card faces numerous legal problems. During the project, however, it became clear that all these requirements can be met by an appropriate construction of the service.

EVALUATION OF V-CARD

Since V-card also has the ability to transmit personalised J2ME applications via MMS (see Figure 5 for an example), it surpasses the capabilities of pure MMS messages creating added value for the user, which normally do not have the possibility to create or modify Java programs. One example is a sliding puzzle where, after solving the puzzle, a user may use the digital camera of the mobile device to change the picture of the puzzle. After the modification, the new puzzle can then be send via V-card to other receivers.

Still, as previously mentioned, V-card requires a MMS client. It can therefore be regarded as an enhancement or improvement for MMS communication and is as such a competitor to the "normal" MMS. Hence, an evaluation framework should be usable to measure the acceptance of both "normal" MMS messaging and "enhanced" V-card messaging, creating results that can be compared with each other to determine the actual effect of the added value hoped to be achieved with V-card. While extensive research exists regarding PC-based software, mobile applications currently lack comprehensive methods for creating such evaluations. Therefore, one possible method was developed and applied in a fieldtest to evaluate V-card (Lehner, Sperger, & Nösekabel, 2004).

At the end of the project on June 3, 2004, a group of 27 students evaluated the developed V-card applications in a fieldtest. Even though the composition and size of the group does not permit to denote the results as representative, tendencies can be identified. The statistical overall probability of an error is 30%, as previously mentioned.

The questionnaire was implemented as an instrument to measure results. To verify the quality and reliability of the instrument, three values

Figure 5. V-card with MIDlet puzzle application

were calculated based on the statistical data. The questionnaire achieved a Cronbach alpha value of 0.89—values between 0.8 and 1.0 are regarded as acceptable (Cronbach, 1951). The split-half correlation, which measures the internal consistency of the items in the questionnaire, was calculated to be 0.77 with a theoretical maximum of 1.0. Using the Spearman-Brown formula to assess the reliability of the instrument, a value of 0.87 was achieved. Again, the theoretical maximum is 1.0. Therefore, the questionnaire can be regarded to be statistically valid and reliable.

One result of the fieldtest was that none of the students encountered difficulties in using any of the V-card applications, even though the usability of the mobile phone used in the fieldtest was regarded as less than optimal.

Overall 66% of the students thought that V-card was easy to use, 21% were undecided. It is very likely that the sample group leaned towards a negative or at least neutral rating as the usability of the end device was often criticised. This factor can not be compensated by the programmers of the mobile application. Another indicator for this rationale is the comparison with the results for the MMS client. Here, 75% of the group agreed to this statement, which is an increase of 9%. The similarity of the results suggests that also the rating for the usability of the MMS client was tainted by the usability of the device.

No uniform opinion exists regarding sponsored messages by incorporating advertising. Forty-two percent of the students would accept advertisements if that would lower the price of a message. Thirty-seven percent rejected such a method. The acceptable price for a V-card message was slightly lower compared to that of a non-sublimated MMS, which on the other hand did not contain content from a sponsor.

An important aspect for the acceptance of mobile marketing is the protection of privacy. In this area the students were rather critical. Sixty-three percent would reject to submit personal data to the provider of V-card. Since this information was not necessary to use V-card, only 17% of the sample group had privacy concerns while using V-card.

The mobile marketing component was perceived by all participants and was also accepted as a mean to reduce costs. This reduction should benefit the user, therefore a larger portion of the sample group rejected for V-card the idea for increased cost incurred by a longer or more intensive usage (88% rejected this for V-card, 67% for MMS).

As already addressed, the pre-produced content of V-card helped 50% of the users to achieve the desired results. The portion rejecting this statement for V-card was 25%, which is higher than the 8% who rejected this statement for MMS. This leads to the conclusion that if the pre-produced content is appropriate in topic and design for the intended message, it contributes to the desired message. However, it is not possible to add own content if the pre-produced content and the intention of the sender deviate. The user is therefore limited to the offered media of the service provider.

Overall, the ratings for V-card by the students were positive. Marketing messages, which were integrated into the communication during the fieldtest, were not deemed objectionable. The usability of V-card was also rated high. Main points that could be addressed during the actual implementation in the mobile market should include privacy and cost issues.

CONCLUSION

The new messaging service MMS has high potential and is being widely adopted today, although prices and availability are far from optimal. Mostly young people tend to use the fashionable messages which allow much richer content to be sent instantly to a friend's phone. This young

user group is especially vulnerable to debts due to their mobile phones though, or they have prepaid subscriptions letting them only send a very limited number of messages. By incorporating a sponsor model in V-card, this user group will be able to send a larger number of messages with no additional cost and thereby offering advertising firms a possibility to market their services and goods. For those users that are not as price sensitive, the large amount of professional media and the ease of the message-composition will be an incentive to use the service. The added value of the service should be a good enough reason to accept a small amount of marketing in the messages. Since V-card offers the sender and receiver an added value, the marketing message will be more acceptable than other forms of advertising where only the sender benefits from the advertisement.

Another advantage of V-card is the fact that the system takes care of the administration and storing of professional media and the complicated formatting of whole messages, thus taking these burdens from the subscriber. At the same time, V-card offers marketers a new way to reach potential customers and to keep in dialogue with existing ones. The ease of sending such rich content messages with a professional touch to a low price or even no cost at all will convince subscribers and help push 3G networks.

Overall, it can be expected that marketing campaigns will make further use of mobile multimedia streaming, aided by available data rates and the increasing computing power of mobile devices. Continuous media (video and audio), either delivered in real-time or on demand, will possibly become the next entertainment paradigm for a mobile community.

KEY TERMS

MMS: Multimedia message service: Extension to SMS. A MMS may include multimedia content (videos, pictures, audio) and formatting instructions for the text.

Multimedia: Combination of multiple media, which can be continuous (e.g., video, audio) or discontinuous (e.g., text, pictures).

SMS (Short Message Service): text messages that are sent to a mobile device. A SMS may contain up to 160 characters with 7-bit length, longer messages can be split into multiple SMS.

Streaming: Continuous transmission of data primarily used to distribute large quantities of multimedia content.

UMTS (Universal Mobile Telecommunications System): 3rd generation network, providing higher bandwidth than earlier digital networks (e.g., GSM, GPRS, or HSCSD).

Chapter 3.32
Acoustic Data Communication with Mobile Devices

Victor I. Khashchanskiy
First Hop Ltd., Finland

Andrei L. Kustov
First Hop Ltd., Finland

INTRODUCTION

One of the applications of m-commerce is mobile authorization, that is, rights distribution to mobile users by sending authorization data (a token) to the mobile devices. For example, a supermarket can distribute personalized discount coupon tokens to its customers via SMS. The token can be a symbol string that the customers will present while paying for the goods at the cash desk. The example can be elaborated further—using location information from the mobile operator, the coupons can only be sent to, for example, those customers who are in close vicinity of the mall on Saturday (this will of course require customers to allow disclosing their location).

In the example above, the token is used through its manual presentation. However, most interesting is the case when the service is released automatically, without a need for a human operator validating the token and releasing a service to the customer; for example, a vending machine at the automatic gas station must work automatically to be commercially viable.

To succeed, this approach requires a convenient and uniform way of delivering authorization information to the point of service—it is obvious that an average user will only have enough patience for very simple operations. And this presents a problem.

There are basically only three available local (i.e., short-range) wireless interfaces (LWI): WLAN, IR, and Bluetooth, which do not cover the whole range of mobile devices. WLAN has not gained popularity yet, while IR is gradually disappearing. Bluetooth is the most frequently used of them, but still it is not available in all phones.

For every particular device it is possible to send a token out using some combination of LWI and

presentation technology, but there is no common and easy-to-use combination. This is a threshold for the development of services.

Taking a deeper look at the mobile devices, we can find one more non-standard simplex LWI, which is present in all devices—acoustical, where the transmitter is a phone ringer. Token presentation through acoustic interface along with general solution of token delivery via SIM Toolkit technology (see 3GPP TS, 1999) was presented by Khashchanskiy and Kustov (2001). However, mobile operators have not taken SIM Toolkit into any serious use, and the only alternative way of delivering sound tokens into the phone-ringing tone customization technology was not available for a broad range of devices at the time the aforementioned paper was published.

Quite unexpectedly, recent development of mobile phone technologies gives a chance for sound tokens to become a better solution for the aforementioned problem, compared with other LWI. Namely, it can be stated that every contemporary mobile device supports either remote customization of ringing tones, or MMS, and in the majority of cases, even both, thus facilitating sound token receiving over the air.

Most phone models can playback a received token with only a few button-clicks. Thus, a sound token-based solution meets the set criteria better than any other LWI. Token delivery works the same way for virtually all phones, and token presentation is simple.

In this article we study the sound token solution practical implementation in detail. First, we select optimal modulation, encoding, and recognition algorithm, and we estimate data rate. Then we present results of experimental verification.

ACOUSTIC DATA CHANNEL

We consider the channel being as follows. The transmitter is a handset ringer; information is encoded as a sequence of sine wave pulses, each with specified frequency and amplitude.

Multimedia message sounds and most ringing tones are delivered as sequences of events in MIDI (musical instrument digital interface) format. A basic pair of MIDI events (note on and note off) defines amplitude, frequency, duration of a note, and the instrument that plays this note. MIDI events can be used to produce information-bearing sound pulses with specified frequency and amplitude.

Widely used support of polyphonic MIDI sequences allows playback of several notes simultaneously. Nonetheless, this has been proved worthless because in order to get distinguished, these notes have to belong to different non-overlapping frequency ranges. Then the bit rate that can be achieved would be the same as if wider frequency range was allocated for a single note.

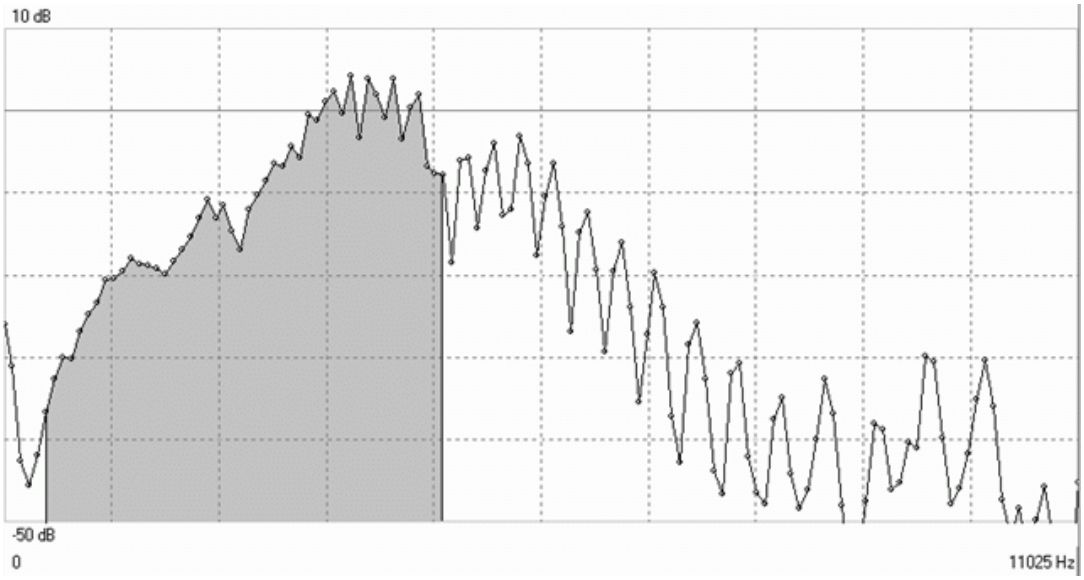
The receiver is a microphone; its analog sound signal is digitized and information is decoded from the digital signal by recognition algorithm, based on fast fourier transform (FFT) technique. FFT is, in our opinion, a reasonable trade-off between efficiency and simplicity.

We investigated acoustics properties of mobile devices. After preliminary comparison of a few mobile phone models, we found that ringer quality is of approximately the same level. All handsets have a high level of harmonic distortions and poor frequency response. The results shown in Figures 1 and 2 are obtained for a mid-class mobile phone SonyEricsson T630 and are close to average.

MIDI-based sound synthesis technology applies limitations on pulse magnitude, frequency, and duration. At the same time, ringer frequency response is not linear and the level of harmonic distortions is very high. Figure 1 shows frequency response measured with a sweeping tone or, to be precise, a tone leaping from one musical note to another. To obtain this, the phone played a MIDI sequence of non-overlapping in-time notes that covered a frequency range from 263 to 4200 Hz (gray area).

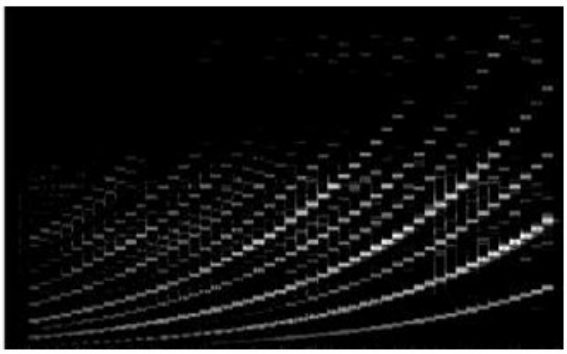
The frequency response varies over a 40 dB range, reaching its maximum for frequencies from approximately 2.5 to 4 kHz. Moreover, spectral

Figure 1. Frequency response measured with test MIDI sequence in hold-max mode



components stretch up to 11 KHz, which is caused by harmonic distortions. This is illustrated also by Figure 2.

Figure 2. A spectrogram of the test MIDI sequence



Horizontal axis is time; overall duration of the test sequence is 15 seconds. Vertical axis is sound frequency, which is in range from 0 to 11025 Hz. Brightness is proportional to sound relative spectral density; its dynamic range is 60 dB, from black to white.

We also found that frequency of the same note may differ in different handsets. Nevertheless, the ratio of note frequencies (musical intervals) remains correct, otherwise melodies would sound wrong.

For a simplex channel with such poor parameters, as reliable a data encoding method as possible is to be used. Frequency shift keying (FSK) is known as the most reliable method which finds its application in channels with poor signal-to-noise ratio (SNR) and non-linear frequency response.

It is not possible to negotiate transfer rate or clock frequency, as it is usually done in modem protocols because acoustic channel is simplex. To make the channel as adaptive as possible, we

have chosen to use differential FSK (DFSK), as it requires no predefined clock frequency. Instead, frequency leaps from one pulse to another provide the channel clocking. The difference between frequencies of consecutive pulses determines the encoded value.

Once encoding scheme is selected, let us estimate possible transfer rate before we can find the balance between data transfer rate and channel reliability. Suppose the transmitter generates a sequence of pulses of duration τ, which follow without gaps with repetition frequency f. If each frequency leap between two consequent pulses carries N bits of information, the overall bit rate p is obviously:

$$p = N \bullet f . \quad (1)$$

In DFSK, for each frequency leap to carry N bits, we must be able to choose pulse frequencies from a set of $2^N + 1$ values. If a pulse frequency can have n values, we will have

$$p = [\log_2(n-1)] \bullet f , \quad (2)$$

where by $[]$ we denote integer part. It follows from (1, 2), that to increase p, we must increase pulse repetition frequency f and the amount of possible values for pulse carrier frequencies n. However, if the recognition is based on spectral analysis, we cannot increase n and f independently. Let us show it. Assume for simplicity that pulse frequency can have any value within frequency range F. Then the number of available values of coding frequencies will be

$$n = [\log_2(F/\Delta f - 1)], \quad (3)$$

where Δf is the minimal shift of pulse frequency between two consecutive pulses. Maximum n is achieved with maximum F and minimum Δf. Both parameters have their own boundaries. Bandwidth is limited by the ringer capabilities, and frequency shift is dependant on pulse repetition frequency f, due to the fundamental rule of spectral analysis (Marple, 1987), which defines frequency resolution δf to be in reverse proportionality to observation time T:

$$\delta f = 1 / T. \quad (4)$$

How can (4) be understood in our case of a sequence of pulses? Having converted the signal into frequency domain, we will get the sequence of spectra. As information is encoded in the frequency pulses, we must determine the pulse frequency for every spectrum. This can only be done with certain accuracy δf called frequency resolution. The longer time T we observe the signal, the better frequency resolution is. So for given pulse duration τ, equation (4) sets the lower limit for frequency difference Δf between two consecutive pulses:

$$\Delta f \geq 1 / \tau = f. \quad (5)$$

This means, that if we increase pulse repetition rate f, then we have to correspondingly increase frequency separation Δf for the consecutive pulses; otherwise the spectral analysis-based recognizing device will not principally be able to detect signal.

Let us now try to estimate the data rate for the system we studied earlier. Figures 1 and 2 show that harmonic distortions are very high, and second and third harmonics often have higher magnitudes than the main tone. Consequently, the coding frequencies must belong to the same octave. Their frequency separation should be no less than defined by (5).

An octave contains 12 semitones, so possible frequency values f_i are defined by the following formula:

$$f_i = f_0 \bullet 2^{i/12}, \; i=0...11. \quad (6)$$

The minimum spacing between consecutive notes is for i=1; maximum for i=11.

In our case, we decided to use the fourth octave—as the closest to the peak area of phone ringer frequency response—in order to maximize SNR and thus make recognition easier. For it, f_0= 2093 Hz, and minimum spacing between notes is 125 Hz. Taking the maximum amount of N = 3 (9 coding frequencies), we can estimate transfer rate as:

$$p_{max} = 3 \bullet 125 = 375 \text{ bps}. \quad (7)$$

Recognition Algorithm (Demodulation)

The following algorithm was developed to decode information transferred through audio channel. Analog audio signal from the microphone is digitized with sampling frequency ***Fs*** satisfying Nyquist theorem (Marple, 1987). A signal of duration ***Ts*** is then represented as a sequence of ***Ts/Fs*** samples. FFT is performed on a sliding vector of ***M*** signal samples, where ***M*** is a power of 2.

- First, sequence of instant power spectra is obtained from the signal using discrete Fourier transform with sliding window (vector) of ***M*** samples. To get consecutive spectra overlapped by 50%, the time shift between them was taken ***M/2Fs***. Overlapping is needed to eliminate the probability of missing the proper position of a sliding window corresponding to the pulse existence interval, when the pulse duration is not much longer than analysis time significantly (at least twice).
- Second, the synchronization sound is found as sine wave with a constant, but not known in advance frequency, and a certain minimum duration.
- Third, the spectrum composed of maximum values over the spectra sequence (so-called hold-max spectrum) is used to find the pulse carrier frequencies. This step relies on the assumption that used frequency range does not exceed one octave. In other words, the highest frequency is less than twice the value of the lowest one.
- Forth, time cross-sections of spectra sequence at found carrier frequencies are used to recognize moments of sound pulse appearances.
- The last step is reconstruction of encoded bit sequence having the time-ordered set of frequency leaps.

Such an algorithm does not need feedback and can work with unknown carrier frequencies in unknown but limited frequency range. Recognizing the beginning of the transmission is critical for the correct work, so we added "synchronization header" in the beginning of the signal. The length of this header is constant, so the throughput of the system will rise with the message length.

Recognizer Parameters

Here we explain how the parameters of analyzer (***Fs, M***) are defined from that of signal (***f,*** Δf). After FFT, we have ***M/2*** of complex samples in frequency domain, corresponding to frequency range from 0 to ***Fs/2***. So for this particular case, frequency resolution obviously equals the difference between the consecutive samples in the frequency domain; namely,

$$df = Fs / M. \quad (7)$$

According to (4), minimum required time of analysis is

$$T = M / Fs. \quad (8)$$

It is obvious, that ***T*** must not exceed burst duration τ. Combining (8) and (5), we get:

$$M / Fs \le 1 / f \quad (9)$$

On the other hand, frequency resolution ***df*** must not exceed spacing Δf between carrier frequencies:

$$Fs / M \leq \Delta f \quad (10)$$

Combining (9) and (10), we will finally get:

$$f \leq Fs / M \leq \Delta f \quad (11)$$

which shows that values of analyzer parameters may be restricted when (5) is close to the equation. This imposes requirements on the sound recognition algorithm to work reliably nearby the "critical points," where the recognition becomes principally impossible.

EXPERIMENTAL RESULTS

We implemented a prototype of acoustic data channel with the mobile phone SonyEricsson T630, whose characteristics are seen in Figures 1 and 2.

For encoding, we developed software that encoded symbol strings in ASCII to melody played by an electric organ. The instrument was chosen from 127 instruments available in MIDI format, because its sound is the closest to the sine wave pulses model we used in calculations. It is maintained at approximately the same level over the whole note duration.

The recognizer consisted of a Sony ECM-MS907 studio microphone for signal recording, and a conventional PC with a sound card was used for signal analysis. FFT processing was done by our own software.

In the beginning of our experiments, we used the parameters described in the theoretical section. Later we found that at the highest possible transfer rate, data recognition is not reliable. So we gradually increased pulse duration until recognition became reliable. Eventually we selected the following modulation parameters: ***n=5*** (each frequency leap carries two data bits), notes were evenly distributed over the octave (C, D#, F, G, A in musical notation, and they correspond to frequencies 2093, 2489, 2794, 3136, and 3520 Hz), and pulse duration was 46 ms.

Figure 3 shows a spectrogram of recognizable signal from the microphone.

Horizontal axis is time, and overall signal duration is 2 seconds. Vertical axis is frequency, and one can see the leaps between consecutive pulses. Brightness is proportional to the signal intensity.

This example signal carries 88 bits of information (a string "hello world," coded as 11 ASCII characters), which makes the data transfer rate approximately 40 bps. Overhead from the synchronization header is ca. 25%; for longer messages the average transfer rate would be higher.

DISCUSSION

We have managed to implement a reliable data channel from the phone; the advantage of the proposed recognition algorithm is that it can work in the same way for every mobile device, independent on acoustic properties of different brands and models, although encoding frequencies are different.

The channel is principally one way: the handset cannot receive any feedback that can be used, for example, for error correction. Nevertheless, developed recognition algorithm provided good reliability. For a handset placed 30 cm from the microphone, in a room environment, recognition was 100% reliable. This condition corresponds to the output of the average phone in a "normal" room environment.

Ensuring reliability does not seem to be a very difficult task. First of all, SNR can be improved by increasing the number of receiving microphones. On the other hand, in practical systems simple shielding is very easy to implement. And finally, even one error in recognition is not fatal: the

user can always have another try. A recognizing device can easily identify cases of unsuccessful recognition and indicate the former case for the user to retry.

The recognition system can be implemented on any PC equipped with a sound card. The algorithm is so simple that the system can also be implemented as an embedded solution based on digital signal processors. Microphone requirements are not critical either: both the frequency response and SNR of entry level microphones are much better than those of mobile device ringers. This means that cheap stand-alone recognizers can be implemented and deployed at the points of service.

It is interesting to note that other devices capable of playing MIDI sequences (e.g., PDAs) can be used as well as mobile phones.

Measured transfer rate (40 bps) was considerably less than the estimation, obtained in our simple model—375 bps. We think that the reason for this was slow pulse decay rate in combination with non-linear frequency response. Amplitude of the note with frequency close to a local frequency response maximum might remain higher than amplitude of the consecutive note through the whole duration of the latter. Thus, the weaker sound of the second note might be not recognized.

However, we consider even such relatively slow transmission still suitable for the purposes of mobile authorization applications, because authorization data is usually small and its transmission time is not critical.

Our example (Figure 3) seems to be a quite practical situation—transmitting 11-symbol password during 2s is definitely not too long for a user. Typing the same token on the vending machine keyboard would easily take twice as long.

The acoustic presentation method might be an attractive feature for teenagers (e.g., mobile cinema tickets being one conceivable application).

ACKNOWLEDGMENTS

The authors would like to thank Petteri Koponen for the original idea.

Figure 3. Encoded "hello world"; note the leading synchronization header. Overall duration is approximately 2 seconds.

KEY TERMS

Fast Fourier Transform (FFT): An optimized form of the algorithm that calculates a complex spectrum of digitized signals. It is most widely used to obtain a so-called power spectrum as a square of a complex spectrum module. Power spectrum represents energy distribution along frequency axis.

Frequency Resolution: The minimum difference in frequencies which can be distinguished in a signal spectrum.

Frequency Response: For a device, circuit, or system, the ratio between output and input signal spectra.

Frequency Shift Keying (FSK): The digital modulation scheme that assigns fixed frequencies to certain bit sequences. Differential FSK (DFSK) uses frequency differences to encode bit sequences.

Harmonic Distortions: Alteration of the original signal shape caused by the appearance of higher harmonics of input signal at the output.

IR: Short-range infrared communication channel.

Musical Instrument Digital Interface (MIDI): A standard communications protocol that transfers musical notes between electronic musical instruments as sequences of events, like 'Note On', 'Note Off', and many others.

Sampling Frequency: The rate at which analogue signal is digitized by an analogue-to-digital converter (ADC) in order to convert the signal into numeric format that can be stored and processed by a computer.

Chapter 3.33
The Design of Mobile Television in Europe

Pieter Ballon
Vrije Universiteit Brussel, Belgium

Olivier Braet
Vrije Universiteit Brussel, Belgium

ABSTRACT

Mobile television is potentially the most anticipated mass-market mobile application across Europe. This chapter examines the business model design of mobile TV by the various stakeholders currently piloting mobile broadcasting in the European national markets. It adapts a generic business model framework to systematically compare five recent pilots of the two mobile broadcasting technologies that are currently trialled most intensively in Europe, that is, digital video broadcasting-handheld (DVB-H) and digital audio broadcasting-Internet protocol (DAB-IP). The article illustrates the cross-impact of cooperation agreements between the various stakeholders with technological, service-related, and financial design choices. It also provides insights as to the likely business models in the upcoming commercialisation phase of mobile broadcasting in Europe.

INTRODUCTION

One of the most anticipated applications in Europe's mobile commerce and multimedia landscape is mobile TV. It is widely argued that mobile digital television has the potential of becoming one of the next high-growth consumer technologies (Kivirinta, Ali-Vehmas, Mutanen, Tuominen, & Vuorinen, 2004; Södergard, 2003), provided it is able to master its inherent complexities in terms of the various stakeholders required to cooperate (Shin, 2006). It has a clear and easily understandable value proposition towards the majority of end users: TV on a mobile device. Also, the technology lies at the crossroads of two powerful socio-technical trends: the ubiquity of mobile phones, and new forms of accessing media content.

In the European mobile market, digital TV on a mobile device is not a novelty. Initial TV services on mobile phones consist of streaming video over the cellular network. Third generation

(3G) cellular networks (i.e., Universal Mobile Telecommunications System [UMTS]) already allow for streaming video for a considerable time. In several European countries, a wide selection of rich video content is available over UMTS, with large markets such as Italy, the UK, and France as front-runners. The downside of this solution is that without network capacity investments the video images degrade in quality if there are too many simultaneous users, since content needs to be streamed to each user in a point-to-point fashion. Therefore, streaming content over cellular is a costly option for serving a mass audience. The Multimedia Broadcast Multicast Service (MBMS) standard could circumvent this by offering a multicast and a broadcast mode for existing cellular networks, but its implementation time path is currently unclear.

An alternative is offered by new point-to-multipoint digital TV standards such as DVB-H, DAB-based standards, and Media-FLO. These are able to offer high quality live broadcast TV, allowing mass-market service delivery in a more scalable way and at more attractive operational costs (but still considerable capital expenditures). However, since the current uptake of mobile video content over 3G is quite slow, some operators have expressed doubts as to whether investments in these new network technologies are necessary and are counting on the fact that their 3G property will be sufficient for the coming years.

Other major technology choices faced by prospective European mobile TV operators include whether or not to combine any new mobile broadcasting technologies with uplink technologies such as *global system for mobile communications* (GSM) and UMTS in order to ensure more flexibility and interactivity in the service offering, and whether new mobile broadcast standards should "piggy-back" on top of existing networks—*digital video broadcasting-terrestrial* (DVB-T) and DAB networks, respectively, - or whether they should be built as stand-alone networks.

The technological outlook on mobile broadcasting will be sketched briefly in the second section of this chapter. However, we aim to demonstrate that the main design choices to be addressed are not only, even not predominantly, techno-economic in nature. It is our assertion that the cross-impact of strategic cooperation and competition issues (e.g., related to control over this new market by broadcasters, content aggregators, or cellular network operators), market expectations (e.g., related to speed of uptake, service offerings, degree of interactivity), and legacy situations (e.g., related to existing networks and customer relations) will to a large extent determine the outcome of mobile digital TV in Europe (see Shin, 2006 for a similar argument on digital multimedia broadcasting [DMB] development in Korea). A four-level design framework, along with a detailed enumeration of mobile TV design issues, is presented in the third section.

To test both technological maturity and marketability of the new service, many mobile broadcast test and experimentation platforms (TEPs)[1] in the form of field trials and market pilots have been started in Europe since 2004. Two multicasting standards are being trialled quite intensively in the European area, that is, DVB-H and DAB-IP/DMB. Their commercialisation is expected to start in earnest from 2007 on, with small-scale commercialisation already available in 2006 in a few countries..

We selected and analysed five of the largest and most documented pilots (four DVB-H pilots and one DAB-IP pilot) using publicly available info, telephone interviews, and e-mail interactions with key pilot participants. The fourth section contains the results of the case analysis in terms of the design choices made, how these were interlinked, and which cooperation schemes were devised. Where possible, the consequences of the design choices for the commercialisation phase are indicated. Finally, the final section offers some concluding remarks in terms of the

models and strategies encountered in European mobile TV pilots.

TECHNOLOGY OUTLINE

The mobile broadcast landscape consists of three primarily non-proprietary standard families (Integrated Services Digital Broadcasting-Terrestrial [ISDB-T], DAB-based standards and DVB-H) developed by industry associations, and of the proprietary Media-FLO technology developed by Qualcomm. This section focuses on the DVB-H and DAB-based standards, as these are currently being piloted intensively throughout Europe. For a deeper analysis, see the rather extensive technological literature available on this subject (e.g., Curwen, 2006; Faria, Henriksson, Stare, & Talmola, 2006; Skiöld, 2006; Weck & Wilson, 2006).

The DVB-H Standard

DVB-H enjoys strong and organised support in Europe, as witnessed by the large amount of trials and pilots currently carried out, and by the forceful backing by European telecommunications giant Nokia, but it also has its supporters abroad. For instance, Intel Corporation, Modeo, Motorola, Nokia, and Texas Instruments created the Mobile DTV Alliance in January 2006 to promote the growth and evolution of DVB-H in the U.S.A.

As an extension of the DVB-T standard, DVB-H is relatively straightforward to implement, with several adjustments that make the standard more suitable for mobile communication. DVB-H uses significantly less bandwidth than DVB-T, approximately 300 kilobits versus 3 Megabytes per channel. Also, DVB-H saves on battery power by using the technique of time slicing, inserting the different video channels into the transmitted transport stream in bursts of data. The additional level of forward error correction (MPE-FEC) inserted in the DVB-H front end contributes to the robustness of the DVB-H signal.

DVB-H detractors regularly dispute the performance of DVB-H. They add that DVB-H channel switching is slow, unlikely to be able to deliver the stated data rates, and is susceptible to signal variations and problems with synchronisation. In fact, even DVB-H supporters acknowledge that the up to 6 seconds to switch channels is an issue, but claim that it is not insurmountable. DVB-H receiver manufacturers are confident they can drive down the channel switching to approximately 1.5 seconds as already achieved with DVB-T receivers.

Data on the amount of channels that DVB-H can carry as opposed to DAB-based standards varies. Currently, DVB-H seems to be able to offer considerably more channels, with between 10 and 20 channels per multiplex being offered in various trials, versus around 5 channels for DMB and DAB-IP.

DAB-IP, T-DMB, AND S-DMB

DAB-based standards include DAB-IP, terrestrial digital multimedia broadcasting (T-DMB), and S-DMB. DAB-IP can be described as a DMB I addition to DAB digital radio. More specifically, the network platform consists of DAB enhanced packet mode (EPM), in conjunction with an IP application. EPM was standardised by the WorldDAB Forum and enables video and other services—that are more sensitive to errors than the native audio services carried by DAB—to be carried.

DMB is an European Telecommunications Standards Institute (ETSI) standard developed in Europe that delivers mobile television services using the Eureka-147 DAB standard with additional error correction. Within the DMB sphere, a distinction is made between T-DMB and S-DMB. DAB-IP and T-DMB are both based on the DAB

transport layer, contrary to S-DMB. T-DMB uses the terrestrial network in Band III and/or Band L while S-DMB uses the satellite network in Band L. To complicate matters, S-DMB is actually not directly related to the DAB standard, but was developed in Korea using the System E International Telecommunication Union (ITU) standard based on code division multiple access (CDMA). S-DMB can deliver 13 video channels in a typical spectrum allocation.

T-DMB supporters argue that the scarcity of available spectrum will cripple the implementation and acceptance of DVB-H and MediaFLO, whereas T-DMB, due to its association with DAB, already has most of the required spectrum and infrastructure in place. T-DMB backers claim that it requires even less power than DVB-H or MediaFLO. Other reasons quoted by the T-DMB camp on why their standard is more suited than DVB-H for mobile digital TV are: lower channel switching time (around 1.5s), 30 frames per second (fps) versus just 15 fps on DVB-H (with traditional TV delivering between 25 and 30 fps), and the usage of 1.5 MHz channels requiring less power and circuit complexity (DVB-H uses 5 to 8 MHz channels).

However, as argued previously, DAB-based standards seem to be disadvantaged vis-à-vis DVB-H in terms of the number of channels per multiplex.

Principal Technical Components

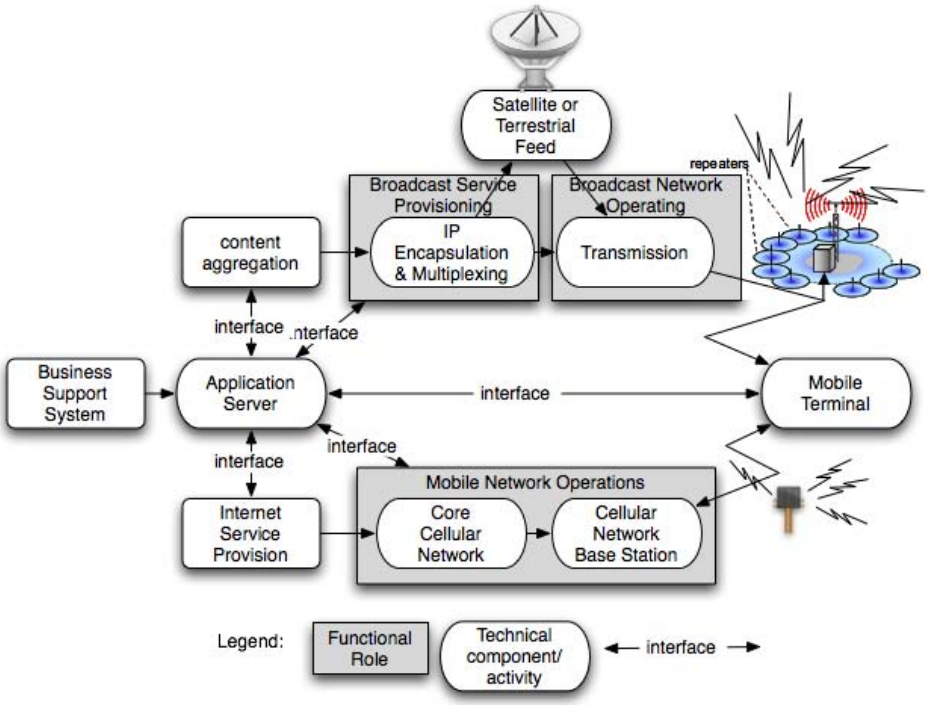
In a complete mobile broadcast system (including an uplink for interactive applications), the following functional roles and their constituting technical components can be distinguished:

- **Business support system:** Back office system for billing and help desk support.
- **Content aggregation:** Entails the collection of content in a content management system
- **Broadcast service provisioning:** Provides frequency allocation, IP encapsulation, and multiplexing
- **Broadcast network operating:** Entails network transmission of the content.
  - Note that, although the technical literature often groups IP-encapsulation, multiplexing, and the ownership + management of the transmitters into one actor—the broadcast network operator (BNO)—we will distinguish these roles, because in the business models these roles may be performed by different actors (see later on).
  - Therefore, the functions performed *before* the transmission will be referred to as broadcast service provisioning. All functions connected with the transmission of the DVB-H signal will be referred to as broadcast network operating.
- **Mobile network operations:** Provide the return channel through its cellular network.
- **The application layer:** provides for communication between the broadcast content and the mobile network operator (MNO) return channel.
- **The mobile terminal:** Has to be equipped with the suitable receiver in order to access the (free, subscribed or pay-per view) content.

METHODOLOGY AND DESIGN ISSUES

As illustrated by the technical architecture, cooperation between various stakeholders is necessary in order to bring mobile broadcasting to the market. Even though there might be significant differences between the pilot and the commercialisation phase, it may be assumed that the cooperation models currently employed in pilots to a certain extent

Figure 1. General technical architecture of mobile broadcasting (based a.o. on Digitag, 2005 and Pieck, 2005)



foreshadow the business models that will arise in the commercialisation phase (see also Dittrich & Van den Ende, 2006). In line with current thinking on strategic management and business model design (Ballon, 2007; Barney, 1991, 1997; Faber et al., 2003; Haaker, Bouwman, & Faber, 2004), our case analysis focuses on four business model design phases, which are equally relevant to the cooperation models used in the different pilots. These phases can be defined as follows:

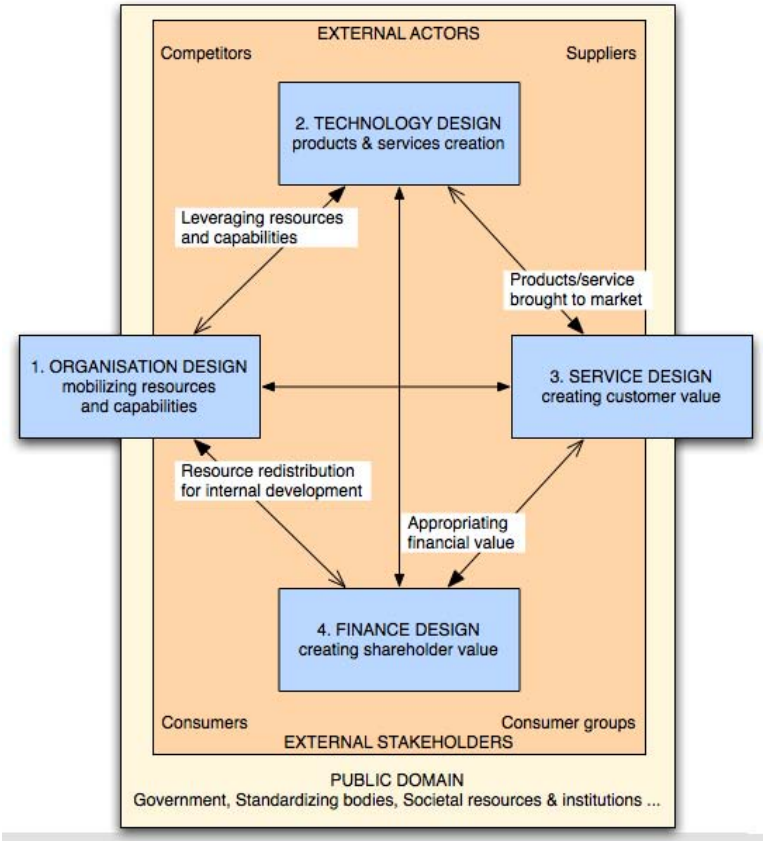
1. **Organisation design phase:** The organisation design involves defining a business scope (what customers will we try to reach and how), identifying distinctive competences, and making business governance decisions (make versus buy decisions).
2. **Technology design phase:** The technology design involved defining the technology scope (which technical design are we trying to develop and how), identifying the systemic competences that will contribute to the business strategies, and deciding on the IT governance (how will we develop or acquire the needed technical competences).
3. **Service design phase:** The service design involves choosing a specific value proposition towards the user, which implies choosing for a specific strategic scope.

4. **Financial design phase:** In a final phase, the financial modalities are formalised in binding contracts that clearly describe each partner's responsibilities, and the financial or other benefits they will receive in return.

Figure 2 illustrates how these design steps occur (chrono)logically, but cross-decisions are also possible, as illustrated by the horisontal and vertical arrows.

The framework presented previously emphasises organisation design as the starting point of any business modelling or cooperation modelling. This is especially relevant in cases such as mobile TV where convergence between various stakeholders and sectors increases the strategic importance of organisational design significantly. The focus of this chapter will be on cooperation models between stakeholders in the pilot phase of bringing mobile TV to the market. Therefore, a generic mobile TV value network model is constructed on which these models are subsequently mapped. They are described with the use of three main building blocks: business actors, business roles, and business relationships (see also Ballon et al., 2005). *Business actors* can be physical persons or corporations that participate in the creation of economic value, through the

Figure 2. Business modeling cycle



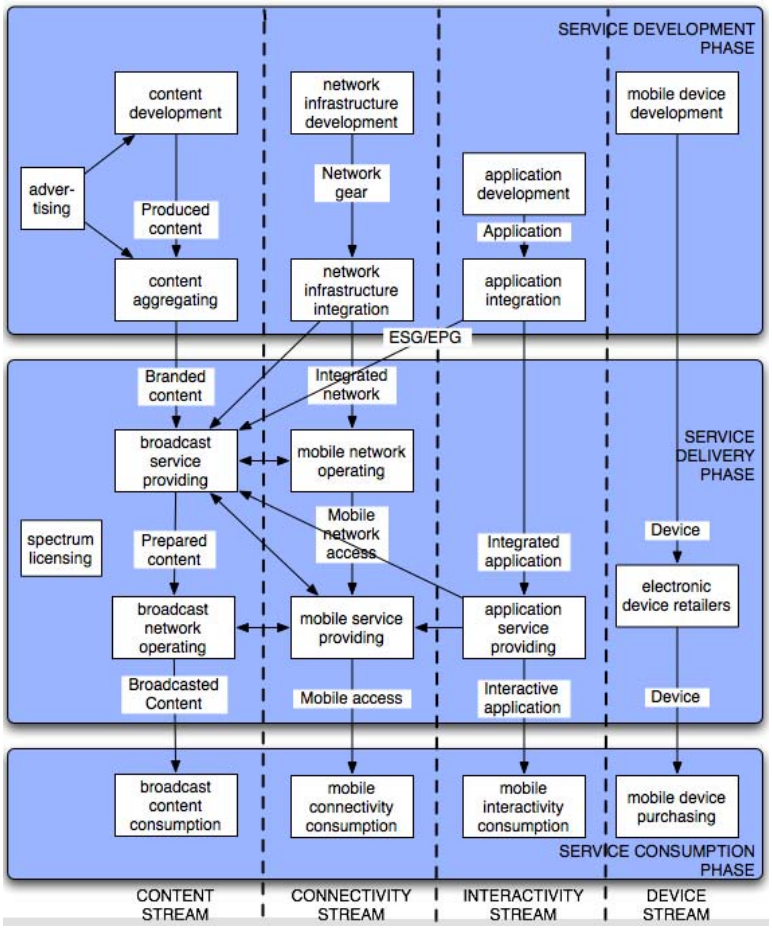
mobilisation of tangible or intangible resources within a business value network. *Business roles* are logical groups of business processes that are fulfilled by one or more actors. Business actors provide value to or derive value from the business roles they play. Finally, *business relationships* are the contractual exchanges of products or services for financial payments or other resources.

Organisation Design

The organisation design dimension concerns the relationships that are adopted between cooperating industrial partners to produce value for end customers. It entails which roles the partners take on, what resources each actor brings to the pilot and will bring during future commercialisation, and what kinds of cooperations arise during the delivery of specific mobile content services.

Figure 3 presents a generic value network for mobile digital TV delivery. The black arrows represent business relationships in the form of delivered services. The blue rectangles depict the different service deployment phases. The white rectangles are the business roles that actors can adopt. Each discrete role can be performed by a

Figure 3. Generic mobile digital TV value network



discrete actor, in which case the actor's name is inferred from the business role. Very often actors will perform more than one business role. Each configuration of roles, actors, and relationships constitutes a different cooperation model.

Absent from Figure 3—since this cannot be inferred from the mobile TV pilots—is the upwardly flow of revenues. Although the services flow more or less chronologically from the upper layers to the lower layers to the end users, the revenues may not. Most often, the infrastructure players receive their revenues in advance, that is, when the network operator purchases the networking gear. It is then up to the network operator to leverage this infrastructure into tempting service offerings towards the end users. To formulate this differently, one can say that there exists asynchronicity between the supply chain and the value chain. Because of the possible disconnect between a network operator's expenses and expected revenues, there are cases of vendor financing, where the infrastructure manufacturers supply credit lines to the network operators so they can foot the initial capex bill.

The following business roles were distinguished:

Service Development Phase

In this phase those business roles are situated that are necessary for the development and integration of the mobile digital content and of essential technical components such as the transmission infrastructure and the terminal devices.

- **Content development:** Development of the content that will be distributed. The distribution and branding of the content to the end user can be done directly by the content developer (which is rare) or via a content aggregator (which is common).
- **Content aggregation:** The acquisition, branding/marketing, and scheduling of the content that will be delivered to the broadcast service provider.
- **Network infrastructure development:** The designing and manufacturing of the network equipment, to be purchased and installed by the network operators (both mobile and broadcast network operators (BNOs).
- **Network infrastructure integration:** The installation of the network equipment acquired from network equipment manufacturing, at the request of the mobile and BNOs.
- **Application development:** The development of applications that will be used in the application layer.
- **Application integration:** The integration—when necessary—of application components into a platform or bundle.
- **Mobile device development:** The design and manufacturing of the end-user mobile devices with which the mobile content can be consumed.

Service Delivery Phase

In this phase the business roles are situated that transport and deliver the products and services to the end user, or prepare them to be sold through middlemen.

- **Broadcast service provision:** Preparation, encapsulation, encryption (with Digital Rights Management [DRM]), and multiplexing of the content so it can be delivered to the mobile devices via the BNO. An actor called the *datacast service operator* usually performs this role.
- **Broadcast network operation:** Operation (but not necessarily ownership) of the broadcast network. This can be combined with other networks. If a business actor, for example, already operates a DVB-T network,

they could be a more logical party to operate the DVB-H network.

- **Mobile network operating:** The operation and management of the mobile cellular network. This business role will be relevant if mobile broadcasting is integrated with a mobile cellular network.
- **Mobile service providing:** This role constitutes a layer between the MNO and the end user. Most often, this role together with the role of mobile network operation is performed by a single actor, which we call an MNO. A *mobile virtual network operator* (MVNO) stands for a special case of a business actor that provides network services to customers without owning the physical network infrastructure, but does sell mobile services to end users.
- **Application service providing:** The daily management and ownership of the (interactive) application service platform built by the application integrator.
- **Electronic device retailing:** The selling of handsets to end users. MNOs can also perform this role through the subsidisation or marketing of specific devices.

Service Consumption Phase

In this final phase the roles are situated that are related to consumption. Usually they are performed by a single actor (the end user), but they can also be unbundled, for example, in the case of a company buying a mobile device or mobile connectivity for its employees but not paying for the content or application consumption by the employees. One of the key questions is to what extent the different services will be combined into a single bill (and thus offered by a single customer owner). The roles are:

- **Broadcast content consumption:** The consumption of the broadcast content.
- **Mobile connectivity consumption:** The consumption of mobile connectivity services.
- **Interactivity consumption:** The return channel will usually but not necessarily run over a MNO's network. If broadcasters decide to sell mobile digital TV services to mobile TV-only devices, they could opt, for example, to use the fixed Internet as a (non-synchronised) return channel, instead of the mobile network.
- **Mobile device purchasing:** The act of purchasing the mobile device, be it a cellular plus DVB-H-enabled device or a stand-alone mobile TV terminal.

It should be noted that no single "service provider" role is included in Figure 3. Most business model literature assumes a unique service provider entity that ensures customer acquisition, billing, and customer care—in short, that possesses "customer ownership." However, in a potential unbundled market, it has to be envisaged that every provider, operator, retailer, or aggregator role can establish such a relationship with the end customer. Therefore, our design approach does not define customer ownership and the activities it entails as a specific role, but will rather treat it as an attribute that can be associated with several roles.

Technology Design

This section will describe the specific technology designs of each pilot, such as the network standard adopted for the pilot and what technological application choices were made. The following criteria were used to describe the technology design.

a. **Technical network architecture and device design:** This first criterion describes the network standard(s) that were adopted during the pilot, and that will possibly be adopted during commercialisation. For ex-

ample, the pilot participants could choose to build a standalone DVB-H network or a hybrid network such as a DVB-H network on top of a DVB-T network, and combinations of DVB-H or DAB-based standards with second generation (2G), 2.5G, or 3G networks as return channel. Also, the end user device used during the pilot is indicated.

b. **Interactivity:** This criterion refers to the kinds of interactive applications and functionalities that were developed during the pilot. This could include one button voting, voting via short message service (SMS), upload functionalities, or other forms of interactive applications.

c. Content protection: This entails the encryption or other security technology used, in order to protect the broadcasted content from being intercepted and/or re-used via other channels.

d. Electronic service guide (ESG): This criterion describes the technical standard chosen for the ESG. While the Electronic Program Guide (EPG) refers to the visual interface shown to the end user, the ESG is a structured document that contains information on all available services. With an ESG one can for instance describe whether a delivered service concerns a video game, home banking, or shopping.

Service Design

The service design dimension describes the specific characteristics of the developed end-user services, such as the degree of user interactivity allowed during the consumption of the services, and the different service bundles presented to the end user.

The potential services that can be delivered within a mobile digital TV value network to the end users can be situated along a continuum ranging from very low interactivity to high interactivity (see Table 2), which will influence the degree

Table 2. Potential mobile TV services

Scale of interactivity	Service
Low interactivity	• Standard broadcast TV channels • Special Interest TV: Niche content TV channels • Electronic Program Guide, personalised for the user • Pay-per-view TV • Scheduled content push or 'Near-Video-on-Demand' • Video on Demand • Mobile TV with integrated location-based services • Mobile TV with on-demand additional information services • Mobile TV with integrated e-commerce applications • Mobile TV with interactive entertainment services such as voting and gaming
High interactivity	• Mobile TV with video upload services • Social networking video applications

to which the mobile broadcast channel needs to cooperate with a mobile return channel.

Mobile phones have proven to be excellent conduits for interactivity using SMS. While SMS voting proves to be very popular while watching TV programs, the limitation of SMS lies in the simplicity of the interaction. For more sophisticated applications—such as allowing viewers to participate in game shows alongside the televised contestants—SMS is not convenient.

Local services can provide viewers with information on a city or region, such as weather forecasts, trailers of movies featured locally, and a teletext guide. With an interactive channel, viewers can request specific information. However, because a standard middleware interface is currently lacking, some further development is necessary before viewers will be able to trigger interactive services directly from the broadcast system.

As a rule, most TV content services listed previously will be delivered most efficiently over a mobile broadcast network. In contrast, interactive services will usually be delivered following a point-to-point distribution model over UMTS or, if the slower speeds are acceptable, over General Packet Radio Service (GPRS) or via SMS (Pilz, 2005). However, it is important to note that broadcast standards such as DVB-H can be used as stand-alone solutions for the delivery of low-interactivity services including near-video-on-demand.

Interactivity may be especially important when trying to reach the first adopter market segment. This segment is generally acquainted with on-demand content consumption such as personal video recorders (PVR), cable TV video-on-demand services, and the Internet and might consider a pure broadcast offering as a step back towards scheduled programming, with fixed viewing times of each show. Pre-downloaded content, which can be consumed when the end user has time to "snack" content, might prove to be at least equally popular. Nokia actually has a service called "Nokia Media Charger," that allows for push delivery of rich content.

The following criteria were used to describe the ways in which the service package was presented to the end users.

a. **User involvement:** This refers to the degree of interactivity experienced by users. User involvement can vary from low (no end-user involvement/interaction) to middle (user can give input, e.g., vote), to high (user can generate and post his/her own content). The degree of user involvement depends on the network characteristics, the chosen return channel, and the implementation of interactive technologies from the technology design.
b. **Product bundles:** This criterion describes the kind of product bundle that is offered to the end user. This can be a *package* (user takes a subscription on a collection of channels and does not have the authority to add or delete channels), *modules* (user can take a subscription on individual channels or theme packages), *individual views* (user can chose individual shows), or *hybrid* (mixes of the aforementioned bundles). Other product bundles that are possible are bundles with existing TV channels, bundles including new channels for specific mobile content, bundles with digital radio, bundles with interactive services, and so on.

Finance Design

Finally, the financial design criteria in this context relate to the costs of the network build-out, the revenue sharing agreements, and the business-to-consumer billing formulas.

In most pilots, no revenues were generated, and no revenue-sharing agreements were negotiated. However, during the interviews some executives provided information on how these financial matters might be resolved during commercialisation,

and this information is included in the pilots' descriptions.

The following criteria were used to describe the financial design decisions:

a. **Cost sharing agreements:** This first financial criterion describes how different actors carry the costs of the service roll-out. Three cost categories are taken into account. First, the **device cost** refers to the primary purchase cost of the handsets and to what degree the consumer has to pay the entire cost of the handset, or whether device subsidies are allowed. Second, the **network infrastructure costs** refer to the cost of building the transmission infrastructure. Third, the **content and application costs** refer to which partner carries what part of the content and/or application development cost. Besides the traditional approach, where content is aggregated by a traditional broadcaster, and applications are developed by or on behalf of a MNO, these efforts (and subsequent costs) could also be borne by other actors. For instance, a MNO could develop mobile TV content by purchasing and aggregating programs under his own brand, or even by building or acquiring a TV station of one's own.
b. **End-user billing:** This criterion describes the ways in which the user pays for the services provided. The billing formula will depend on the kinds of product bundles offered, but does not follow directly from that criterion. For example, being able to select individual shows does not necessarily imply pay-per-view pricing. Three basic end-user billing models can be distinguished: subscription based, pay-per-use, and free-to-air with advertisements. Between these three pure forms of revenue generation, any number of hybrid combinations can also arise.
c. **Revenue-sharing agreements.** The last criterion describes the ways in which the service supplier(s) agree on how the revenues generated through end-user billing are distributed throughout the value network, including the broadcasters, other content providers, and the MNOs.

CASE STUDY ANALYSIS

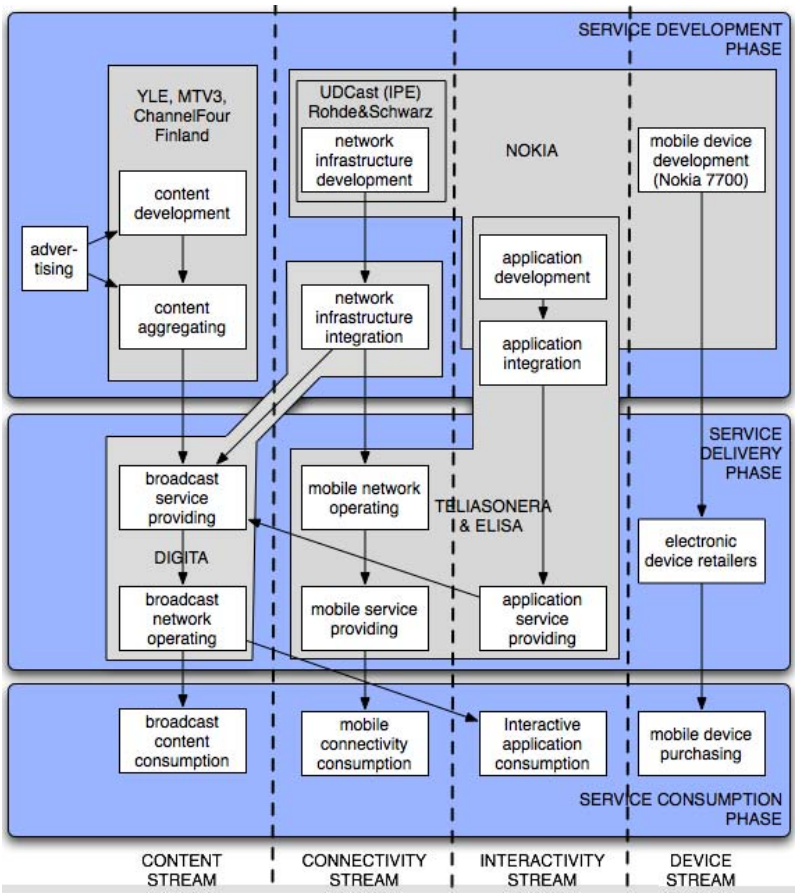
This section systematically compares a selection of European pilots using the framework defined previously. Five of the largest and most documented pilots (four DVB-H pilots and one DAB-IP pilot) were selected, that is, in Helsinki, Berlin, Paris, Oxford, and London. They were analysed using publicly available info, telephone interviews, and e-mail interactions with key pilot participants.[2] First, the organisational design of each pilot is addressed, highlighting the respective cooperation model. Next, the technical, service and financial design repercussions of these models are outlined.

Organisation Design

In this section the organisational cooperation that arose between the different pilot partners during the pilots is illustrated. Each figure is accompanied by a list of the roles performed by the business actor involved. When information could be obtained about the business roles and value networks during the future phase of commercialisation, the text expands on this issue. The information presented here is based on interviews with executives and publicly available pilot presentations.

Figure 4 illustrates the cooperation model adopted during the Helsinki trial. Note that the visual overlapping of one business actor by another, such as Nokia encapsulating UDCast and Rohde & Schwartz in Figure 4 does not imply that UDCast is a department of Nokia, but that different actors mutually performed different segments of the business role of "network infrastructure development" in the example below.

Figure 4. Helsinki pilot cooperation model

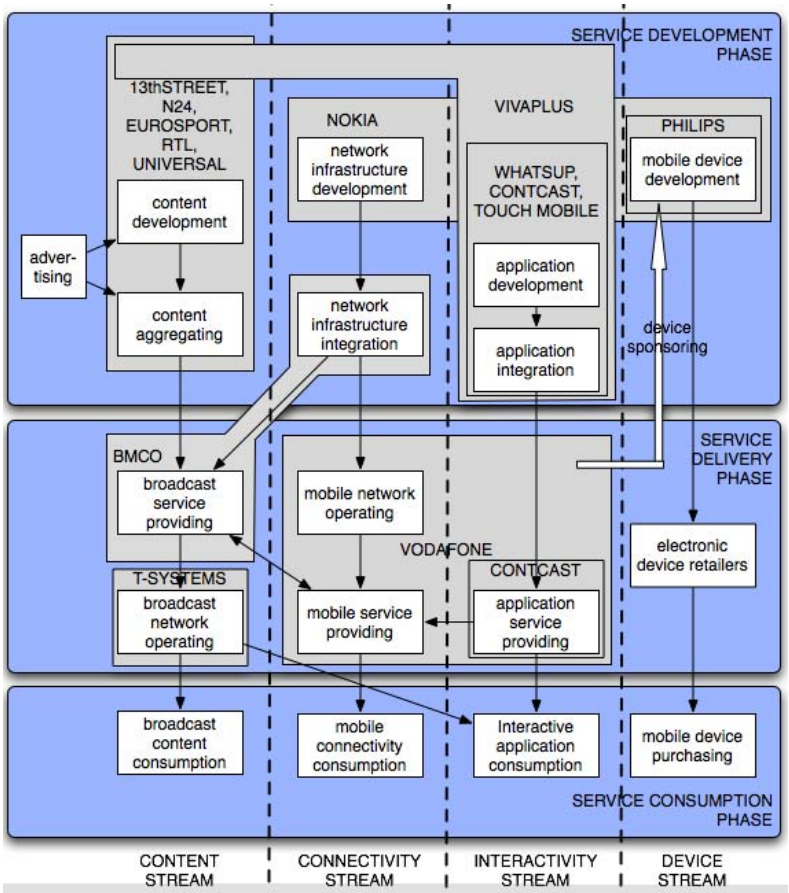


In Finland the MNOs Teliasonera and Elisa retained customer ownership during the pilot by offering the TV content service to the end users and offering help desk support. Nokia used the pilot to focus on the further development of its mobile service platform (later branded as Mobile Broadcast Solution or MBS 3.0). Digita (a unit of the French media group TDF) is the builder and owner of the DVB-T network in Finland. It used the pilot to learn about the pitfalls of rolling out a DVB-H transmission network. This practical experience proved fruitful when in March 2006 Digita won the Finnish DVB-H license beating Elisa, TeliaSonera, and Telemast Nordic. In May 2006 Digita announced that it had signed a contract with Nokia to use its DVB-H platform for the service. By the end of this year, Digita plans to reach 30% of the population by providing coverage in the Helsinki region as well as the cities of Turku, Tampere, and Oulu. Digita will hold the license for a period of 20 years.

During commercialisation, it is foreseen that Digita will adopt two business roles: broadcast service providing and broadcast network operating. Digita will be solely responsible for the management of the DVB-H digital multiplex and the transmission network, but will not offer mobile TV services directly to any end customers. The license includes a condition under which the license holder is obliged to sell network capacity to service operators. Digita will as BNO utilise an open network model for the DVB-H network, by offering access to the broadcast network to all service providers under equal, fair, and transparent terms. The role of *network infrastructure integration*, performed alone by Digita during the pilot given the lower complexity of the pilot context, will during commercialisation be jointly performed by the MNOs and Digita.

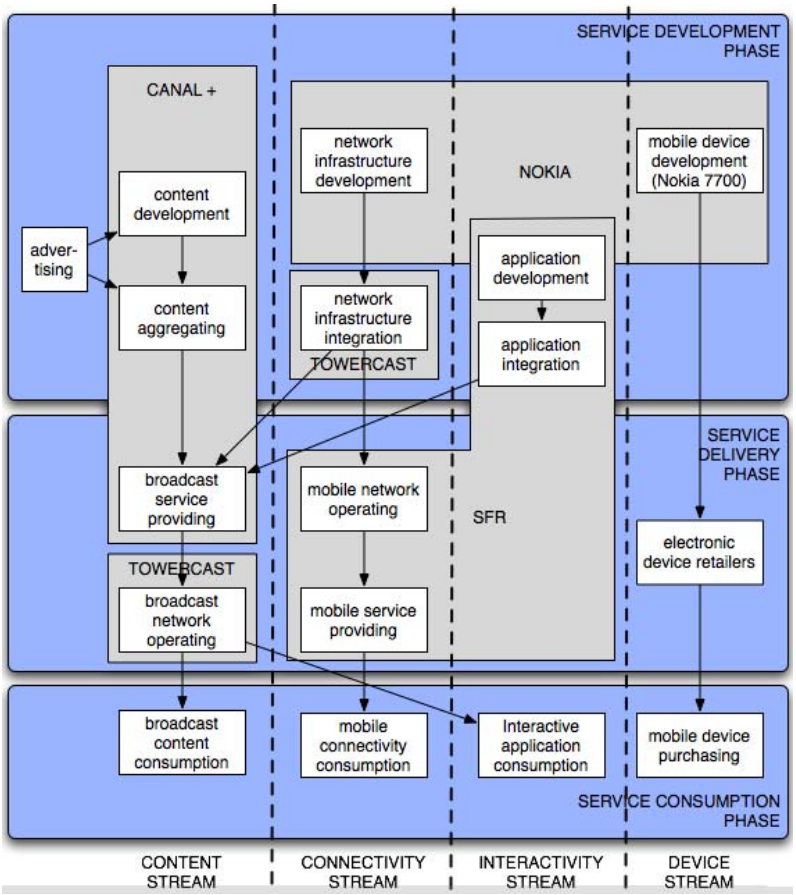
The basic cooperation model in the pilot, where Digita functioned as a common broadcast service provider for competing mobile operators, will nevertheless be replicated in the commercialisation phase, in which Digita will provide open access to its DVB-H platform to various service providers. Also, while functional roles related to broadcasting will remain in the hands of Digita,

Figure 5. Berlin pilot cooperation model



and will not be taken up by mobile operators, these mobile operators (and possibly other service providers) will most probably leverage their existing customer base to act as integrated service providers towards the customer (see also the sections on service and financial design). Figure 5 illustrates the cooperation model adopted during the Berlin trial. The role of broadcast network operator was taken by T-Systems, being already the DVB-T network operator in Berlin. During the pilot phase, half of a T-Systems DVB-T multiplex was used for DVB-H transmission, while the other half continued to provide commercial DVB-T programmes without any problems. This did cause the number of available TV programs to be restricted to four channels. BMCO provided network infrastructure integration and broadcast service provisioning. GPRS was used as the return channel (Sattler, 2005). Vodafone retained customer ownership and partially outsourced application service provision to Contcast. The development of the Berlin City Guide, ring tones downloading, and Get the Clip applications entailed cooperation between content aggregators and application developers.

Figure 6. Paris pilot cooperation model



During the commercialisation phase, it is expected that MNOs such as Vodafone will apply for a license to broadcast DVB-H. They will need to cooperate with an actor that has a media license, which is the local government's responsibility. While in Germany the spectrum license is handed out by the Bundesnetzagentur on a national level, the media licenses have to be applied for locally, namely each of the 15 regulators of the 16 federal states.

Already in the cooperation model used during the trial, and different from the Finnish model, there is a split between the BNO (T-Systems, the current DVB-T network owner) and the broadcast service provider (a consortium including Vodafone), which can be explained by the fact that two competing network operators are involved as network owner and network user, respectively. Figure 6 illustrates the cooperation model adopted during the Paris trial.

Until now, four multicasting pilots have been conducted in France, of which one was based on the DAB-IP standard, and three others based on the DVB-H standard. While the pilot under review here combined Towercast, Nokia, SFR, and Canal+Group, the other pilots used Sagem phones (instead of Nokia), and had TDF as BNO (instead of Towercast). The other pilots also involved more MNO partners (Orange, SFR, and Bouygues Telecom), and more content aggregators (TF1, TPS France Television, Radio France, and RTL, among others).

During the pilot described here, a DVB-H only pilot network was built and operated solely by Towercast. Also during the pilot, Nokia worked together with SFR for the development of the service platform. Canal+Group retained customer ownership.

During commercialisation, the DVB-H network is not expected to be built by the MNOs, but by TDF or Towercast, who are currently involved in constructing a DVB-T network. In France, no DVB-T operating licenses have been issued yet. Before analogue switch-off only one multiplex per French region is expected to be in place. In the commercialisation phase, it is expected that Canal+Group will come to market with an offering that will also target devices that only have mobile TV functionalities, without an integrated mobile phone. According to the interviewed executives, MNOs that come to market with a DVB-H brand will always choose a service that targets DVB-H + mobile phone terminal devices and will not introduce a second line of terminal devices that do not have integrated mobile telephony.

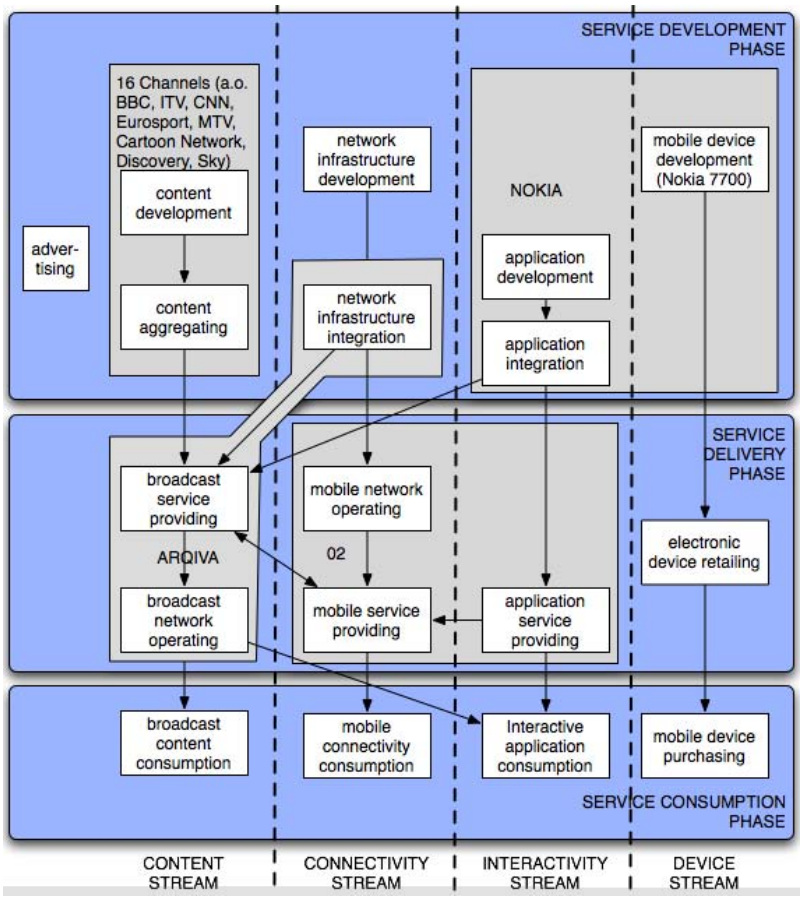
Again, it is interesting to see that the cooperation model in the pilot, in which broadcaster Canal+Group took an important role and combined the roles of content aggregation and broadcast service providing, will be mirrored in the commercialisation phase, in the sense that the broadcaster will probably come up with specific offers towards end customers, and thus will be competing with MNOs for the mobile TV market. Figure 7 illustrates the cooperation model adopted during the Oxford trial.

A DVB-H-only pilot network was built by Arqiva, while O2's network bandwidth was used as mobile telephony channel. Arqiva is also the company developing and implementing the digital terrestrial network for BBC, one of the digital terrestrial license holders in the UK.

During the pilot, all actors involved focused on their core competence. Nokia delivered the service platform software to Arqiva and mobile terminals to O2. The content suppliers provided content for the DVB-H broadcast, but did not interfere with the broadcast service provisioning side. The MNO O2 focused on mobile network operating, application service provisioning, and mobile service provisioning. The BNO Arqiva did have a more expanded role when compared to the Berlin or Paris pilot, in that it simultaneously performs the roles of broadcast provisioning and network operating. In the next pilot, Arqiva is restricted to broadcast network operation.

The Oxford pilot cooperation model is similar to the Helsinki pilot, in the sense that Arqiva

Figure 7. Oxford pilot cooperation model

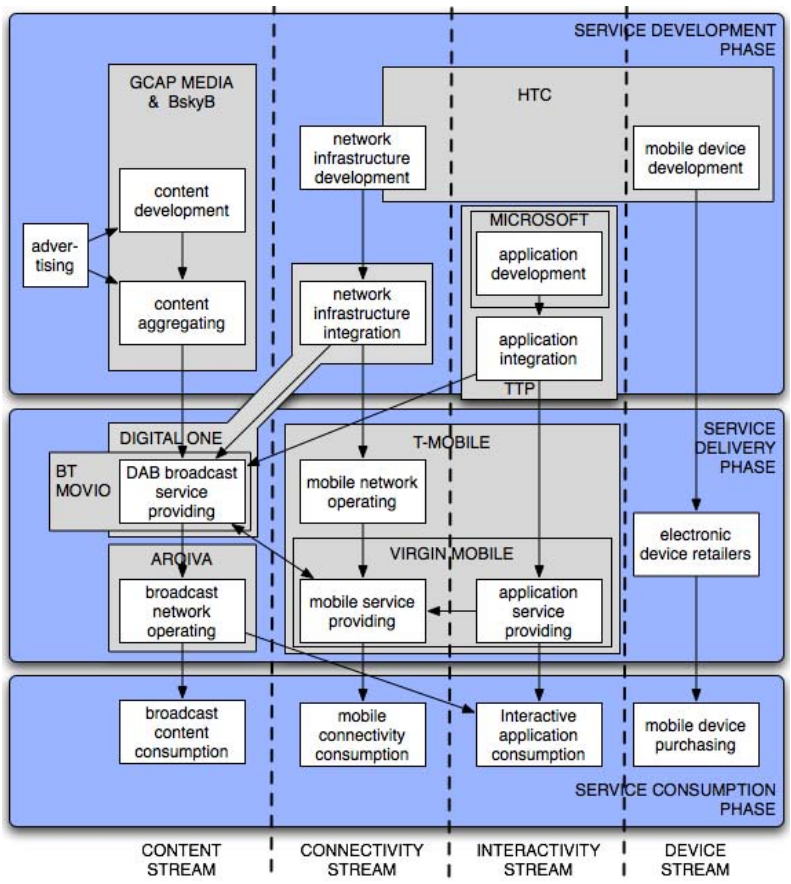


provided and operated the platform on which an MNO offered its services. The difference with the Helsinki trial is that no competing MNOs were involved in the Oxford pilot. There is little information on the commercialisation trajectory envisaged, but it may be expected that the MNO will want to retain full customer ownership. Figure 8 illustrates the cooperation model adopted during the London DAB-IP trial.

During the pilot, BT Movio, which leases 20% (later 30%) of the spectrum capacity on Digital One's DAB network, led the network build-out effort and acted as middleman between the content aggregators and the MNOs. The radio and TV content were delivered over the DAB-IP transmission network built by Arqiva, while T-Mobile's network was used as the return channel for additional interactivity and mobile telephony. T-Mobile offered Virgin Mobile, mobile network access, allowing Virgin Mobile to adopt the role of MVNO.

During commercialisation, BT Movio will probably act as a middleman between the owner of the broadcast network (which will be GCap

Figure 8. BT Movio London pilot cooperation model



Media, see next section on financial design) and the content aggregators, by offering a bundled wholesale package of broadcast access plus bundled content to the MNOs.

The pilot cooperation model already demonstrated the BT Movio wholesale model by leasing capacity from existing DAB network owner and granting access to MNOs and MVNOs under specific terms, as will be continued in the commercialisation phase.

Technology Design

The first technology design choices to be made concern the end-user devices and the network standards adopted during the pilots.

Three out of four of the DVB-H pilots built a DVB-H only pilot network, while in Berlin the network was built on top of DVB-T, which had an effect on the amount of TV content channels that could be used in Berlin. The Nokia 7710 was the dominant device during the four DVB-H

pilots. Only the Berlin pilot also conducted tests with another device, the Philips HoTMAN2. The London pilot used a smart phone developed jointly by BT, TTP, and HTC, and adopted the DAB-IP network standard.

Most users considered the Nokia 7710 as too big and unpractical. The Nokia N92 that is now arriving in the market is user friendlier, according to interviewed executives.

In most cases it is currently unknown what specific network technology choices will be made for the commercialisation phase. For instance, most pilots opted for DVB-H stand-alone configurations and many interviewees stressed the need for as many channels to be available as possible. On the other hand, the fact that in most cases DVB-T or DAB network owners were actively involved in the pilots seems to suggest that the mobile broadcast networks will be combined as much as possible with existing infrastructure.

Another design decision is whether the interactive applications that were developed during the pilots will have a direct effect on the degree of end-user interactivity in the service design (see section 5.2). Limited, "red button" interactivity was present in most pilots. The Paris pilot, in which broadcaster Canal+Group was the main actor, stands out as the only pilot where no extended forms of interactivity were developed, and where the focus remained primarily on downstream content delivery. The partners involved in the Berlin pilot developed the most interactive applications, that is, one-button voting for music videos, push of cinema trailers (users could then book cinema tickets directly through an interactive application), and the download of ring tones (a list of ring tones corresponding to currently played songs was broadcasted. Ring tones could be downloaded via the cellular network).

Concerning content protection, Berlin and Oxford did not implement content protection, considering the pilot context a controlled situation. While Helsinki adopted Nokia's content protection solution, Paris opted for the alternative conditional access through a SIM-card solution. Within the DAB-IP pilot, the industry participants opted for Windows Digital Rights Management solution. Interviewees stated that the choice of standards to be adopted during the commercialisation phase is an issue that will have to be cleared with the content owners beforehand. All observers agree that the choice of DRM is highly strategic and closely connected to the organisational design. If there is no lock-in by a SIM card, this might prove more interesting for actors who do not have a vested interest in mobile networks. Operators that do not have investments in a mobile network will not opt for a SIM-based solution, since this ties the customer to a MNO. Technical arguments can be given on why the SIM-based solution is still suitable in an age of convergence. SIM is a proven solution that provides a high level of security and reliability. But with the advent of converged services, using one service to tie the customer to a series of other services is experiencing pressures from non-MNO players.

Concerning the ESG, within the DVB-H field there are two camps with regard to the ESG standards (Yoshida, 2006). Nokia implemented its own version of the Open Mobile Alliance's OMA-BCAST specification on its DVB-H handsets, in a move against proponents of digital video broadcast-convergence of broadcast and mobile services (DVM-CBMS). Because of this rift, the two camps are promoting different ESGs. The Finnish and German Pilot adopted Nokia's non-standardised ESG, while in Paris the competing solution was chosen. Interviewed executives, even from pilots where the Nokia ESG was used, expressed doubts whether the Nokia non-standardised solution will be broadly adopted. In the DAB-IP pilot BT Movio developed a proprietary ESG.

Service Design

Given the aforementioned organisational and technological design decisions, the business actors then proceeded to offer the test users access

to a variety of service packages. The service bundles that were offered mostly consisted of TV content, but in some cases content was enriched with interactive applications.

The Helsinki pilot ran from March until July 2005. Five hundred test users received a basic package, which consisted of seven "free to air" television channels and three radio stations. In addition to the basic package users could subscribe to a supplementary package of seven premium service television channels. For some special events, like the Formula 1 Grand Prix in San Marino and Monaco, users had the possibility to buy one day's access in a pay-per-view model for $.50 a day.

The Berlin pilot started in July 2004 and took 8 weeks, during which the 20 test users had access to four television channels, one interactive channel and an interactive city guide of Berlin. The four television channels, with exception of the news channel, concentrated on the entertainment potential of mobile television.

In Paris, the pilot was conducted from September 2005 until June 2006, with 250 users. Access was provided to 10 television channels, four radio stations, and one channel that offered short programs to watch on mobile television (SFR TV). The user had also the possibility to subscribe individually to three additional channels or to choose the entire package of the three channels (Canal+, Sport+, and CineCinema Premier). Furthermore the user could watch additional content through a pay-per-view model.

In the Oxford pilot, which started in June 2005 and ran for 6 months, 400 users were offered 16 television channels among which 12 free-to-air channels, three pay-TV channels and one made-for-mobile channel: ShortsTV, a channel which offers short programmes developed for mobile television.

In the London pilot, BT Movio and Virgin Mobile let 1,000 users test their mobile digital TV service in the region of London, inside the M25 highway area. The users of this pilot were able to access three television channels and 52 radio stations.

It was already discussed shortly whether forms of interactivity were offered to the end user. Usage of an EPG is considered as the most basic form of interactivity. Additional types of interactivity were found in Berlin, Oxford and London.

In the Finnish pilot the focus was on TV content delivery, and interactivity was limited to the use of the EPG and some on-demand downloads (Sandell, 2005). In Berlin users were able to consult movie trailers and book cinema tickets for Berlin movie theatres through the What's Up application. The Vivaplus application was an interactive music channel where users could vote for music clips. Finally, users could download ring tones that were delivered over the cellular network. In Paris, besides the interactions with the EPG some on-demand downloads were possible. In Oxford users were able to record short content to their mobile device. In the London trial, the degree of interactivity was not very high. Although the user could use the red button functionality, a proportion of them were afraid to use it because of lack of good communication towards the user, concerning the price of each interaction.

The section on financial design will detail the customer ownership models in the pilots. It can already be stated here that most interviewees agreed that cooperation between business actors on the service design level is necessary in order to offer the consumer an integrated package.[3] It would be too confusing for consumers if they have to buy access from a separate firm, and their content from another firm. The consumer will expect that the purchase of network access will come together with a reasonable amount of basic content. Therefore, the MNOs (supposing most do retain full customer ownership) will have to negotiate content deals in order to be able to offer attractive packages.

The youth market (ages 18-35) is considered as the most important market segment for mobile TV (Page, Watt, & Menon, 2005), so it is expected that

content aggregators geared towards the youngest demographic segment such as music TV stations, will have important bargaining power as part of entering the bouquet. Jason Hirschhorn, MTV's chief digital officer, has stated that MTV would enter into discussions with operators over an advertising-based business model (Best, 2006).

While the chances are slim that telecom operators will massively start developing or commissioning the development of content on their own, it is very probable that the content aggregators will also develop interactive applications or services alongside their TV content. But as a rule it is foreseen that existing content aggregators will provide most of the video content, while MNOs will mainly develop the interactive services. Therefore, cooperations between the MNOs and the broadcast service platform will have to be guaranteed for interactive applications that can run over DVB-H.

Concerning time-shifting services, design choices between near-video on demand (near-VOD), VOD, and PVR have to be made. MNOs appear to favour VOD most, since this offers an opportunity to utilise their 3G property. Near-VOD, where content is downloaded at an earlier point in time (e.g., overnight) ranks second, but PVR creates tensions with the content aggregators. In reality, it is feasible that a hybrid solution will be implemented to circumvent the content industry's doubts about copyright protection. In this solution, content can be downloaded at an earlier time, but a one-time activation over a mobile network is then necessary to unlock the downloaded content. Content providers do not prefer lock-in by a SIM-based solution, since this hampers the amount of platforms they can offer their content on. Ideally, only one encryption scheme is used across several platforms.

Financial Design

In this final section, the financial design decisions taken during the pilots and the possible repercussions on the commercial financial design are described. Three design criteria are considered: (1) the sharing of the infrastructural cost, (2) the pricing of the product bundle offered to the end users, and (3) the revenue sharing arrangements (if any) among the different partners involved. It needs to be noted that during the pilots little to no revenues were generated, except in the Helsinki pilot and the London DAB-IP pilot. Therefore both revenue and cost-sharing agreements were rare to nonexistent during the pilots. Contacts with executives from the different pilots did however offer some insight into the financial arrangements that could arise during commercialisation. If not mentioned otherwise, the pilot costs incurred were carried by each individual pilot participant individually.

Concerning who will bear the cost of network roll-out during commercialisation, the discussions are still ongoing within most pilot consortia. In most countries there seems to be a movement away from cooperative models that were considered in a number of pilots, where various partners jointly funded the DVB-H roll-out, towards a wholesale model, where a single entity deploys and funds the roll-out of the network, and then gets the right to resell it. Some variation can arise on who will be able to resell access to the platform to interested parties. The wholesalers are not necessarily the actors with existing DVB-T or DAB networks (see BT Movio). In Germany, where T-Systems is currently building out the DVB-T network, the situation is still unclear on who will apply for the service licenses, and who will fulfil the role of reseller.

Only during the Finnish, French, and the London BT Movio pilot the end users were billed (and only some in the French case). No specific total amounts were made publicly available of the revenues collected, though. The pricing plans of the partners does show that all the MNOs are planning on retaining customer ownership. Only in France Canal+Group is counteracting this logic by also planning to include a mobile

digital TV subscription in its pay-TV bundle. It is expected that some pay-TV business actors in other European countries (e.g., Sky in the UK) will follow this example.

Concerning customer ownership, most MNOs are aiming to leverage their intimate customer relations during the DVB-H roll-out. But in each country any actor that has a customer base such as pay-TV broadcasters (France) or MVNOs (UK) may wish to be able to extend their service offering towards their customers.

Given the informal character of the pilots, no revenue-sharing arrangements were negotiated. Interviewed executives did express numerous hypotheses on what they thought would probably happen during the commercialisation phase. However, it was clearly expressed that the revenue split would be primarily between the end user service provider ("the customer owner") and the broadcast service provider ("the spectrum owner"). Although only a limited amount of data were available on the financial design from the pilots and the subsequent commercial roll-outs. However, at least some information could be obtained on the commercialisation phase. It appears that the license holder (or the party that leases spectrum from the license holder) on the one hand, and the customer owner (the actor that sells the subscription/service to the end customers) on other hand will divide the lion's share of revenues between them. Some anxiety among the content aggregators that occupy neither of these roles about revenue-sharing agreements that might be suboptimal for them was already reported in a few pilots.

CONCLUSION

This chapter aimed to provide a detailed and systematic analysis of the issues for bringing mobile broadcasting to market, and of the solutions found in five major pilots throughout Europe. We focused on organisation design, and in particular on the cooperation models employed by various stakeholders during the pilot phase.

Various cooperation models were found, specifically regarding the roles of broadcast service provider and BNO. It became clear that pilot cooperation models in this sense already foreshadow envisaged business models in commercialisation phase. However, some significant differences were found and reported in this chapter, particularly regarding the (types of) actors assuming the new and important role of broadcast service provider, and on the (types of) actors assuming customer ownership.

In Helsinki and Oxford, the role of BNO and the role of broadcast service provisioning were performed by one actor. In the other cases different actors performed these two roles. This split of responsibilities is expected to persist in many cases during commercialisation, with BNOs, content aggregators, MNOs, and intermediaries all taking an interest in broadcast service provisioning and/or spectrum ownership.

The business responsibility of customer ownership includes customer acquisition, end-user billing (including handling bad debt), and customer care (help desk support). The BNOs did not retain customer ownership in any pilot, nor did the broadcast service providers or the content aggregators (such as broadcasters), except in France where a content aggregator (pay-TV channel owner Canal+Group) retained customer ownership alongside one MNO (SFR). This scenario is expected to repeat itself during French commercialisation.

Concerning technical design, a majority of European pilots has chosen the DVB-H standard, although a sizeable minority opts for DAB-IP/DMB. It is not entirely clear to what extent the new mobile technologies will be tied in with the existing DVB-T and DAB networks, but given the cost advantages and the involvement of current DVB-T and DAB network owners, coupling, at least to a certain degree, seems probable in most countries. It also became clear that organisational

arrangements (e.g., whether MNOs or broadcasters respectively took the lead in the project) affected technical design decisions such as the selected standard for the ESG, or the degree of interactive applications.

In terms of service design, the pilots experimented with a wide variety of product bundles, subscription and pay-per-view schemes, and usually—but not necessarily—including some forms of interactivity. The combination of basic packages with premium packages was widespread throughout the pilots.

Regarding network roll-out, there seems to be a move away from the cooperative models (i.e., various partners jointly funding the roll-out) that were at one time considered in various pilots, towards a wholesale model, where a single entity deploys and funds the entire roll-out and then resells access to various service providers. These wholesalers are often actors currently owning or building out DVB-T or DAB networks, although not necessarily so, as the BT Movio example demonstrates. In Germany, where telco T-Systems is currently building out the DVB-T network, the situation is still unclear. In most cases, the MNOs seem to limit their involvement in the infrastructural effort to opening their network for the placement of repeaters necessary for full coverage.

Most of the MNOs aimed to leverage their current customer base into the mobile broadcasting arena. But other types of actors with an established customer base such as pay-TV broadcasters (France) or MVNOs (UK) also showed interest in acquiring access to the platform, or acquiring a service license, in order to offer mobile TV services directly to customers themselves.

Finally, from the information available, it appears that the spectrum owner (i.e., the license holder or the actor that leases spectrum from the license holder) on the one hand, and the customer owner (the actor that sells and guarantees the service to the end customer) on the other hand will divide the lion's share of revenues among them. Several content aggregators that neither own spectrum nor have direct customer ownership have expressed fears that revenue share agreements may turn out to be suboptimal for them. The evidence gathered here suggests that these fears may well materialise.

ACKNOWLEDGMENT

This article is based on results from the MADUF project (IBBT project 0052), which is funded by the IBBT (Interdisciplinary Institute for BroadBand Technology) of Flanders, Belgium, as well as by various partner companies. The authors gratefully acknowledge their interview partners for the information provided on various mobile TV pilots, as well as Dr. Jo Pierson, Katrien Dreessen (both IBBT-SMIT), and the other MADUF partners involved for their insightful comments and suggestions.

3 It was not within the scope of this chapter to assess the way the new service was experienced by the end users. Most pilots reported favourably on the way their service was received by the end users. Nevertheless, some critical results can be quoted. Users were not happy with some of the first generation devices such as the Nokia 7710, which were considered too heavy and clumsy. Also, users complained when there were not enough channels available, a result recorded during BT Movio's DAB-IP pilot (three TV channels) and the German pilot (four TV channels). Finally, the BT Movio pilot proved that users were reluctant to use interactive applications if the pricing model was unclear.

Chapter 3.34
The MP3 Player as a Mobile Digital Music Collection Portal

David Beer
University of York, UK

INTRODUCTION

MP3 players are often described as *music collections in our pockets* or the *pocket jukebox*. Indeed, it would seem that MP3 players have significantly transformed music collections, music collecting practices, and contemporary understandings of the music collection. The MP3 player may be used to store, retrieve, and reproduce digital music files, and, therefore, it can be described as a portal—if we define the term portal as an entrance, doorway, or gateway—into these simulated (Baudrillard, 1983) mobile music collections. It is an interface between the human body and archives of digitally compressed music. This can perhaps be understood as constituting a kind of *musical cyborg*, a cybernetic organism, a hybrid of human and machine (Haraway, 1991). The MP3 player, in this hybridised sense, is a gateway into the digital, virtual, or simulated (Baudrillard, 1983) material cultural realm of music, a mobilised cyber-collection. The question then is what becomes of the music collection and the music collector when music shifts from the objectified disc and spool to the digital compression format and MP3 player portal? And, what are the social and cultural implications of the MP3 player portal's increasing pervasiveness and embeddedness in the flows of everyday life? The purpose of this article is to briefly introduce and discuss these questions alongside some of the technical details of the MP3 player. This article aims to use the material and technical details and definitions of the MP3 player to open up a range of possible questions that may be pursued in future research in this area. I will begin by defining the MP3 and the MP3 player.

BACKGROUND: MP3

The MP3 player, such as those manufactured by Sony, Creative, and Apple, can perhaps best be understood as a music retrieval interface that provides a portal for its appropriator to access an archive of digitally stored music files. These

may be selected and reproduced or illuminating the increasingly inert user, the device may select the tracks on behalf of the listener. An example of this is the *Shuffle* function on the Apple iPod (see next). This extension of the random play function of the compact disk (CD) player can perhaps be offered as an example of the increasing intelligence of the machine and the increasing inertia of the appropriator (Gane, 2005; Kittler, 1999).

According to Duncan and Fox (2005):

One of the oldest—and probably best known—compression/decompression formats (codecs) is MP3. It is popular with users for its near-CD quality and relative high speed of encoding and decoding. It is less popular with the music industry because it lacks controls to prevent copying. (Duncan et al., 2005, p. 9)

MP3, an abbreviation of *Motion Picture Experts Group One Audio Layer Three*, originated in 1991 as a system for broadcasting media files. MP3 is a file compression format that has the capacity to reduce music files to around one-twelfth of their original size (Mewton, 2001, p. 25), thus making the transfer across the Internet far more rapid and the space required to store the music much smaller. However, and contrary to the utopian rhetoric of the information or digital age, these are not perfect reproductions. The process of compression removes elements from music files so as to reduce them in size effectively; this leads to some of the subtleties of the music being removed. This then is a somewhat alternative vision to the perfect and infinite reproducibility that digitalisation has come to represent.

The MP3 format can be understood to have mobilised the music collection by compressing it, or miniaturizing it (Haraway, 1991), to fit into these pocket sized retrieval and reproduction devices.

THE MP3 PLAYER

The MP3 player, then, is a device that may be networked with the Internet (usually) through a connection with a computer, provided that the relevant software is installed upon it. A CD containing the required software usually comes with a newly purchased MP3 player. This connection made via the USB (Universal Serial Bus), USB2, or Firewire port or connector on the back of the computer enables music files stored on the computer's hard drive or accessed directly through the Internet to be downloaded onto the MP3 player where they are stored. The MP3 player then enables the appropriator to retrieve their music and reproduce the music file, often through headphones, although a variety of technologies are now available through which MP3 players may be docked (amplifying the music through speakers around open spaces).

MP3 players vary somewhat in size but, to give an idea of dimensions, are usually somewhere between the size of a box of matches and a pack of playing cards (more exact dimensions are included in the following discussion of the iPod). However, contrary to the image this suggests, the MP3 player is not a discrete, standardised, or self-contained device that takes on a single form or design. The current trend is for the combination of MP3 players with other technologies to create hybrid devices, the most significant of which is the combination of MP3 and mobile telephone technologies. This creates always-already networked MP3 players that may access networked archives of music files and therefore, exceed the storage capabilities of an isolated MP3 player and the collecting practices of its owner. Recently, highlighting their dynamic form, MP3 players have also been hybridised with camcorders, sunglasses, and even confectionary packaging to create novelty devices.

MP3 players are highly mobile portal technologies upon which anything between around 120

and 15,000 songs may be stored, dependent on the device. The music collection is then entirely mobile and may be comfortably carried around; weight is bypassed as an inhibiting problematic. It is now a common site in the street to see people interfacing with MP3 players and other mobile music devices (mobile CD, tape, and MiniDisk players). Indeed the scale of use and the details of the practices of these cyborgs (Haraway, 1991) may well represent one of the biggest challenges facing studies of contemporary music collecting practices. This is not to mention the implications that these devices have for the human body and the everyday spaces, which they populate (Bull, 2000, Thibaud, 2003). Before developing these future research questions, and to crystallize the material dimensions of the MP3 player, I will first focus briefly on a specific example of the MP3 player, the Apple iPod.

THE iPOD

The Apple iPod (see www.apple.com) has come to dominate the emerging MP3 player market. Due to a series of high profile advertising campaigns and innumerable editorial pieces, it has obtained a high international profile. Possibly the most interesting of these advertising campaigns came in 2003. This incorporated a two-page advert, which juxtaposed images of what had become the conventional record collection, records, tapes, and CD on the left hand page, and the image of the iPod on the right hand page. This attempt to redefine or "recraft" (Haraway, 1991) the music collection had some success, although it is not clear what part, or to what extent, this advertising campaign had in this shift in musical consciousness. Yet from purely anecdotal evidence, and the sales figures available for the iPod, it appears that music collecting practices have indeed shifted to momentarily rely on the outdated dualism from the actual or physical to the virtual and non-physical.

We now find the iPod dominates contemporary music discourse; the non-capitalised "i" prefix appears frequently in media discourse to evoke the downloading phenomenon and issues related to it. Furthermore, the descendant term Podcasting (Crofts, Dilley, Fox, Retsema, & William, 2005) is now becoming increasingly widely used to describe a practice of downloading pockets of music from the Internet onto the hard drive of computers and MP3 players. A practice that numerous companies such as British Telecom and the BBC (Radio 4) are buying into, as well as musician community sites such as www.garageband.com, in addition to the vast numbers of private podcasters.

In terms of its form, there are now five distinct models of iPod on the market, these are the original iPod, the iPod Mini, the iPod Shuffle, the iPod Nano, and the new iPod with video screen. Although the iPod Mini has now been discontinued to be replaced, it seems, by the iPod Nano. These iPod's come in various sizes and have the capability to hold various numbers of songs. To highlight this, and to give some sense of scale, I will look at the iPod, with the largest memory, and the iPod Shuffle, with the smallest memory.

The new video screen iPod, which has replaced the original iPod, is available (at the time of writing) in two forms or models; these are the 30GB memory model, which holds up to 7,500 songs, weighs 136g, and measures 103.5 x 61.8 x 11mm, or the 60GB memory model, which holds up to 15,000 songs, weighs 157g, and measures 103.5 x 61.8 x 14mm. The iPod Shuffle, the smallest of the iPods, also comes in two forms, a 512MB memory model, which holds up to 120 songs, and weighs 22g, or the 1GB memory model, which holds up to 240 songs, and weighs 22g (www.apple.com/uk).

These iPod's, despite the fact that they have come to be described as an MP3 player, in fact, like the connected iTunes Internet site (www.itunes.com), use the advanced audio coding

(AAC) format. MP3 is one of a number of digital compression formats; there are innumerable other similar formats that are available such as AAC, WMA, some of which are encrypted like liquid audio for example, yet it is the dominance of the MP3 that has caused it to become the representative label for an entire series of music compression technologies.

RECONTEXTUALISATIONS AND SIMULATIONS

To return to the broader question of the implications of the MP3 player, we find that the collection is recontextualised in two senses. First, it has moved from discs to digital files. Second, it has moved the collection on mass from private domestic spaces to public spaces—thereby extending the work of the personal stereo or car stereo by providing instant access to entire music collections rather than being restricted to a tape, CD, or MINIDisk's worth.

In light of these recontextualisations, the iPod and other similar digital technologies have created the possibility for a reconsideration of the music collection. And as such, along with other digital technologies, have generated a vast series of questions around ownership and the way in which we approach material cultural artefacts. The spaces taken up by racks, boxes, stands, rooms, shelves, piles, holders, wallets, sleeves units, and record bags have been transposed onto the hard-drive. The digital music file collection takes up space on a hard drive, a kind of virtual space.

On the issue of collecting, Walter Benjamin has suggested that:

One has only to watch a collector handle the objects in his glass case. As he holds them in his hands, he seems to be seeing through them into their distant past as though inspired. (Benjamin, 1999, p. 62)

If we cannot hold and feel these collections, admire them, have them populate the spaces of our everyday lives, or present them as a concretised representation of aspects of identity, what are the consequences (Sterne, 2003)? What becomes of Benjamin's book collector and the experiences of collecting when music collections are no longer rows or piles of discs or tapes but are merely lists of artists and songs on a screen, a collection that cannot be held in the hand, touched, and smelt. Indeed the MP3 music collection never grows in a physical sense (used here in a conventional form). Rather it is a kind of simulated (Baudrillard, 1983) music collection, a collection in hyperspace, or perhaps, a hyperreal (Baudrillard, 1983) music collection that is neither real nor illusion, virtual nor actual, but rather it moves freely between these interlocked spheres, or to use Haraway's terminology, this music collection, as it is reproduced from the virtual music file into actual material sounds that reverberate around the spaces and organisms, or as it is "burnt" or inscribed from the MP3 file onto a CD, permeates the boundary between these dualisms (Haraway, 1991). This then opens up vast sets of complex and problematic questions concerning the understanding of music. One consequence of this recontextualising and redefinition of the music collection is the recent explosion in music theft in the form of music file sharing, which has lead to a number of ongoing legal battles. It would seem that the MP3 file has far exceeded the music theft possibilities of bootlegging, piracy, and shoplifting. Perhaps the removal of the object form, the physical disk, or spool, has radically transformed the notion of ownership and has created the possibility for large-scale music theft. This again is a question that requires further examination as the numerous legal conflicts ensue and conclude. These questions concern the issues of ownership and theft in the digital age, and the related issues of copyright, security, access, and encryption.

FUTURE ISSUES

The important issue from the point of view of this brief exploratory article is what future issues relating to the MP3 player require examination. These future research questions can perhaps be understood to fall into three interrelated categories: *mobility*, *ownership*, and *collecting*. The central question that informs these three categories is that of transformation and the implications of the MP3 player. These perceived transformations require rigorous empirical examination in the form of close-up analyses of the MP3 player in praxis (Beer, 2005a), the MP3 player in the mundane flows of everyday life (Beer, 2005b), in short, studies of the MP3 in/and the "richness of the ordinary" (Sandywell, 2004). To obtain even a tentative notion of transformation these studies must be historically (Sandywell, forthcoming) and culturally embedded.

Existing approaches in this area present a number of opportunities for extended study. Take for example, the empirically grounded approaches to music and music technologies in everyday life found in the work of Bull (2000, 2004), DeNora (2000, 2003), and Shuker (2004), the theoretically informed radical posthumanism of Kittler (1999) (Gane, 2005), the historically and culturally embedded descriptions of Sterne (2003), or, even, the critical or dialectical materialist approach to music technologies of Adorno (2002a, 2002b, 2002c, 2002d). We also find now an emerging and varied (practical, instructional, legal, and analytical) body of literature on music and the Internet (see for example Beer, 2005c; Jones, 2000; Mewton, 2001; Waugh, 1998), which, over the coming years, as the implications of networked communications technologies and music production and reproduction proliferate, is certain to escalate rapidly.

It is perhaps now time to consider the MP3 player as a deeply embedded everyday technology around which individualised yet networked everyday practices are structured and defined. This then requires a system of analysis that accesses these everyday practices and uncovers the complex appropriations of MP3 technologies within the broader context of the digital or information age. This is the challenge for a sociology or social psychology of music technologies, or a technologically focused cultural studies, as the MP3 player portal mobilises, re-contextualises, and networks the digital music collection.

KEY TERMS

CD: An abbreviation of compact disk. CD is a digital storage and reproduction technology commonly associated with music.

Compression Format: A technology (or software) for reducing the size of files to enable storage and transfer, some are encrypted some are not, for example MP3, AAC, and Liquid Audio.

Cyborg: A cybernetic-organism, a hybrid of human and machine, organic and inorganic. Most famously appropriated from cyberpunk literature in the social theory of Haraway and other socialist-feminist writers.

IPod: Perceived as the dominant "MP3 player" (also plays AAC format) on the market. A product of Apple (see www.apple.com).

Jukebox: A device through which selections of records may be chosen and played back, usually activated by the insertion of a coin and the depression of a series of numbered buttons corresponding to the demarcated number of the chosen record. These are predominantly found in public spaces such as bars, restaurants, cafeterias, and public houses.

MP3: A file compression format capable of reducing the size of music files to facilitate transfer and storage.

Music Collection: The practice of accumulating and storing objects on which music is inscribed. Such as vinyl records, tapes, CDs, MiniDisks, and, more recently, MP3 and other digital compression files.

Podcasting: This term is a combination of "iPod" and "Broadcasting." Podcasting is often described as musical blogging (Web Logging), by which selections of music may be accessed and downloaded in relation to chosen genres, types, and styles.

Posthuman: An emergent theory of technologies that places technologies at the forefront of the analysis. It is based centrally on the premise that technologies are increasingly intelligent and that human experience is centred around technological interfaces and interfacing. See for example the work of McLuhan, Haraway, Kittler, and Hayles.

Simulation: A concept of the French philosopher Jean Baudrillard that deals directly with the inseparability of the real and the non-real in the contemporary media age. See Jean Baudrillard's 1983 text *Simulations* (New York: Semiotext[e]).

Chapter 3.35
Wireless Technologies for Mobile Computing and Commerce

David Wright
University of Ottawa, Canada

INTRODUCTION

At the time of writing (1Q06) most countries have a small number (2-6) of major cellular operators offering competing 2.5G and 3G cellular services. In addition, there is a much larger number of operators of WiFi networks. In some cases, a major cellular operator, for example, Deutsche Telekomm and British Telecom, also offers a WiFi service. In other cases, WiFi services are provided by a proliferation of smaller network operators, such as restaurants, laundromats, airports, railways, community associations and municipal governments. Many organizations offer WiFi free of charge as a hospitality service, for example, restaurants. Cellular services offer ubiquitous, low data rate communications for mobile computing and commerce, whereas WiFi offers higher data rates, but less ubiquitous coverage, with limitations on mobility due to business as opposed to technology reasons.

Emerging networks for mobile computing and commerce include WiMAX and WiMobile (Wright, 2006), which offer higher data rates, lower costs and city-wide coverage with handoff of calls among multiple base stations. These new technologies may be deployed by the organizations that currently deploy cellular and WiFi networks, and also may give rise to a new group of competitive wireless network operators.

This article identifies the capabilities needed for mobile computing and commerce and assesses their technology and business implications. It identifies developments in the wireless networks that can be used for mobile computing and commerce, together with the services that can be provided over such networks. It provides a business analysis indicating which network operators can profitably deploy new networks, and which network operators need to establish business and technology links with each other so as to better serve their customers. The resulting

range of next generation service, technologies and network operators available for mobile computing and commerce is identified.

WIRELESS NETWORK ARCHITECTURES

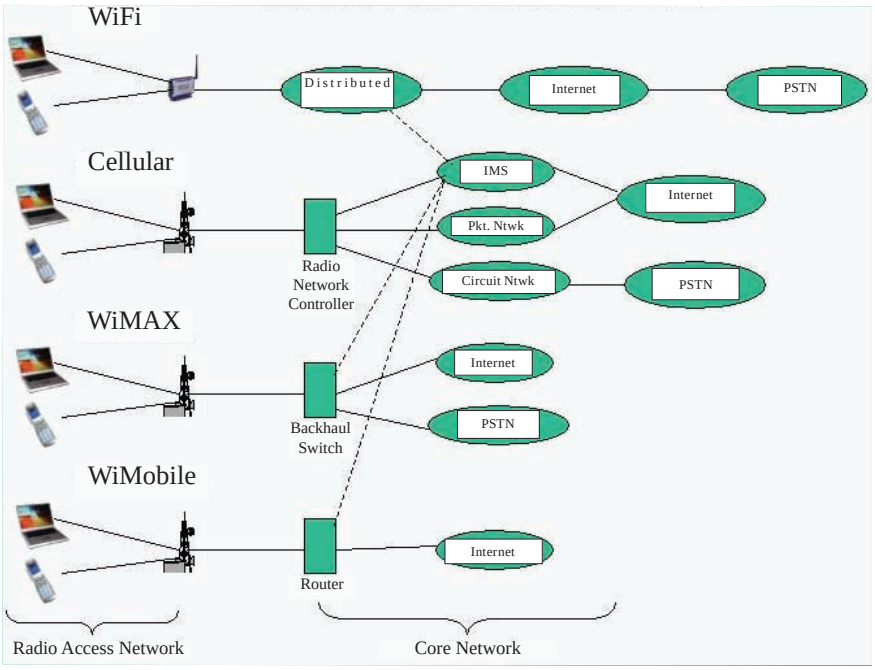
Figure 1 illustrates the network architectures for WiFi, Cellular, WiMAX and WiMobile, including the radio access network on the left and the wired core network on the right.

The cellular architecture is the most sophisticated in that the core network includes a circuit network (for legacy circuit switched voice calls), a packet network (for data calls) and an IP Multimedia Subsystem, IMS (for migration of all traffic onto the Internet).

These three networks essentially allow the cellular operator to maintain control over all calls to and from the mobile device, and hence derive revenue from them. In particular the IMS network contains servers for establishing voice and video calls over IP, authenticating users, maintaining records of the current location of a mobile user, accounting, and security. Cellular operators are migrating traffic from their circuit and packet networks onto the IMS.

By contrast, WiFi (IEEE, 1999a, 1999b, 1999c, 2003), WiMAX (IEEE, 2006; Ghosh et al., 2005), and WiMobile (IEEE, 2006; Lawton, 2005) are simply radio access technologies and do not specify a core network. They therefore allow more direct access from a mobile device to the Internet. In particular, the WiMobile specification, which is under development at the time of writing, emphasizes that its design is being optimized for operation with IP. This more open access to the Internet allows a mobile user to set up, for instance, a VoIP call using a third party

Figure 1. Wireless network architectures



service without the involvement of the wireless network operator. As the user moves from one access point to another, the call can be maintained using Mobile IP, involving servers maintained by the user's ISP, not by the wireless network operator. Mobile IP can operate over diverse wireless access technologies as described by Benzaid et al. (2004).

If the operator of a WiFi, WiMAX or WiMobile network wishes to maintain more control over the traffic passing through their network and hence participate more in the revenue generated by that traffic, they can build an IMS network. Alternatively if they already operate a cellular network, they can provide access to their existing IMS network, as shown by the dashed lines in Figure 1.

REQUIREMENTS FOR MOBILE COMPUTING AND COMMERCE

Any wireless transmitter/receiver has a limited range in order to comply with government regulations regarding maximum power output. A mobile user therefore may move out of the range of its current wireless access point, and it is necessary to handoff the communication to another access point using either the same or a different wireless technology. Handing off the communication means that the current IP session is maintained, for example, the user continues to browse a Web site as a registered user, a VoIP call is not interrupted, and an enterprise user with a laptop-based secure VPN to an enterprise network continues to use the same VPN. There are four requirements in order to achieve handoff suited to mobile computing and commerce:

1. It must be possible to switch the call from one access point to another
2. If the user is receiving quality of service, QoS, for example, a guaranteed low latency, that QoS is maintained after the handoff, and an acceptable number of packets are lost during handoff.
3. If the access points are operated by different network operators, there must be a business arrangement between them regarding mediation of the billing for the call.
4. The organization deploying the wireless access network must be able to make a profit or to have a business model that focuses on hospitality service.

Requirements 1 and 2 are technology related and are discussed next, followed by the business requirements 3 and 4.

TECHNOLOGY ISSUES

A mobile device that is capable of using multiple wireless access technologies, such as those described above, can continuously scan its radio environment to search for access points that it could potentially use. Some of them may not be available, if, for instance, they are operated by companies with which the user does not have a subscription. In order to choose among the available access points within range the mobile device can apply criteria including: data rate, cost, ability to handoff seamlessly, and QoS; delay (important for voice) and packet loss rate (important for data). For instance, a mobile device with an interactive voice/video call in progress could choose the lowest cost network that provides acceptable delay. A device downloading a large data file could choose the network with the highest data rate given limitations on cost and packet loss rate. Once the network is selected, handoff is initiated.

Handoff among WiFi, WiMAX and WiMobile is handled by IEEE (2006). Handoff between cellular and one of these three technologies is complicated by the need to interwork with the cellular circuit, packet and IMS networks.

- In the case of WiFi, this interworking is provided by a specification from the industry consortium UMA, Unlicensed Mobile Access (2006), which is incorporated as part of the GSM cellular network specifications, release 6.
- In the case of WiMAX, similar issues are involved and are being resolved by the WiMAX Forum (2006).
- WiMobile is at an early stage of development and interworking with cellular is not a priority at this stage. A specification may be developed later, or alternatively, WiMobile may differentiate itself from the other technologies by becoming a "native-IP" access mechanism, similar to DSL and cable modem in which customers have direct access to the Internet.

This discussion addresses requirements 1, 2 above. We now move on to requirements 3, 4.

BUSINESS ISSUES

This section presents business strategies for wireless access network operators that take into account sources of revenue related to mobile computing and commerce, plus the need to compete with other technologies and network operators. Earlier work in this area (du Preez & Pistorius, 2003) dates from a time when 3G and wireless data services were emerging technologies. The present section incorporates developments in technology and services to date.

The sources of revenue are given in Table 1 and are classified in two ways:

1. Whether the service is provided by a content provider or a network operator, which may be the wireless access network operator or another network operator. For instance, a VoIP service could be provided by the wireless operator or by a third party such

Table 1. Wireless access network operators revenue sources

Revenue Source	**Service provided by:** **(N) Network Operator** **(C) Content Provider**	**Revenue accrues to:** **(W) Wireless Network Operator** **(3) Third Party Service Provider** **(S) Shared with Content Provider**
Voice/video calls	N	W 3
Audio content	C	S
Video content	C	S
Gateway to PSTN	N	W 3
Geographic info (e.g., travel directions, highway safety)	N C	W S
Location enabled advertising	N C	W S
Location enabled buddy lists	N	W
Multimedia Messaging Service	C	W 3 S
Gaming	C	S
QoS	N	W
VPN	N	W 3

as Vonage. Either way it is provided by a network operator.

2. Who receives the revenue for the service: the wireless access network operator, a third party or a sharing arrangement with a content provider.

It can be seen from Table 1 that there is a large number of mobile computing and commerce services that can be provided by a mix of wireless network operators, content providers and third parties. In addition there are non-revenue generating services such as e-mail and Web browsing. A clear business strategy is needed to operate successfully in competition with the other players. Strategies suited to the different types of wireless network operators are given in Table 2.

Table 2 divides wireless access network operators into three groups: incumbent cellular operators, hospitality providers such as restaurants and municipalities, and new competitors, who are starting operations based on the availability of new technology. The incumbent cellular operators have complex core networks as shown in Figure 1 and incur costs of operating legacy technologies. They seek to deploy all possible wireless technologies in order to accommodate the needs of all customers. By contrast the new competitors seek to reduce their costs by only operating the most recent technologies. Both these groups are operating commercial services and therefore use licensed spectrum so that their customers do not experience interference from other users. The hospitality providers, however, are providing a free service. Their customers accept that the performance may vary according to the demands of other users and therefore the operators reduce their costs by using unlicensed spectrum.

Both the incumbents and the new competitors aim to deliver the full range of services listed in Table 1 to their customers, typically from the IMS, so as to maintain control over the revenue. The hospitality providers, however, are typically providing access only, allowing their customers to get services from any third party they wish, since they do not seek to generate revenue from

Table 2. Strategy for wireless access network operators

	Cellular Operators	**Hospitality providers**	**Competitive Wireless Network Operators**
Technologies	2.5G, 3G, WiFi, WiMax, WiMobile	WiFi, unlicensed WiMAX	WiMAX, WiMobile
Revenue sources	Generate revenue from the full range of services	Provide Internet access for the full range of services.	Generate revenue from the full range of services
IMS strategy	Lock customers into IMS-based services.	Establish partnerships and interfaces to the IMS of other operators	Build IMS. Establish partnerships and interfaces to the IMS of other operators
Competitive strategy	Buy up competitors.	Avoid competing with other operators by a competitive bid process.	Differentiate from incumbents by offering low cost services, focusing on IP, developing next generation services, for example, presence, location, QoS.

their networks. For location-based services, the hospitality provider can provide the third party with information about the customer's current location.

The cellular incumbents typically already have an IMS in place and aim to lock customers into service provided by that IMS. The new competitors need to build an IMS and then establish partnerships with other wireless operators so that calls originating on one IMS can be handed off to another operator. These partnerships are also important to the hospitality providers since they typically have no interest in developing their own IMS.

The competitive strategy of incumbent cellular operators towards WiFi operators historically has been to buy them up, and this strategy is also appropriate for WiMAX and WiMobile operators. The strategy of hospitality operators is to avoid competition, and this is particularly important for municipalities, who should not be seen to use tax dollars to compete against private industry. In order to avoid this perception, they can use a competitive bid process allowing any operator the opportunity to bid on the contract to build and operate their network. The strategy of the new competitors is to compete on three fronts. First, they can offer low cost services, since they do not have the cost of operating legacy networks. Second, they can offer a full range of next generation services, such as presence and location-based services, thus positioning themselves as state-of-the-art suppliers. Third, they can sell QoS guarantees to their customers, since new technologies such as WiMAX and WiMobile are particularly suited to providing such guarantees.

CONCLUSION

The enabling technologies for mobile computing and commerce are developing rapidly. New wireless technologies such as WiMAX and WiMobile offer extended coverage and improved QoS compared to WiFi; and higher data rates and lower costs compared to 2.5G and 3G cellular. A wide range of services is available over these technologies including services that generate revenue (a) for the wireless operator, such as location-based services, (b) for a third party, such as VoIP and (c) for a content provider, such as entertainment. Wireless network operators, including incumbent cellular operators, hospitality providers and new competitive wireless network operators, need to develop strategies that allow handoff of calls among the different technologies and operators. Strategies include locking customers into an IMS, interworking with other operators' IMSs, buying out competitors and developing a broad range of state-of-the-art services such as location and presence services.

The mobile computing and commerce user can therefore expect a proliferation of services (Table 1), a number of different network operators (Table 2), an array of different wireless technologies, WiFi, 3G, WiMAX and WiMobile, and a mobile device that can make the best choice among these alternatives at any point in time and space.

KEY TERMS

IMS, IP Multimedia Subsystem: Part of the wired core network containing servers for establishing voice and video calls over IP, authenticating users, maintaining records of the current location of a mobile user, accounting, and security.

Location-Based Services: Services that take into account the users current geographical location, for example, advertising locally available products and services, providing directions and alerting drivers to traffic congestion and road accidents.

Mobile IP: An Internet standard that allows a mobile user to move from one point of attachment of the network to another while maintaining an existing TCP/IP session. Incoming packets to the user are forwarded to a server in the user's new access IP subnetwork.

Presence: The ability of a user device to specify characteristics, such as whether the user is online, whether the user is willing to receive calls, whether the user is willing to receive calls of a given type (e.g., voice, video, data, MMS) from specified other users and what is the user's current location to a specified degree of accuracy.

Quality of Service (QoS): Features related to a communication, such as delay, variability of delay, bit error rate and packet loss rate. Additional parameters may also be included, for example, peak data rate, average data rate, percentage of time that the service is available, mean time to repair faults and how the customer is compensated if QoS guarantees are not met by a service provider.

WiFi: A commercial implementation of the IEEE 802.11 standard in which the equipment has been certified by the WiFi Alliance, an industry consortium.

WiMAX: A commercial implementation of the IEEE 802.16 standard in which the equipment has been certified by the WiMAX Forum, an industry consortium.

WiMobile: Another name for the IEEE 802.20 standard, which is in course of development at the time of writing (1Q06).

INTRODUCTION

With the introduction of the World Wide Web, electronic commerce has revolutionized traditional commerce and boosted sales and exchanges of merchandise and information. Recently, the emergence of wireless and mobile networks has made possible the extension of electronic commerce to a new application and research area: mobile commerce (MC), which is defined as the exchange or buying and selling of commodities, services, or information on the Internet through the use of mobile handheld devices. In just a few years, mobile commerce has emerged from nowhere to become the hottest new trend in business transactions. Despite a weak economy, the future of mobile commerce is bright according to the latest predictions (Juniper Research Ltd., 2004). Internet-enabled mobile handheld devices are one of the core components of a mobile commerce system, making it possible for mobile users to directly interact with mobile commerce applications. Much of a mobile user's first impression of the application will be formed by his or her interaction with the device, therefore the success of mobile commerce applications is greatly dependent on how easy they are to use. This article first explains the role of handheld devices in mobile commerce systems and then discusses the devices in detail. A mobile handheld device includes

six major components: (a) a mobile operating system (OS), (b) a mobile central processor unit (CPU), (c) a microbrowser, (d) input and output (I/O) devices, (e) memory, and (f) batteries. Each component is described, and technologies for the components are given.

BACKGROUND

Internet-enabled mobile handheld devices play a crucial role in mobile commerce as they are the devices with which mobile users interact directly with mobile commerce applications. This section first introduces a mobile commerce system and then illustrates how it is used to carry out a mobile transaction. A mobile commerce system is inherently interdisciplinary and could be implemented in various ways. Figure 1 shows the structure of a mobile commerce system and a typical example of such a system (Hu, Lee, & Yeh, 2004). The system structure includes six components: (a) mobile commerce applications, (b) mobile handheld devices, (c) mobile middleware, (d) wireless networks, (e) wired networks, and (f) host computers.

To explain how the mobile commerce components work together, Figure 2 shows a flowchart of how a user request is processed by the components in a mobile commerce system.

Figure 1. A mobile commerce system structure

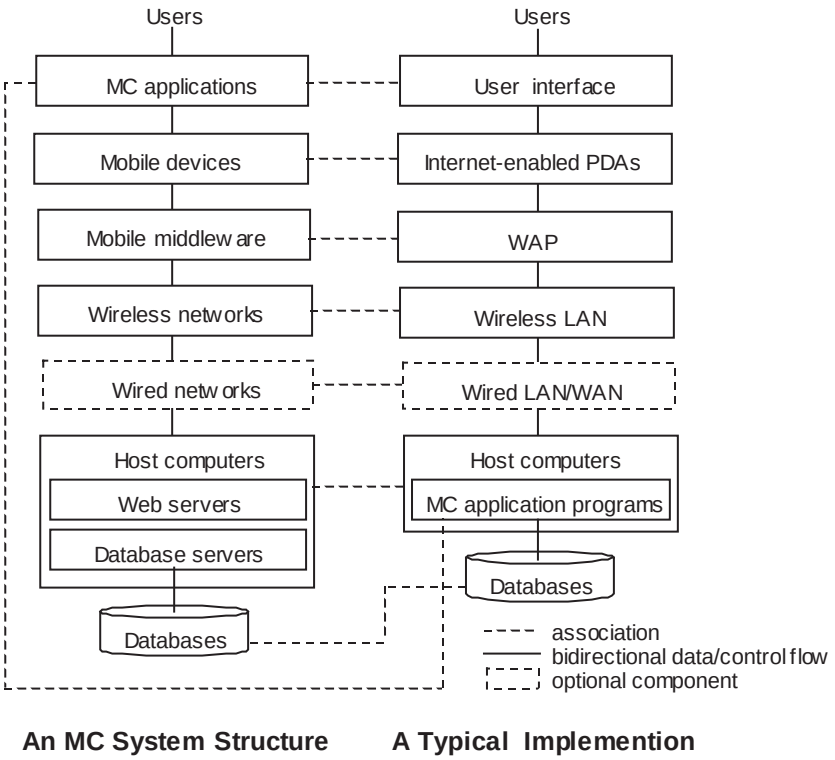

Figure 2. A flowchart of a user request processed in a mobile commerce system

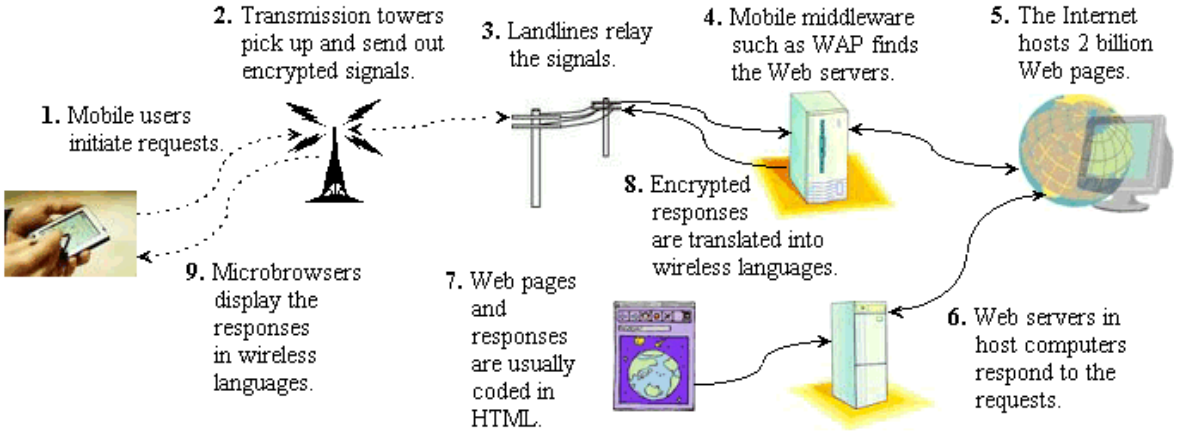

MOBILE HANDHELD DEVICES

Mobile users interact with mobile commerce applications by using small wireless Internet-enabled devices, which come with several aliases such as handhelds, palms, PDAs (personal digital assistants), pocket PCs (personal computers), and smart phones. To avoid any ambiguity, a general term, mobile handheld devices, is used in this article. Mobile handheld devices are small general-purpose, programmable, battery-powered computers, but they are different from desktop PCs or notebooks due to the following special features.

- Mobility
- Low communication bandwidth
- Limited computing power and resources such as memory and batteries

Figure 3 shows a typical system structure for handheld devices, which includes the following six major components: (a) a mobile operating system, (b) a mobile central processing unit, (c) a microbrowser, (d) input and output devices, (e) memory, and (f) batteries. Brief descriptions of all the components are given in the coming sections.

Mobile Operating Systems

Simply adapting desktop operating systems for mobile handheld devices has proved to be a futile endeavor; an example of this effort is Microsoft Windows CE. A mobile operating system needs a new architecture and different features in order to provide adequate services for handheld devices. Several mobile operating systems are already available and each employs a different architecture and implementation. Figure 4 shows a generalized mobile operating system structure, which can be visualized as a six-layer stack.

Although a wide range of mobile handheld devices are available in the market, the operating

Figure 3. System structure of mobile handheld devices

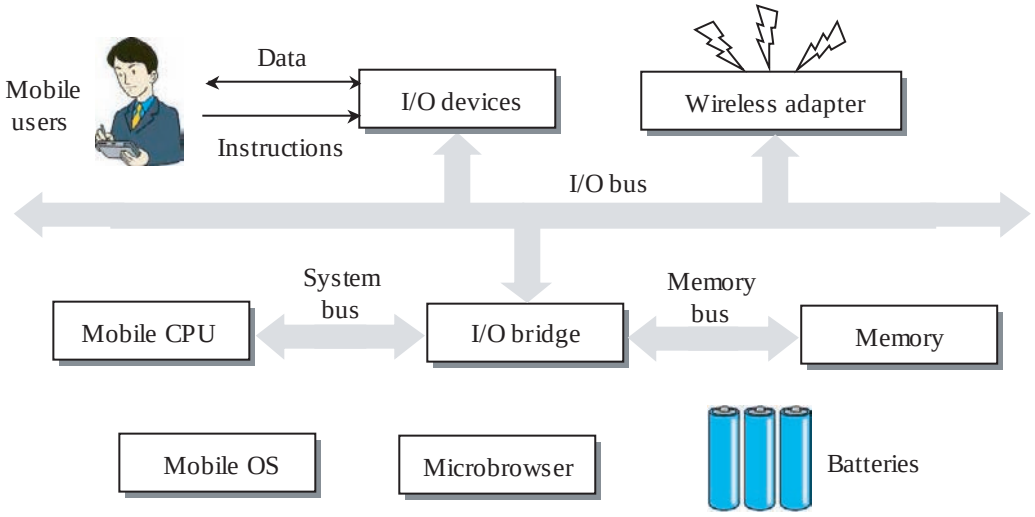

Figure 4. A generalized mobile operating system structure

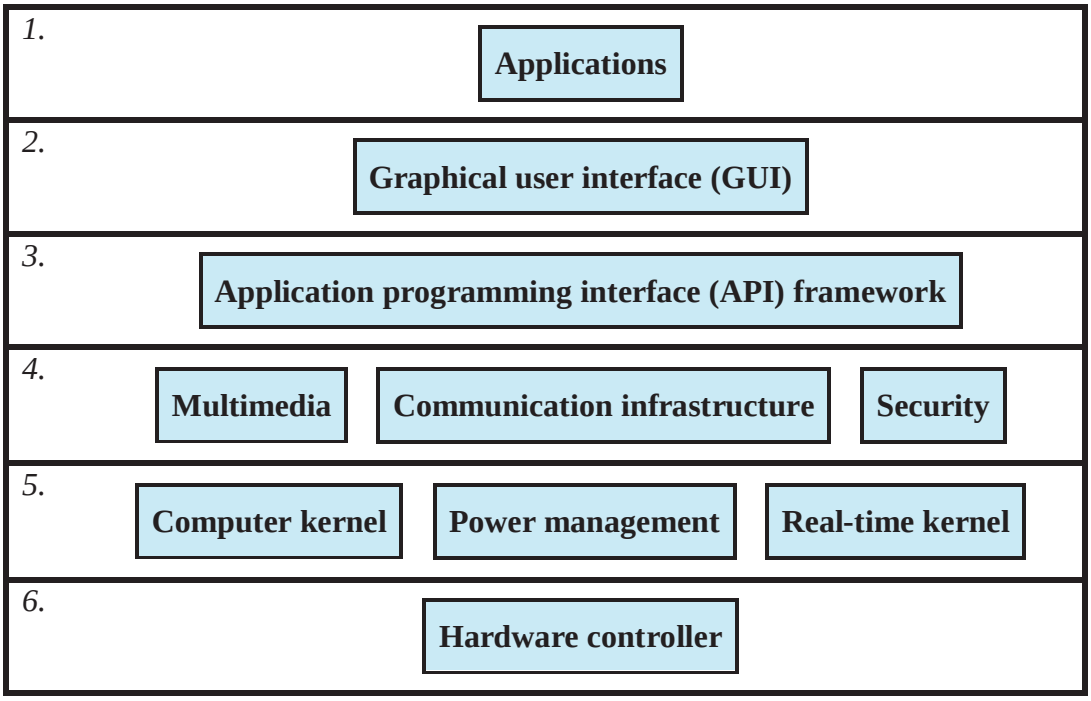

systems, the hubs of the devices, are dominated by just three major organizations. The following two lists show the operating systems used in the top three brands of smart cellular phones and PDAs in descending order of market share.

- **Smart Cellular Phones:** Microsoft Smartphone 2002, Palm OS 5, and Symbian OS 7 (Vaughan-Nichols, 2003)
- **PDAs:** Palm OS 5, Microsoft Pocket PC 2002, and Symbian OS 7 ("Mobile Computing," 2003)

The market share is changing frequently, and claims concerning the share vary enormously. It is almost impossible to predict which will be the ultimate winner in the battle of mobile operating systems.

Mobile Central Processing Units

The core hardware in mobile handheld devices are the mobile processors, and the performance and functionality of the devices are largely dependent on the capabilities of the processors. There used to be several brands available, but recently mobile processors designed by ARM Ltd. have begun to dominate the market. Handheld devices are becoming more sophisticated and efficient everyday, and mobile users are demanding more functionality from the devices. For example, in 2002, *In-Stat/MDR* predicted that worldwide mobile Internet-access device unit shipments would increase from approximately 430 million that year to approximately 760 million in 2006 ("Demand Increasing," 2002). To achieve this advanced functionality, in addition to the obvious feature, low cost, today's mobile processors must have the following features.

- **High Performance:** The clock rate must be higher than the typical 30 MHz for Palm OS PDAs, 80 MHz for cellular phones, and 200 MHz for devices that run Microsoft's Pocket PC.
- **Low Power Consumption:** This prolongs battery life and prevents heat buildup in handheld devices that lack the space for fans or other cooling mechanisms.
- **Multimedia Capability:** Audio, image, and video applications are recurring themes in mobile commerce.
- **Real-time Capability:** This feature is particularly important for time-critical applications such as voice communication.

Microbrowsers

Microbrowsers are miniaturized versions of desktop browsers such as Netscape Navigator and Microsoft Internet Explorer. They provide graphical user interfaces that enable mobile users to interact with mobile commerce applications. Due to the limited resources of handheld devices, microbrowsers differ from traditional desktop browsers in the following ways.

- smaller windows
- smaller footprints
- fewer functions and multimedia features

Several microbrowsers, such as Microsoft Mobile Explorer and Wapaka Java Micro-Browser, are already available. America Online (AOL), Inc., the parent company of the Netscape Network, and Nokia are developing and marketing a Netscape-branded version of Nokia's WAP microbrowser, with AOL-enhanced features, for use across a wide variety of mobile handheld devices. Figure 5 shows a typical microbrowser, Mobile Browser version 7.0 from Openwave Systems, which includes the following features: compatibility with WAP (Open Mobile Alliance Ltd., n.d.) or i-mode (NTT DoCoMo, n.d.), multimedia support, color images and animation, and dual network-stack, HTTP (hypertext transfer protocol) and WSP, support (Openwave Systems Inc., n.d.).

Figure 5. Openwave® Mobile Browser version 7

Input and Output Devices

Various I/O devices have been adopted by mobile handheld devices. The only major output device is the screen, whereas there are several popular input devices, including the following:

- **Keyboards:** There are two kinds of keyboards: built-in keyboards and external, plug-in keyboards. The problem with the former is that they are too small for touch-typing, whereas the latter suffers from inconvenience. Fabric keyboards that can be rolled up or folded around the handheld devices are being developed to relieve the problem of external keyboards.
- **Touch Screens and Writing Areas with Styli:** A touch screen is a display that is sensitive to human touch, allowing a user to interact with the applications by touching pictures or words on the screen. A stylus is an input device used to write text or draw lines on a surface as input to a handheld device. A handheld device equipped with a writing area and a stylus needs a handwriting-recognition function, but existing systems do not yet have a satisfactory recognition rate. Graffiti, employed by many handheld devices, is the most popular writing software.

Some mobile handheld devices can also react to voice input by using voice-recognition technology.

Memory

Desktop PCs or notebooks usually have between 64 to 256 MB of memory available for users, whereas handheld devices typically have only 4 to 64 MB. PDAs normally have more storage space than smart cellular phones. The former commonly have 16 MB, and the latter may have a memory size as low as a few kilobytes. Three types of memory are usually employed by handheld devices.

- **Random Access Memory (RAM):** There are two basic types of RAM: dynamic RAM (DRAM) and static RAM (SRAM). Dynamic RAM, the more common type, needs to be refreshed thousands of times per second in order to hold data, whereas static RAM does not need to be refreshed, making it faster but also more expensive than dynamic RAM.
- **Read-Only Memory (ROM):** ROM is manufactured with fixed contents, and it is usually used to store the programs that boot the device and perform diagnostics. It is inherently nonvolatile storage, in contrast to RAM.
- **Flash Memory:** This is a kind of nonvolatile storage similar to EEPROM (electrically erasable, programmable read-only memory), but updating can only be done either in blocks or for the entire chip, making it easy to update. Flash memory is not as useful as random access memory because RAM can be addressable down to the byte (rather than the block) level.

It is expected that hard disks, which provide much more storage capacity, will be adopted by handheld devices in the near future. A comprehensive survey of storage options can be found in Scheible (2002).

Batteries

Rechargeable lithium ion batteries are the batteries most commonly used by handheld devices. The life of this kind of battery is short, generally only a few hours of operating time. Battery technology will not significantly improve unless and until manufacturers begin to switch to fuel cells, which is unlikely in the near future. A fuel cell operates like a battery, but unlike a battery, a fuel cell does not run down or require recharging and will continue to produce energy in the form of electricity and heat as long as fuel is supplied. Since the fuel cell relies on chemical energy rather than combustion, emissions would be much lower than emissions from the cleanest existing fuel-combustion processes.

Synchronization

Synchronization connects handheld devices to desktop computers, notebooks, and peripherals in order to transfer or synchronize data. The traditional method of synchronization uses serial cables to connect handheld devices and other computing equipment. Now, however, many handheld devices use either an infrared (IR) port or Bluetooth technology to send information to other devices without needing to use cables.

- IrDA Data, a standard formulated by the Infrared Data Association (n.d.) to ensure the quality and interoperability of infrared hardware, is designed for data transfer over distances of up to 1 meter, acting as a point-to-point cable replacement.
- Bluetooth wireless technology is a specification aiming at simplifying communications among handheld devices, printers, computers, and other devices based on short-range radio technology. The Bluetooth 1.1 specification (Bluetooth SIG, Inc., n.d.) consists of two documents: the core, which provides design specifications, and the profile, which provides interoperability guidelines.

FUTURE TRENDS

Mobile handheld devices are usually divided into two types: smart cellular phones and Internet-enabled PDAs. These two kinds of devices started out as very different products, but they have gradually blended into each other. In the near future, it will be difficult to tell the differ-

ence between these two types of devices. The newest products such as tablet PCs belong to the category of PDAs because both have similar functionality. There are numerous mobile devices available in the market today. Table 1 lists some major mobile-device specifications, although several table entries are incomplete as some of the information is classified as confidential due to business considerations.

From Table 1 and previous discussions, the future trends of mobile handheld device components are observed.

1. **Operating Systems:** There are several popular operating systems available; the big three are (a) Palm OS, (b) MS Pocket PC/Smartphone, and (c) Symbian OS. It is hard to tell the eventual winner at this moment.
2. **CPU:** The ARM processors (Cormie, 2002) have already dominated and will dominate the market.
3. **Microbrowsers:** Most HTML pages cannot be displayed on microbrowsers, which

Table 1. Specifications of some major mobile handheld devices

Vendor & Device	Operating System	Processor	Installed RAM/ROM	Input Methods	Key Features
Compaq iPAQ H3870	MS Pocket PC 2002	206 MHz Intel StrongARM 32-bit RISC	64 MB/32 MB	Touchscreen	Wireless email/ Internet
Handspring Treo 300	Palm OS 3.5.2H	33 MHz Motorola Dragonball VZ	16 MB/8 MB	Keyboard/ Stylus	CDMA network
Motorola Accompli 009	Wisdom OS 5.0	33 MHz Motorola Dragonball VZ	8 MB/4 MB	Keyboard	GPRS network
Nokia 9290 Communicator	Symbian OS	32-bit ARM9 RISC	16 MB/8 MB	Keyboard	WAP
Nokia 6800	Series 40			Keyboard	Innovative keyboard integration
Palm i705	Palm OS 4.1	33 MHz Motorola Dragonball VZ	8 MB/4 MB	Stylus	Wireless Email/ Internet
Samsung SPH-i330	Palm OS 4.1	66MHz Motorola Dragonball Super VZ	16 MB/8 MB	Touchscreen/ Stylus	Color screen
Sony Clie PEG-NR70V	Palm OS 4.1	66 MHz Motorola Dragonball Super VZ	16 MB/8 MB	Keyboard/ Stylus/ Touchscreen	Multimedia
Sony Ericsson T68i			800KB	Keyboard	Multimedia Messaging Service
Toshiba E740	MS Pocket PC 2002	400 MHz Intel PXA250	64 MB/32 MB	Stylus/ Touchscreen	Wireless Internet

will be gradually improved to adopt more HTML pages.

4. **Input Methods:** The two major input methods are and will be touch screens and styli, and keyboards.
5. **Memory:** 64 MB or even 128 MB memory for a handheld device will be common.
6. **Batteries:** Fuel cells are likely the most promising method for extending battery life. However, they will not be available in the near future.

CONCLUSION

The emerging wireless and mobile networks have extended electronic commerce to another research and application area: mobile commerce. Internet-enabled mobile handheld devices are one of the core components of mobile commerce systems as they are needed for mobile users to directly interact with mobile commerce applications. Understanding the devices and knowing their functions and capabilities is vital for the success of mobile commerce applications. A handheld device relies on a wide range of disciplines and technologies for its success. To facilitate understanding, this article broke down the functions of a handheld device into six major components, which can be summarized as follows.

1. **Mobile Operating Systems:** Simply adapting desktop operating systems for handheld devices has proved to be futile. A mobile operating system needs a completely new architecture and different features to provide adequate services for handheld devices. A generalized mobile operating system structure can be visualized as a six-layer stack: (a) applications, (b) a GUI, (c) an API framework, (d) multimedia, a communication infrastructure, and security, (e) a computer kernel, power management, and a real-time kernel, and (f) a hardware controller.
2. **Mobile Central Processing Units:** Handheld devices are becoming more sophisticated and efficient everyday, and mobile users are demanding more functionality from their devices. To achieve this advanced functionality, in addition to the obvious feature, low cost, today's mobile processors must have the following features: (a) high performance, (b) low power consumption, (c) multimedia capability, and (d) real-time capability. The cores and architectures designed by Cambridge-based ARM Holdings Ltd. have begun to dominate the mobile CPU market.
3. **Microbrowsers:** Microbrowsers are miniaturized versions of desktop browsers such as Netscape Navigator and Microsoft Internet Explorer. They provide graphical user interfaces that allow mobile users to interact with mobile commerce applications. Microbrowsers usually use one of the following four approaches to return results to the mobile user: (a) wireless language direct access, (b) HTML direct access, (c) HTML to wireless-language conversion, and (d) error.
4. **Input and Output Devices:** Various I/O devices have been adopted by mobile handheld devices. The only major output device is the screen, but there are several popular input devices; among them are (a) keyboards and (b) touch screens and writing areas that need styli.
5. **Memory:** Three types of memory are usually employed by handheld devices: (a) RAM, (b) ROM, and (c) flash memory. Hard disks, which provide much more storage capacity, are likely to be adopted by handheld devices in the near future.
6. **Batteries:** At present, rechargeable lithium ion batteries are the most common batteries used by handheld devices. However, the life of this kind of battery is short, and the technology will not significantly improve

unless and until manufacturers begin to switch to fuel cells, which may not happen for at least several years.

Synchronization connects handheld devices to desktop computers, notebooks, or peripherals to transfer or synchronize data. Without needing serial cables, many handheld devices now use either an infrared port or Bluetooth technology to send information to other devices.

KEY TERMS

Electronic Commerce: It is the exchange or buying and selling of commodities, services, or information, or the transfer of funds on the Internet through the use of desktop computers.

Flash Memory: This is a kind of nonvolatile storage similar to EEPROM, but updating can only be done either in blocks or for the entire chip, making it easy to update.

Microbrowsers: They are miniaturized versions of desktop browsers such as Netscape Navigator and Internet Explorer. Microbrowsers, due to the limited resources of handheld devices, are different from the traditional desktop browsers in the following features: (a) smaller windows, (b) smaller footprints, and (c) less functions and multimedia features.

Mobile Commerce: It is the exchange or buying and selling of commodities, services, or information, or the transfer of funds on the Internet (wired or wireless) through the use of Internet-enabled mobile handheld devices.

Mobile Handheld Device: It is a small general-purpose, programmable, battery-powered computer that can be held in one hand by a mobile user. It is different from a desktop or notebook computer due to the following features: (a) mobility, (b) low communication bandwidth, and (c) limited computing power and resources such as memory and batteries. There are two major kinds of handheld devices: (a) smart cellular phones and (b) PDAs.

Stylus: A stylus is an input device used to write text or draw lines on a surface as input to a handheld device.

Synchronization: Synchronization connects handheld devices to desktop computers, notebooks, and peripherals in order to transfer or synchronize data. Other than using serial cables to connect handheld devices and other computing equipment, many handheld devices use either an infrared port or Bluetooth technology to send information to other devices.

Chapter 3.37
Mobile Commerce Multimedia Messaging Peer

Kin Choong Yow
Nanyang Technological University, Singapore

Nitin Mittal
Nokia Pte Ltd, Singapore

INTRODUCTION

In a mobile-commerce world, shops could provide product brochures, cards, sounds, songs and so forth in the form of multimedia messaging presentations, which could be used by a customer to send to friends. Shopping malls will have information kiosks equipped with wireless access capabilities, and could perform searches across the mall's network to update its multimedia message repository. Customers can download and distribute to their friends such multimedia content via mobile messaging, leading to increased revenue for the shops.

Over the years, mobile messaging has become an essential means of communication, and it is going to be even more so with the merging of the Internet and Mobile Networks. The ability to message from a phone to a computer on the Internet and vice versa is making messaging a powerful means of communication (Yeo, Hui, Soon, & Lau, 2001).

This article discusses the development of a multimedia messaging client for a personal digital assistant (PDA) and a Kiosk providing multimedia messages composition, search, share and send capabilities. Various messaging technologies, enabling wireless technologies and the peer-to-peer model, are also discussed and evaluated in this article. We substantiate the ideas discussed in this article with a description of an MMS PDA client application using JXTA with specific references to a shopping mall scenario.

BACKGROUND

Short Messaging Service

Text messaging uses the short messaging service (SMS, 100-200 characters in length), and involves

sending text messages between phones. Examples include "C U L8ER" and "OK. AT FLAT OR OFFICE." It is quick and dirty, hard to use the keypad, abrupt, punctuation challenged and incredibly useful and popular. Text messaging also has a lot of advantages, such as its convenience, availability on all phones and discreteness.

Text messaging is most prevalent in the youth market (Tan, Hui, & Lau, 2001), and especially teenagers, who are able to manipulate the difficulty of entering text with the mobile phone keypad. In fact, it is suspected that this steep learning curve and the necessary insider knowledge are two of the things that appeal to the youngsters (Bennett & Weill, 1997).

Multimedia Messaging Service

The multimedia messaging service (MMS), as its name suggests, is the ability to send and receive messages comprising of a combination of text, sounds, images and video to MMS-capable handsets (MMS Architecture, 2002). The trends for the growth in MMS are taking place at all levels within GSM (Patel & Gaffney, 1997), enabling technologies such as GPRS, EDGE, 3G, Bluetooth and Wireless Access Protocol (WAP).

MMS, according to the 3GPP standards, is "a new service, which has no direct equivalent in the previous ETSI/GSM world or in the fixed network world." Here is an introduction to the features of this innovative new service:

- MMS is a service environment that allows different kinds of services to be offered, especially those that can exploit different media, multimedia and multiple media.
- MMS will enable messages to be sent and received using lots of different media, including text, images, audio and video.
- As more advanced media become available, more content-rich applications and services can be offered using the MMS service environment without any changes.

Table 1. SMS vs. MMS

Feature	**SMS**	**MMS**
Store and Forward (non real time)	Yes	Yes
Confirmation of message delivery	Yes	Yes
Communications Type	Person to person	Person to person
Media Suppored	Text plus binary	Multiple- Text, voice, video
Delivery mechanism	Signalling channel	Data traffic channel
Protocols	SMS specific e.g. SMPP	General Internet e.g. MIME SMTP
Platforms	SMS Center	MMS Relay plus others
Applications	Simple person to person	Still images

- The MMS introduces new messaging platforms to mobile networks in order to enable MMS. These platforms are the MMS Relay, MMS Server, MMS User Databases and new WAP Gateways.
- MMS will require not only new network infrastructure but also new MMS-compliant terminals. MMS will not be compatible with old terminals, which means that before it can be widely used, MMS terminals must reach a certain penetration.

Implications of SMS on MMS

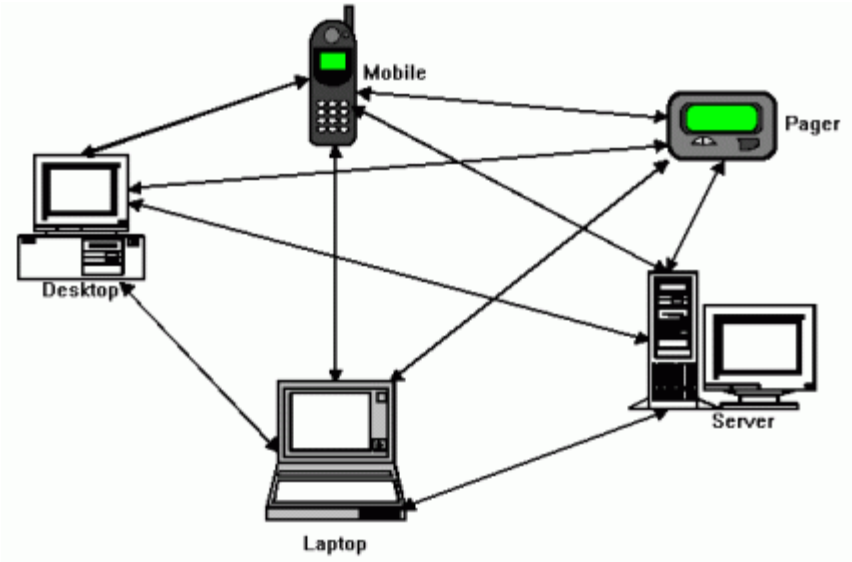
The current SMS has some unique advantages that other non-voice services do not have, such as store and forward and confirmation of message delivery. However, SMS also has some disadvantages, such as limited message length, inflexible message addressing structures and signalling channel slowness.

Person-to-Person (P2P) Model

Today, the most common distributed computing model is the client-server model (Chambers, Duce, & Jones, 1984). In the client-server architecture, clients request services and servers provide those services. A variety of servers exist in today's Internet: Web servers, mail servers, FTP servers and so forth. The client-server architecture is an example of a centralized architecture, where the whole network depends on central points to provide services. Regardless of the number of clients, the network can exist only if a server exists (Berson, 1992).

Like the client-server architecture, P2P is also a distributed computing model (Yemini, 1987). However, the P2P architecture is a decentralized architecture where neither client nor server status exists in a network (Madron, 1993). Every entity in the network, referred to as a peer, has equal status, meaning that an entity can either request a

Figure 1. P2P model



service (a client trait) or provide a service (a server trait). Figure 1 illustrates a P2P network.

Though peers all have equal status in the network, they do not all necessarily have equal physical capabilities. A P2P network might consist of peers with varying capabilities, from mobile devices to mainframes (Budiarto & Masahiko, 2002). A mobile peer might not be able to act as a server due to its intrinsic limitations, even though the network does not restrict it in any way.

JXTA

Jxta strives to provide a base P2P infrastructure over which other P2P applications can be built (Project Jxta, 2002). This base consists of a set of protocols that are language independent, platform independent and network agnostic. These protocols address the bare necessities for building generic P2P applications (Jxta Technology Overview, 2002). Designed to be simple with low overheads, the protocol's target is to build, to quote the Jxta vision statement, "every device with a digital heartbeat."

JXTA vs. .NET and JINI

Jxta's XML-based messaging is similar to Microsoft's .Net and SOAP technologies. But that is a very thin foundation for comparison. As more and more third-party protocols make use of XML, it will become obvious that just using XML as a message format says nothing at all about an actual networking technology. Comparing the high-level, policy-rich, Web-services-based infrastructure that is .Net to the low-level, fundamental, policy-neutral nature of Jxta is a futile exercise.

Project Jxta and the Jini project are also fundamentally different. Both of them have some similarity in higher-level interaction, enabling true distributed computing over a network. However, the similarity abruptly ends there. Strategic differences between the two are: Jxta started life as a completely interoperable technology (any platform, any programming language, any vendor). Sun is a mere contributor in the community. Jini is a Java-centered technology that Sun will integrate and deploy strategically in future product offerings. Sun will maintain a degree of control over Jini's evolution.

MULTIMEDIA MESSAGING PEER FOR MOBILE COMMERCE

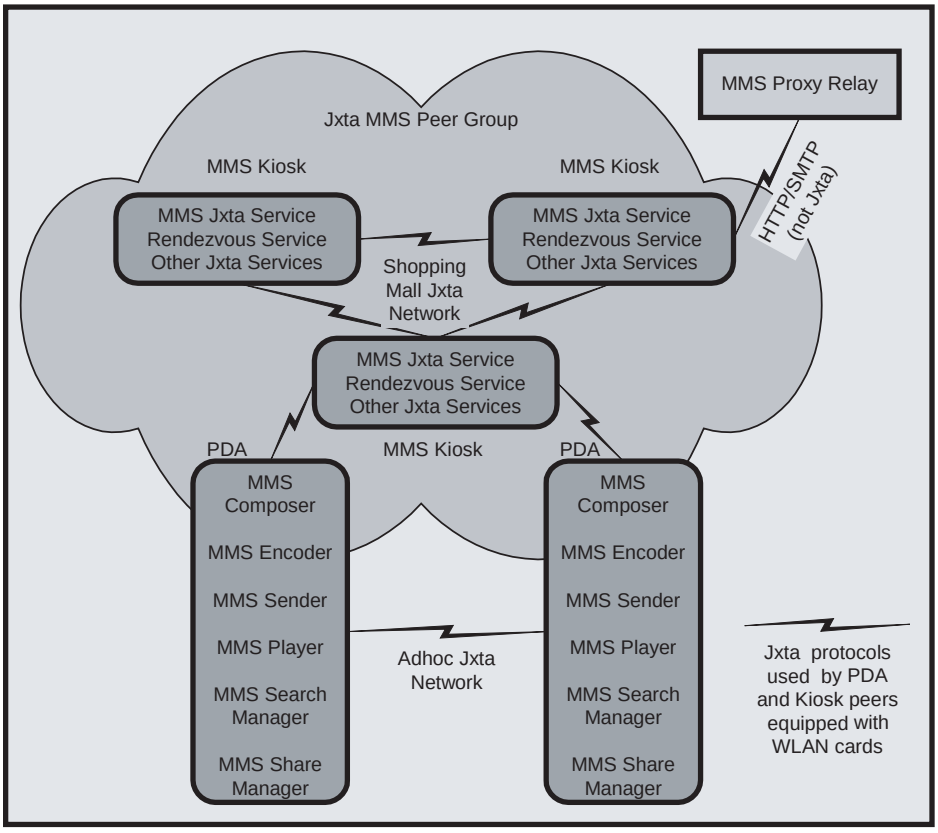
Most shopping malls have information kiosks, which could be equipped with a network point and wireless service access capabilities using technologies like Bluetooth and WiFi. These kiosks could perform searches across the mall's network to update its multimedia content repository and provide a common contact point for all the shops in the mall.

The kiosks could provide product brochures, cards, postcards, pictures, comic strips, sounds, songs and so forth in the form of MMS presentations, which could be used by a customer to send to another person. The customer need not visit all the shops and need not verbally describe a product to another person before making a decision to buy something. This leads to increased revenue for the shops. These kiosks could also provide multimedia messages intended for fun and entertainment purposes and charge for them.

MMS Peer and Kiosk Architecture

An MMS Peer would not only be a multimedia messaging client like the one on a mobile phone today but also would provide the capabilities to search for content and share content with other mobile devices in the vicinity. It would also not require a WAP stack, as it would send the messages directly to the MMS Proxy using either its HTTP or SMTP interface, which are expected to be accessible through the Jxta-based MMS service

Figure 2. MMS Peers and kiosk architecture



provided by a peer like the kiosk or another more powerful mobile device like a laptop, which is connected to the Internet and in the vicinity.

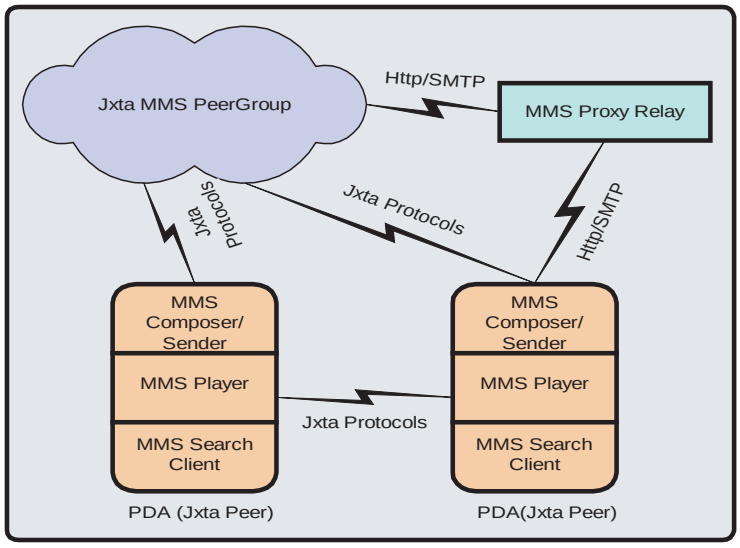
MMS Kiosk and Jxta

In a P2P environment like Jxta, commonly accessed information gets replicated (the peers have a choice to keep a copy of content passing through them) and becomes available at peers fewer hops away. This avoids "hotspots" and is ideal for content sharing, where the content can be of any type. For an MMS Kiosk searching for multimedia messages, the situation is no different and it would thus be ideal to use a P2P framework to advertise and search for multimedia messages and media content.

Design and Implementation of MMS Peers

Figure 3 shows the architecture due to the availability of the Jxta platform for a PDA (Jxta Platform, 2002). This architecture is almost fully P2P except the interaction between the Jxta Peer and the MMS Proxy-Relay. This offers the advantage

Figure 3. MMS kiosk environment architecture



that a customer can become part of a Peer Group due to other customers around him. This opens opportunities for customers to exchange MMS messages they have on their devices.

The PDA has been shown to have only an MMS Composer, MMS Player and MMS Sender. The MMS Composer composes a message by aggregating all the media and presentation information provided by the user. The MMS Sender performs an HTTP Post to the MMS Proxy-Relay to send the message to its destination. An MMS Player is also provided to the PDA client to view an MMS message before sending. The Kiosk/Shop is what provides the service to allow a customer to search for MMS messages and send them. The kiosk and the shops are part of a Jxta MMS Peer Group.

The protocols that the PDA can use to directly send to the MMS Proxy are either HTTP or SMTP (if the MMS Proxy-Relay provides an SMTP interface). The communication between the kiosk/shop and the PDA can be over Bluetooth, IEEE 802.11b or Infrared. Infrared is not a good choice due to its very limited range.

PDA MMS Peer Design

The MMS Peer on the PDA consists of four modules:

- MMS Composer
- MMS Encoder and Sender
- MMS Player
- MMS Jxta Search and Share

MMS Composer

This module allows a user to compose an MMS on the move. It allows the user to select the media content and provide layout details and timing information for the slides of the MMS presentation.

The process results in the generation of an SMIL file, which contains the presentation details of the media. Subsequently, a Jar file (JAR Documentation, 2002) is created with all the media files and the SMIL file. The MMS Sender (in the next section) takes the Jar as its input, encodes it into an MMS and sends it.

MMS Encoder and Sender

MMS can be sent either using HTTP Post or SMTP if the MMS Proxy-Relay provides both interfaces. The two modes of sending the message could be chosen based on the priority of the message. Using SMTP takes longer to send, as the message has to be ultimately encoded according to MMS standards (MMS Encapsulation Specification, 2002). Hence, SMTP could be used to send low-priority messages.

MMS Player

The MMS Player uses takes a Jar as input, extracts all the media and SMIL parts, and uses a SMIL parser to parse the SMIL and play it. The slides in the SMIL presentation are rendered using *double buffering.* The AMR audio is first converted to the WAV format and then played. Imelody (.imy files) files cannot be played by the application at this stage.

MMS Jxta Search and Share

The MMS application, once started, represents a Jxta peer. The peer becomes a member of a universal group called the NetPeerGroup. The peer then starts to discover its peers and available peer groups. The Search and Share module relies on two main modules called the Peer Group Manager

Figure 4. MMS Player and Sender

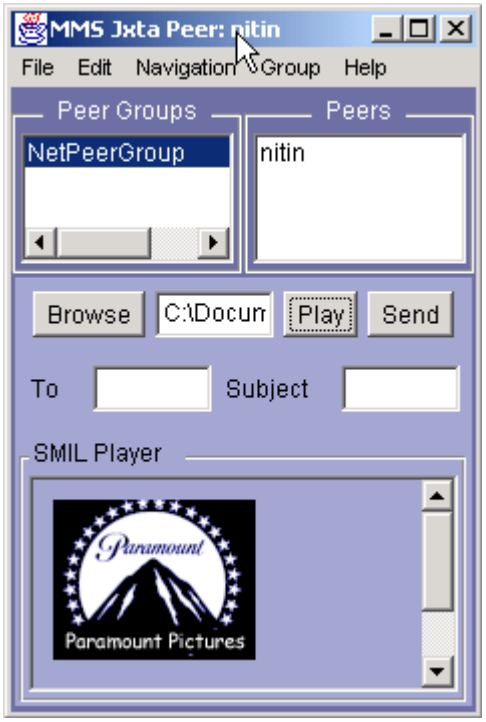


Figure 5. MMS Search

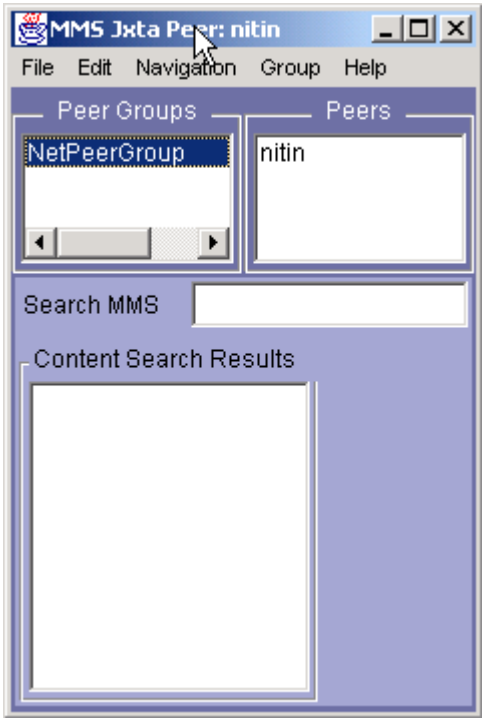

and the Search Manager. The Search and Share use the Content Management Service.

Graphical User Interface (GUI) Design

The GUI was designed keeping the PDA in mind. The GUI uses as many components that can be either easily clicked or tapped with a stylus. The following things were taken into consideration for the GUI design:

- A user would always want to have the list of peers and peer groups in front of him or her because of constant interaction with these entities.
- The limited screen size of the PDA requires that every function be provided without cluttering the screen. Thus, every function is provided on a new screen.
- This sort of layout would be ideal if service clients are to be loaded dynamically upon discovery of a service.

Figure 4 shows the MMS player and sender GUI. It also shows the list of peer groups and peers currently visible. The peer groups and peers list keeps getting updated automatically. Figure 5 shows the MMS Search GUI. A user can enter the keywords and press enter to search. A button will be added also to allow easy use on the PDA.

Comparison with Other MMS Solutions

There are some other MMS clients for the PDA that exist now. The one from Anny Way (MMS—Opportunities, migration and profits, 2003) is specifically for Pocket PC. EasyMessenger (EasyMessenger, 2003) from Oksijen Technologies is the only other Personal Java-based MMS client but without the additional P2P features provided by us. Electric Pocket's Pixer (Pixer MMS, 2003) is another MMS Client that only supports Pocket PC and Palm OS and can be used to send images only. There seems to be no work done on using MMS and Jxta together or, for that matter, not even EMS or SMS and Jxta.

All the solutions above are MMS clients with a view to sending multimedia messages, a progress from SMS or EMS. The MMS Peer was developed with a view to making not only messaging a more pleasant and easier experience but also to provide features that would facilitate access to a variety of content. The searching and sharing of content from peers in the vicinity (shoppers) as well as content stores (kiosks) make it a compelling multimedia messaging solution.

FUTURE TRENDS

MMS Message Receiver Module for the PDA

The next step is to implement a receive module for the PDA so the MMS Peer is able to achieve two-way messaging. When a message is retrieved directly from the MMS Proxy-Relay using the HTTP GET method, the MMS Proxy-Relay will return with a message along with the HTTP headers. The HTTP headers can be easily skipped by looking for two consecutive carriage returns and line feed pairs. After this, the encoded MMS header are read byte by byte until the byte of number of body parts is reached. In this way, the MMS Peer will be able to both send and receive messages with other peers.

Service Client Plug-In Feature

The Service Client Plug-In feature refers to the client download option. The current implementation assumes the client for a service to be there on the peer. As the peer already has core Jxta functionalities, it is a good idea to use them to provide this feature. The advertisements of a service could specify the location of a client,

which could be transferred over to the peer and dynamically loaded. This is possible in Java using the API for loading classes. To enable this feature, one could create a Jxta Service that has clients registered with it.

PDA to PDA Messaging

With the existing application framework, PDA to PDA MMS messaging can be easily enabled using the Jxta messaging layer. As PDAs are more capable than mobile phones, even video could be enabled for PDA to PDA messaging. All it would mean is using another media type in the SMIL or encoded message.

To account for different PDAs communicating, the User Agent Profile Specification (UAProf) could be used for capability negotiation. The UAProf schema for MMS characteristics (client transactions) could be adapted to the PDA situation. The XML messaging layer for Jxta would enable the use of this XML scheme effectively.

CONCLUSION

The Jxta platform Personal Java port came out very recently and the application was designed and implemented with it in mind. If the basic platform functionalities have been ported correctly, then it should not take long to port this whole application to the PDA. The application conforms to the Personal Java standard when checked with the compliance tool. This implies it should work on the PDA without requiring any changes.

Currently, the MMS client by itself works on the PDA. An MMS Player and sharing of content were developed. The former was implemented while searching for a reasonably priced Bluetooth SDK for WinCE and trying various Bluetooth PCMCIA cards with the freely available Bluetooth stack called CStack. This project will have a commercial value when shopping malls in Singapore install wireless networks or have wireless kiosks.

In conclusion, with the increase in memory and processing power of a plethora of mobile devices found in the market, and the ongoing improvements in available bandwidth to the user, MMS is a service to look forward to, and more so with peer-to-peer technologies like Jxta, which will make it truly ubiquitous.

KEY TERMS

Application Programming Interfaces (APIs): Programming tools that provide developers with a simple, consistent mechanism for extending the functionality of an application and for accessing existing computing systems.

Distributed System: A system made up of components that may be obtained from a number of different sources that together work as a single distributed system, providing the run-time infrastructure supporting today's networked computer applications.

Multimedia: Involving or encompassing more than one concurrent presentation medium, such as text, sound and/or motion video.

Peer-to-Peer: A communications model in which each party has the same capabilities and either party can initiate a communication session.

Plug-In: Programs that can easily be installed and used as part of a Web browser. A plug-in application is recognized automatically by the browser and its function is integrated into the main HTML file that is being presented.

Protocol: A special set of rules that end points in a telecommunication connection use when they communicate with each other.

WAP Stack: A set of protocols that covers the whole process of wireless content delivery, from the definition of WML and WMLScript for creating and layout of the actual content and the specification of security measures in the WTLS to the lowest parts of the stack dealing with the actual transport of content.

ABSTRACT

The emergence of wireless and mobile networks has made possible the introduction of electronic commerce to a new application and research subject: mobile commerce. Understanding or constructing a mobile or an electronic commerce system is an arduous task because the system involves a wide variety of disciplines and technologies and the technologies are constantly changing. To facilitate understanding and constructing such a system, this article divides the system into six components: (i) applications, (ii) client computers or devices, (iii) mobile middleware, (iv) wireless networks, (v) wired networks, and (vi) host computers. Elements in these components specifically related to the subject are described in detail and lists of current technologies for component construction are discussed. Another important and complicated issue related to the subject is the mobile or electronic commerce application programming. It includes two types of programming: client-side and server-side programming, which will be introduced too.

INTRODUCTION

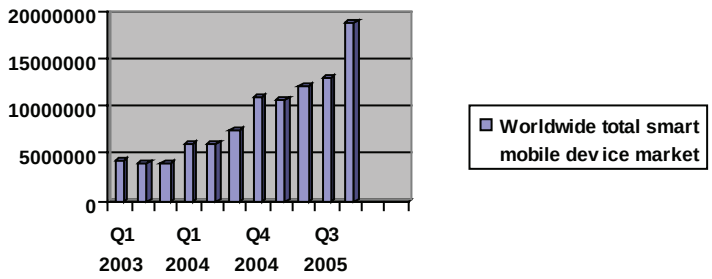
With the introduction of the World Wide Web, electronic commerce has revolutionized traditional commerce and boosted sales and exchanges of merchandise and information. Recently, the emergence of wireless and mobile networks has made possible the extension of electronic commerce to a new application and research area: mobile commerce, which is defined as the exchange or buying and selling of commodities, services, or information on the Internet through the use of mobile handheld devices. In just a few years, mobile commerce has emerged from nowhere to become the hottest new trend in business transactions. The future of mobile commerce is bright according to the following predictions:

- Figure 1 shows the growth in demand for smart mobile devices including handhelds, wireless handhelds, and smart cellular phones through 2006, as estimated by the research firm Canalys (2004a, 2004b, 2004c, 2005a, 2005b, 2005c, 2005d, & 2006).
- Cumulative sales of smartphones will reach 1 billion units by the first quarter of 2011 according to IDC, a market research company (Symbian Limited, 2006).
- According to various reports, the estimated worldwide shipments of the following three equipments in 2006 were:
  - *PDAs and smartphones*: 84 million (Gartner, Inc., 2006);
  - *Celular phones*: 986 million (cellular-news, 2006); and
  - *PCs*: 250 million (Silicon Valley Daily, 2006).

The worldwide shipments of PDAs and smartphones in 2006 had a 57% increase from the same period last year, according to Gartner, Inc. Smartphone shipments bolstered the market growing 75.5% to reach 34.7 million units, more than four times the size of the PDA market. PDA shipments increased by 5.7% totaling 7.4 million units. Though the unit sales were less than one tenth of the worldwide mobile phone sales in 2006, they were not too far away from the worldwide PC sales in 2006.

- Juniper Research has published a report forecasting that the global mobile commerce market will be an $88 billion industry by 2009 (Glenbrook Partners, LLC., 2004) compared to $8.5 trillion of business-to-business electronic commerce in 2005 (Gartner, Inc. 2001).

Figure 1. Worldwide total smart mobile device market



- Jupiter Research says ringtone revenues, which have been doubling in recent years, will reach $724 million in 2009. Mobile gaming revenues should reach $430 million the same year. The market research firm forecasts that total m-commerce sales globally could reach $3.6 billion in 2006 (Brad, 2006).

Mobile commerce is an effective and convenient way of delivering electronic commerce to consumers from anywhere and at any time. Realizing the advantages to be gained from mobile commerce, companies have begun to offer mobile commerce options for their customers in addition to the electronic commerce they already provide (Yankee Group, 2001). However, it requires a tremendous effort to understand or construct a mobile or an electronic commerce system because it involves such a wide range of disciplines and technologies. To lessen the difficulty, this article will divide the system into six components: (i) applications, (ii) client computers or devices, (iii) mobile middleware, (iv) wireless networks, (v) wired networks, and (vi) host computers. Since each component is large enough to be a research area by itself, only elements in components that are specifically related to mobile or electronic commerce are explained in detail. Lists of the technologies used for component construction are also discussed. Related research on mobile commerce systems can be found in the article by Varshney, Vetter, and Kalakota (2000).

System Requirements

A wide variety of technologies are used to build mobile or electronic commerce systems. No matter what kinds of technologies are used, the requirements for both mobile and electronic commerce systems include:

- The system uses the state-of-the-art technologies.
- The system is easy to deploy and adapt by content providers, telecommunication companies, and computer/device manufacturers.
- The system allows end users to perform transactions easily.
- The system allows products to be personalized or customized upon request. For example, Web content can be viewed via either browsers or micro browsers.
- Maximum interoperability is desirable because so many technologies are now available and new techniques are constantly being invented for the use of mobile or electronic commerce systems.
- Program/data independence is held, that is, changing the system components will not affect the existing programs/data.
- End-to-end security and user privacy are rigorously enforced.

Requirements solely for mobile commerce systems include:

- The system allows end users to perform transactions easily, in a timely manner, and ubiquitously.
- The system provides supports for a wide variety of mobile commerce applications such as location finding to content providers.
- The applications can be accessed from a wide range of handheld devices.

SYSTEM STRUCTURES

This section illustrates the system structures of electronic and mobile commerce and explains the procedures of mobile commerce transactions. A modular approach will be used to study the systems.

An Electronic Commerce System Structure

Electronic commerce describes the manner in which transactions take place over networks, mostly the Internet. It is the process of electronically buying and selling goods, services, and information. An electronic commerce system is inherently interdisciplinary and there are many different ways to implement it. Figure 2 shows the structure of a traditional electronic commerce system and a typical example of such a system. The system structure includes four components, some of which are at least partly shared by mobile commerce systems: (i) electronic commerce applications, (ii) client computers, (iii) wired networks, and (iv) host computers.

Figure 2. An electronic commerce system structure

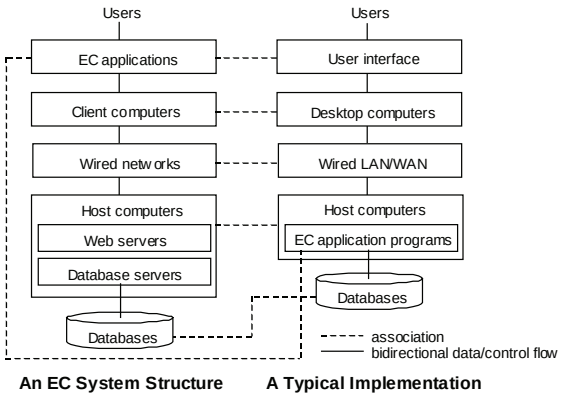


Figure 3. A mobile commerce system structure

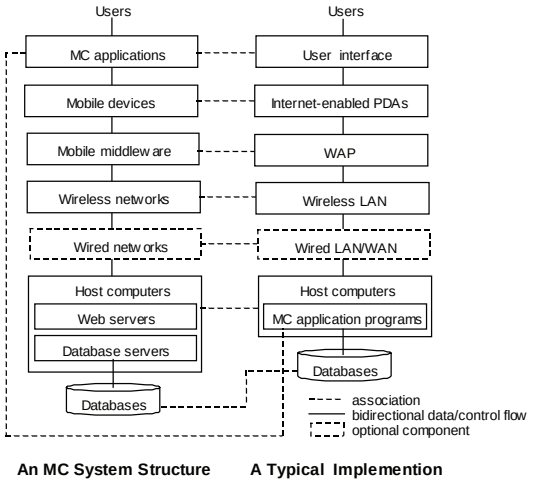


A Mobile Commerce System Structure

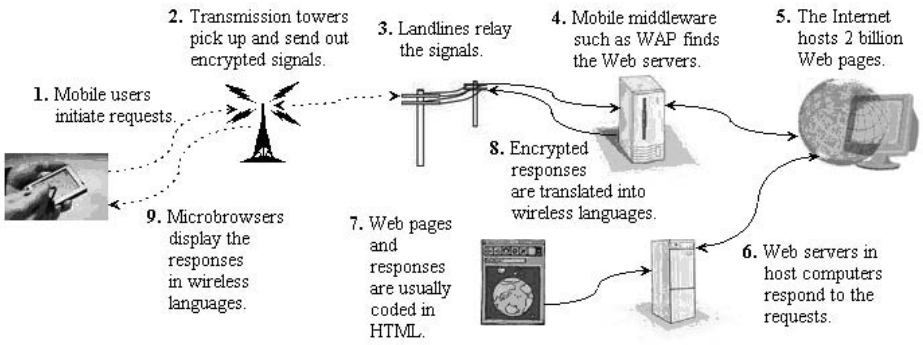
Much like the concept of e-commerce, mobile commerce is a type of business conducted 100% electronically through computer networks; m-commerce is a concept of buying and selling goods and services via wireless networks with a mobile device. Compared to an electronic commerce system, a mobile commerce system is much more complicated because components related to mobile computing have to be included. Figure 3 shows the structure of a mobile commerce system and an example of such a system that is currently possible based on the existing technologies (Hu, Lee, & Yeh, 2004). The system structure includes six components: (i) mobile commerce applications, (ii) mobile handheld devices, (iii) mobile middleware, (iv) wireless networks, (v) wired networks, and (vi) host computers. The network infrastructure for mobile commerce systems consists of mobile middleware and wired & wireless networks. The wired networks component has the same structure and implementation as that needed by an electronic commerce system.

Mobile Commerce Transaction Processing

Mobile commerce transaction processing is complicated. To explain how the mobile commerce components work together for a transaction, Figure 4 shows a flowchart of how a user request is processed by the components in a mobile commerce system, along with brief descriptions of how each component processes the request:

1. *Mobile commerce applications*: A content provider implements an application by providing two sets of programs: client-side programs, such as user interfaces on micro browsers, and server-side programs, such as database access and updating.
2. *Mobile handheld devices*: Handheld devices present user interfaces to the mobile end users, who specify their requests on the interfaces. The devices then relay the user requests to the other components and later display the processing results using the interfaces.

Figure 4. A flowchart of a user request processed in a mobile commerce system



3. *Mobile middleware*: The major purpose of mobile middleware is to seamlessly and transparently map Internet contents to mobile stations that support a wide variety of operating systems, markup languages, micro browsers, and protocols. Most mobile middleware also encrypts the communication in order to provide some level of security for transactions.
4. *Wireless and mobile networks*: Mobile commerce is possible mainly because of the availability of wireless networks. User requests are delivered to either the closest wireless access point (in a wireless local area network environment) or a base station (in a cellular network environment).
5. *Wired networks*: This component is optional for a mobile commerce system. However, most computers (servers) usually reside on wired networks such as the Internet, so user requests are routed to these servers using transport and/or security mechanisms provided by wired networks.
6. *Host computers*: Host computers process and store all the information needed for mobile commerce applications, and most application programs can be found here. They include three major components: Web servers, database servers, and application programs and support software.

APPLICATIONS

The emergence of electronic and mobile commerce creates numerous business opportunities and applications. Electronic commerce, defined as the buying and selling of goods and services and the transfer of funds through digital communications, includes a wide variety of applications, such as auctions, banking, marketplaces and exchanges, recruiting, and retailing, to name but a few. Mobile commerce applications not only cover the electronic commerce applications, but also include new applications, for example, mobile inventory tracking, which can be performed at any time and from anywhere by using mobile computing technology.

Electronic Commerce Applications

This sub-section discusses some new business models, which were not seen before, created by electronic commerce. Other than the "buy-and-sell" model, the following list gives some other common models created by e-commerce (Turban, et al, 2004):

- *Affiliate marketing:* Affiliate marketing is a marketing method, which allows other Websites to receive a commission by selling your products or services. For the example of Amazon.com's Associates Program, the associates drive Internet traffic to Amazon through specially formatted links that allow Amazon to track sales and other activities. The partners can receive up to 10% in referral fees on all qualifying revenue made through their links to Amazon's products and services. Amazon sends monthly payments to those associates.
- *Comparing prices:* This method presents a list of services or products based on a consumer's specifications. mySimon.com is a comparison shopping site for apparel, computers, electronics, jewelry, video games, and more. It gathers prices on millions of products from thousands of stores, so customers can compare products and find the best price before he or she buys.
- *Customization and personalization:* Customization or personalization is to design and creation of content that meets a customer's specific needs. For example, Dell is based on a simple concept: by selling computer systems directly to customers. This direct business

model eliminates retailers that add unnecessary time and cost. Instead of picking one from few standard models, Dell customers can specify their requirements such as memory sizes and CPU models and Dell will build the systems based on their specifications.

- *Electronic marketplaces and exchanges:* Electronic marketplaces are Internet Websites acting as a meeting point between supply and demand and electronic exchanges are a central marketplace with established rules and regulations where buyers and sellers meet to trade futures and options contracts or securities. Electronic marketplaces and exchanges provide benefits to both buyers and sellers because they are more efficient than traditional ones.
- *Electronic tendering systems:* Tendering is potential suppliers bid competitively for a contract, quoting a price to the buyer. Large buyers usually make their purchases through a tendering (bidding) system, which is more effective and efficient with the help of electronic commerce.
- *Group purchasing:* Large-quantity purchasing usually receives lower prices than small-quantity purchasing does. Electronic commerce allows a group of customers or organizations to place their orders together and negotiate for a better deal. For example, Amerinet members saved more than $300 million in 2003 through group purchasing health care equipments and products.
- *Name your price:* With this model, the product or service prices are set by customers instead of sellers. Priceline.com is the first company applying this method. The following example shows how the "Name Your Price" of Priceline.com works. With Priceline's "Name Your Own Price" hotel reservation service, customers choose the star level of hotel they want, along with the desired neighborhood, dates and price they want to pay. Priceline then works to find a hotel room at the customer's desired price. There is no guarantee that any offer will be accepted due to the changeability of room availability and pricing. Customers learn the specific hotel name and location after the purchase is completed.
- *Online auctions:* Traditional auctions usually require bidders to attend the auctions, whose items are limited. Online auctions allow bidders from everywhere to bid products or services provided by various sellers without needing to show up. eBay.com is the world's largest online auction site. It offers an online platform where millions of items are traded each day.

Mobile Commerce Applications

Mobile commerce applications cover almost everything in our daily lives such as traveling and foods. Table 1 lists some major mobile commerce applications along with explanations of three applications related to traveling (Sadeh, 2002):

- *Map services*: Map services provide various useful functions to mobile users. Some of the functions include:
  - *Directions*, which are driving/walking directions from the starting location to destination;
  - *Maps*, which include traditional clear maps;
  - *Local hangouts and businesses recommendations*, which provide suggestions for restaurant/gas-station/grocery-store/movie-theater; and
  - *Satellite imagery*, which includes real images from satellites.

  A few mobile map services are available. Google Maps for Mobile (n.d.) lets users find local hangouts and businesses across

Table 1. Major mobile commerce applications

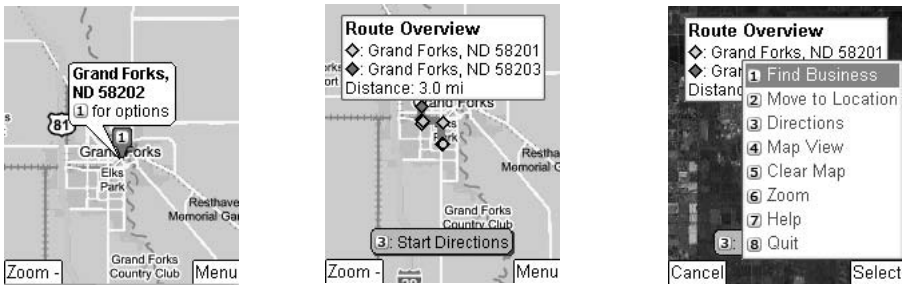
Mobile Category	Major Applications	Clients
Advertising	Targeted ads, location-based ads	Business
Commerce	Mobile transactions and payments	Business
Education	Mobile classrooms and labs	Schools and training centers
Enterprise resource planning	Resource management, managing a mobile workforce	All
Entertainment	Games/images/music/video downloads and on-line gaming	Entertainment industry
Health care	Accessing and updating patient records	Hospitals and nursing homes
Inventory tracking and dispatching	Product tracking and dispatching	Delivery services and transportation
Traffic	Global positioning, routing services, toll paying, traffic advisories	Transportation and auto industries
Travel and weather	Reservation services	Airlines, hotels, travel agencies

town or across the country—right from their phones. Figure 5 shows three screenshots from the Google's map services where

a. a clear map of the location with a postal code 58202;
b. directions from the postal code 58201 to 58203; and
c. a satellite map of (b) and a menu.

- *Travel*: Travel expenses can be costly for a business or an individual. Mobile commerce could help reduce operational costs by providing mobile travel management services to travelers. It can be used to provide assistance to customers by using the mobile channels to locate a desired hotel nearby, purchase tickets, make transportation arrangements, and so on. The travel section of Yahoo! Mobile (n.d.) includes the following services:
  - *Travel guides*: Allow mobile users to research 500,000 places to stay and things to do in over 40,000 cities worldwide with user reviews, photos, and maps, save favorite places into a custom trip plan, and get good travel deals.
  - *Trip planner*: It is a tool that lets mobile users save hotels, attractions, restaurants, maps, and more to a customized travel guide. Users can add travel dates, their own comments, even bookmarks for other sites to their trip.
  - *FareChase*: Yahoo! FareChase is a travel search engine that helps travelers scour the Web for the best flights and hotels that meet their budget and travel schedules.
  - *Deals*: This service provides various top deals from hotels to car rentals.

Figure 5. Screenshots of the Google's map services



(a) a clear map *(b) directions* *(c) a satellite image of (b) and a menu*

Figure 6. Screenshots of Yahoo! Mobile: Travel

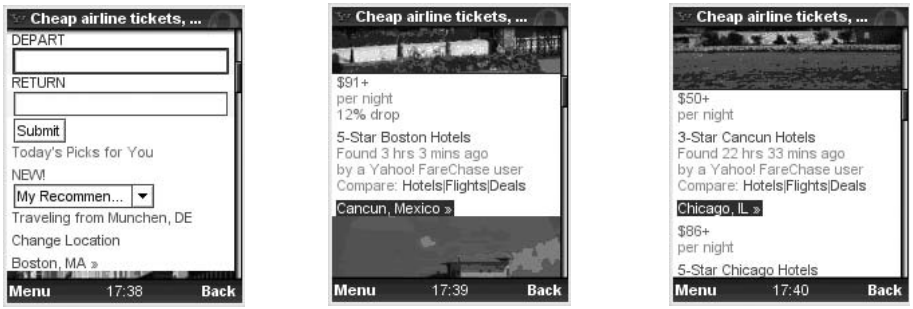


Figure 7. Screenshots of Google weather reports

Of course, mobile users can search travel-related information on Yahoo! Travel. Figure 6 shows screenshots of Yahoo! Mobile: Travel.

- *Weather*: Weather reports are important for travelers, who may pack their bags or plan their trips based on the weather predictions. Most mobile service providers offer weather reports. For example, the Google provides the following local weather information: (i) 3-day weather forecasts including lowest and highest temperatures, (ii) current temperature, (iii) humidity, (iv) weather conditions with pictures, and (v) wind including direction and speed. Figure 7 shows screenshots of Google weather reports.

CLIENT COMPUTERS OR DEVICES

Desktop and laptop computers are on the client-side of electronic commerce systems, whereas mobile handheld devices are for mobile commerce systems. An Internet-enabled mobile handheld device is a small general-purpose, programmable, battery-powered computer that is capable of handling the front end of mobile commerce applications and can be operated comfortably while being held in one hand. It is the device via which mobile users interact directly with mobile commerce applications. The differences between these two client machines are given in Table 2. There are other kinds of computers such as tablet computers, which are a special kind of PCs.

Client-Side Programming

Mobile or electronic commerce application programming involves a variety of technologies and languages. It consists of two kinds of programming:

- *Client-side programming*, which is to develop software running on client computers or devices. It is mostly related to Web interface

Table 2. Differences between desktop & laptop computers and handheld devices

	Desktop and Laptop Computers	**Mobile Handheld Devices**
Browser	Desktop browsers	Micro browsers
Functions	Full	Limited
Major Input Methods	Keyboards and mice	Stylus and soft keyboards
Major Output Methods	Screens and printers	Screens
Mobility	Low	High
Networking	Wired	Wireless and mobile
Transmission Bandwidth	High	Low
Power Supply	Electrical outlets	Batteries
Screen	Normal	Small
Size	Desktop	Handheld
Weight	Normal	Light

construction. Popular languages for Web interface construction include CSS, DOM, (X)HTML, JavaScript, WML, WMLScript, XML, XSL(T), and so forth. Other than Web interface construction, client-side programming can be used to build client-side applications such as address and schedule books. The tools and languages used for client-side application development are based on the client-side operating systems, for example, Visual Studio for Windows and C/C++ for Palm OS.

- *Server-side programming*, which is to develop software running on servers. The software normally receives requests from browsers and sends the results from databases/files/programs back to the browsers for display. Popular server-side languages include C/C++, Java, Perl, PHP, and so forth. Other than Web applications, it can be used to implement numerous applications such as instant messaging and telephony. However, this kind of applications is normally related to network programming such as TCP/IP programming and will not be covered in this book.

This sub-section discusses Web interface construction. The server-side programming will be covered in the section of host computers. Other than building a Web system from scratch by using various languages and tools, some common software packages are available for developing Web applications easily and quickly. Those packages can be divided into three categories: (i) multimedia editors, (ii) HTML editors, and (iii) integrated development environments (IDEs):

- *Multimedia editors*, which are used to create, edit, and post animation, audio, images, and videos on Web pages. Adobe Systems, Inc. provides two popular multimedia editors:
  - *Flash*, which is an authoring environment for creating animations, advertisements, and various Web page components, to integrate video into Web pages, and more recently, to develop rich Internet applications. Flash Professional is an IDE while Flash Player is a virtual machine used to run, or parse, the Flash files.
  - *Photoshop*, which is image-editing and graphics creation software.
- *HTML editors*, which are used to create static Web pages. Three popular HTML editors are:
  - *Adobe Dreamweaver*, which is WYSIWYG (what you see is what you got) authoring software that allows Web developers to generate HTML and JavaScript source code while viewing the site as they work.
  - *Microsoft Expression Web*, which is a design tool to create sophisticated standards-based Web sites. It combines both FrontPage and Visual Studio technologies in a new user interface for creating XHTML, CSS, XML, XSLT, and ASP.NET 2.0. Where appropriate, the user interface and features of Expression Web and Visual Studio are identical.
  - *Microsoft SharePoint Designer*, which will enable information workers to develop applications and solutions on top of the SharePoint platform to enable organizational agility, business process automation, and get the value of Microsoft Office applications on the SharePoint platform.

The category of integrated development environments (IDEs) will be covered in the section of Host Computers.

MOBILE MIDDLEWARE AND WIRELESS NETWORKS

Mobile middleware and wireless networks are for mobile commerce systems only. The mobile middleware is optional, but the system will be greatly simplified with it. A mobile commerce system is already complicated enough. Without mobile middleware, the mobile system becomes even more complicated.

Mobile Middleware

The term middleware refers to the software layer between the operating system and the distributed applications that interact via the networks. The primary mission of a middleware layer is to hide the underlying networked environment's complexity by insulating applications from explicit protocols that handle disjoint memories, data replication, network faults, and parallelism (Geihs, 2001). The major task of mobile middleware is to seamlessly and transparently map Internet contents to mobile handheld devices that support a wide variety of operating systems, markup languages, micro browsers, and protocols. WAP and i-mode are the two major kinds of mobile middleware:

- *WAP (wireless application protocol)*, which is a secure specification that allows users to access information instantly via mobile handheld devices such as smart phones and PDAs (Open Mobile Alliance Ltd., n.d.). WAP supports most wireless networks including CDPD, CDMA, GSM, PDC, PHS, TDMA, FLEX, ReFLEX, iDEN, TETRA, DECT, DataTAC, and Mobitex. WAP is supported by all operating systems. Ones specifically engineered for handheld devices include PalmOS, EPOC, Windows CE, FLEXOS, OS/9, and JavaOS. Although WAP supports HTML and XML, the WML language is specifically designed for small screens and one-hand navigation without a keyboard.
- *i-mode*, which is a mobile Internet service that has caused a revolution in both business and private lifestyles in Japan (NTT DoCoMo, Inc., 2007). Forty-six million subscribers have been attracted to this service since its debut in February 1999 and currently more than 95,000 Internet sites are providing a variety of contents. The use of packet transmissions offers continuous access, while the use of a subset of HTML makes content creation easy and provides simple conversion of existing websites.

Table 3 compares i-mode to WAP.

Table 3. A comparison between the two major types of mobile middleware

	WAP	**i-mode**
Developer	Open Mobile Alliance	NTT DoCoMo
Implementation	A protocol	A complete mobile Internet service
Web Language	WML (wireless markup language)	CHTML (compact HTML)
Major Technology	WAP gateway	TCP/IP development
Key Features	Widely adopted and flexible	Highest number of users and easy to use

Wireless Networks

Wireless communication capability supports mobility for end users in mobile commerce systems. Wireless LAN, MAN, and WAN are the major components used to provide radio communication channels so that mobile service is possible. In the WLAN category, the Wi-Fi standard with 11 Mbps throughput dominates the current market. However, it is expected that standards with much higher transmission speeds, such as IEEE 802.11a and 802.11g, will replace Wi-Fi in the near future. Compared to WLANs, cellular systems can provide longer transmission distances and greater radio coverage, but suffer from the drawback of much lower bandwidth (less than 1 Mbps). In the latest trend for cellular systems, 3G standards supporting wireless multimedia and high-bandwidth services are beginning to be deployed. The wireless telephone technology includes several generations as follows:

- *0G (1945-1973),* which refers to mobile radio telephone systems.
- *1G (1980s),* which is analog cell phone standards including NMT and AMPS.
- *2G (1990s),* which is digital cell phone standards divided into TDMA-based and CDMA-based standards depending on the type of multiplexing used.
- *2.5G (late 1990s),* which is implemented a packet switched domain in addition to the circuit switched domain.
- *3G (early 2000s),* which includes wide-area wireless voice telephony and broadband wireless data, all in a mobile environment.
- *4G (2000s),* which provides end-to-end IP solution where voice, data, and multimedia streaming can be served at higher data rates with anytime-anywhere concept.

A wide variety of technologies and standards for wireless telephones are available. Some of the major ones include:

- *CDMA (code division multiple access),* which is based on a spread spectrum method. The method transmits a signal by "spreading" it over a broad range of frequencies. This provides reduced interference and can increase the number of simultaneous users within a radio frequency band. With CDMA, each conversation is digitized and then tagged with a code.
- *GSM (global system for mobile communications),* which is one of the most popular standards for mobile phones and is specifically developed to provide system compatibility across country boundaries, especially the Europe. It is based on TDMA (time division multiple access) technology, which works by dividing a radio frequency into time slots and then allocating slots to multiple calls. Therefore, GSM allows eight simultaneous calls on the same radio frequency.
- *IEEE 802.11,* which includes an encryption method, the wired equivalent privacy algorithm. WLAN (wireless local area network), based on 802.11, allows a mobile user connecting to a local area network (LAN) through a wireless (radio) connection. This wireless data transmission speed of WLAN is up to 54 Mbps.
- *IEEE 802.16,* which ensures compatibility and interoperability between broadband wireless access equipment. WiMAX (worldwide interoperability for microwave access), based on 802.16, provides wireless data over long distances, in a variety of different ways, from point to point links to full mobile cellular type access. In practical terms this enables a user, for example, to browse the Internet on a laptop computer without

Table 4. Wireless telephone technology evolution

	2G (10 Kbps – 40 Kbps)	**2.5G** (20 Kbps – 171 Kbps)	**3G** (60 KBps – 54 Mbps)	**4G** (50 Mbps – 1 Gbps)
CDMA track	IS-95	CDMA 2000	W-CDMA	UMTS Revision 8 (LTE)
GSM track	GSM	GPRS	EDGE	
IEEE 802.11 track			Wi-Fi	
IEEE 802.16 track				WiMAX

physically connecting the laptop to a wall jack.

Table 4 shows major technologies and standards used in the wireless telephone generations.

Wired Networks

Wired networks are used to transmit data for electronic and mobile commerce. This component is a requirement for electronic commerce, but not necessary for mobile commerce, though mobile commerce would be greatly benefited by applying wired networks to its data communication because data transmission using wireless networks is more expensive than using wired networks. Among several types of wired networks, three major types are:

- *Local area network (LAN),* which spans a relatively small space of only a few square kilometers or less such as an office building. It generally offers a throughput of 10 Mbps or 100 Mbps and is usually based on ethernet technology, which is a network protocol using a bus topology and defining a specific implementation of the physical and data link layers in the OSI model (IEEE 802.3).
- *Metropolitan area network (MAN),* which spans a geographical area greater than an LAN but less than a WAN, such as few city blocks or a whole city. MAN typically uses wireless infrastructure or optical fiber connections to link its sites and it may connect multiple LANs together. Its maximum throughput is no less than 44 Mbps and it uses the distributed queue dual bus technology based on the IEEE 802.6 standard.
- *Wide area network (WAN),* which spans a wide geographic area, such as state or country, and uses specialized computers to connect smaller networks, such as LANs. It generally offers a throughput of 1.5 Mbps or more. WANs typically use wide area network services from telecommunications carriers, whose technologies include standard phone lines, ISDN (integrated services digital

network), or other high-speed services. Two examples of WAN are the Internet, the largest network in the world, and an airline corporation using WAN to connect its offices around the world.

HOST COMPUTERS

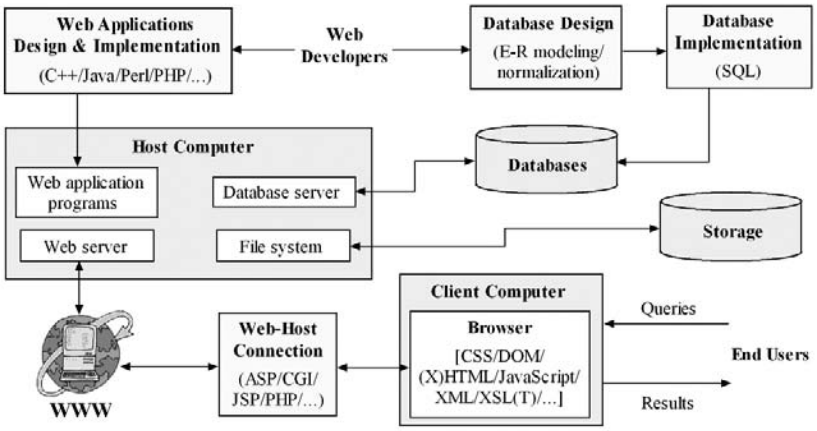
This component is similar for both electronic and mobile commerce systems because host computers are usually not aware of the differences among the targets, browsers, or micro browsers they serve. The application programs are responsible for apprehending their clients and responding to them accordingly. Most of the electronic/mobile commerce application programs reside in this component, except for client-side programs such as cookies or user interface using markup languages. A user request such as checking out or adding items to the shopping cart is actually processed at a host computer, which contains three major kinds of software specifically for electronic or mobile commerce transactions: (i) Web servers, (ii) databases and database servers, and (iii) application programs and support software. Figure 8 shows a structure of three-tiered client-server Web systems. Before examining the three kinds of software in more detail, the following sub-section studies the LAMP stack, which is one of the popular Web technologies used these days.

The LAMP Stack

One of the popular technologies for Web content implementation is the LAMP stack, which includes four components (Lawton, 2005):

1. *Linux*, which is a free open-source operating system based on Unix.
2. *Apache Web server*, which is an open-source HTTP server for modern operating systems including UNIX and Windows NT.
3. *MySQL*, which is an open source relational database management system (RDBMS) that uses structured query language (SQL), the most popular language for adding, accessing, and processing data in a database.
4. *Script languages*, such as Perl, PHP, and Python:

Figure 8. Three-tiered client-server Web system structure



- *Perl (practical extraction and report language),* which is often used for scanning text and printing formatted reports. It provides extensive support for regular expression matching, dynamically scoped variables and functions, extensible run-time libraries, exception handling and packages, and provide/require. The use of Perl has grown significantly since its adoption as the language of choice of many World Wide Web developers. CGI interfaces and libraries for Perl exist for several platforms and Perl's speed and flexibility make it well suited for form processing and on-the-fly page creation. Perl5 is a major rewrite and enhancement of Perl version 4. It adds nested data structures and object-oriented features.
- *PHP (HyperText preprocessor),* which is a general-purpose server-side scripting language that is especially suited for dynamic and interactive Web sites and can be embedded into HTML. It is the widely-used, free, and efficient alternative to competitors such as Microsoft's ASP. The PHP syntax is very similar to Perl and C. PHP is often used together with MySQL (DBMS) and Apache (Web server) on various operating systems. A PHP file may contain text, HTML tags, and scripts. Scripts in a PHP file are executed on the server.
- *Python*, which is a dynamic object-oriented programming language that can be used for many kinds of software development. It offers strong support for integration with other languages and tools, comes with extensive standard libraries, and can be learned in a few days. Python runs on Windows, Linux/Unix, Mac OS X, OS/2, Amiga, Palm Handhelds, and Nokia mobile phones. Python has also been ported to the Java and .NET virtual machines. Python is distributed under an OSI-approved open source license that makes it free to use, even for commercial products.

LAMP has several key advantages over proprietary software development approaches. Two of them are:

- *Cost*: Open source software is either free or low cost compared to proprietary software.
- *Open source*: Anyone can review, modify, and work with open source software; developers can improve and fix the technology faster.

Web Servers

A Web server is a server-side application program that runs on a host computer and manages the Web pages stored on the Web site's databases or files. There are several kinds of Web server software including public domain software from NCSA and Apache, and commercial packages from Microsoft, Netscape, and others. Three popular Web servers are:

- *Apache HTTP servers*, which are a collaborative software development effort aimed at creating a freely-available source code implementation of an HTTP (Web) server. They are jointly managed by a group of volunteers located around the world. Since April 1996, Apache has been the most popular HTTP server on the Internet. It was developed in early 1995 based on code and ideas found in the most popular HTTP server of the time, NCSA httpd 1.3. It has since evolved to rival almost any other Unix

based HTTP server in terms of functionality and speed. It features highly configurable error messages, DBM-based authentication databases, and content negotiation (Apache Software Foundation, n.d.).

- *Microsoft's Internet information services (IIS)*, which provide a Web application infrastructure for all versions of Windows servers (Microsoft, Corp., n.d.a). It is the world's second most popular Web server after Apache.
- *Sun Java system Web servers*, which provide organizations with a single deployment platform for Web services, JavaServer Pages (JSP), Java Servlet technologies, NSAPI, and CGI (Sun Microsystems, Inc., n.d.). They also offer built-in HTTP reverse-proxy capabilities to provide a highly scalable HTTP front-end to application servers or other HTTP origin servers. Its bundled FastCGI interface provides a stable and scalable platform for third party scripting technologies such as PHP, Ruby On Rails, Perl, Python, and more.

Database Servers

A database server manages database access functions, such as locating the actual record being requested or updating the data in databases. Some popular databases include:

- *IBM DB2*: DB2 9 is a hybrid data server with management of both XML and relational data. It includes the following major features:
  - XML data store;
  - Integration with relational data;
  - Eclipse-base developer workbench; and
  - Integration with leading application infrastructures like PHP, Java, and .NET
- *Microsoft*: Microsoft provides two kinds of databases: (i) *Access* for desktop computers and (ii) *SQL Server* for the server engines in client-server solutions:
  - *Access*: The Microsoft Access is a full-featured multi-user relational database management system that designed for the Microsoft Windows operating systems. It makes extensive use of drag-and-drop and visual design for queries, forms, and reports. Access comes with an integrated development environment, including incremental compilation, a fully interactive visual debugger, breakpoints, and single step-through. These capabilities combine to make Microsoft Access a powerful platform for developing client-server database solutions.
  - *SQL Server*: The SQL Server is a comprehensive database software platform providing enterprise-class data management and integrated business intelligence (BI) tools (Microsoft, Corp., n.d.b). The SQL Server data engine lies at the core of this enterprise data management solution. In addition to providing support for relational databases or XML, SQL Server combines the functions in analysis, reporting, integration, and notification. Close integration with Microsoft Visual Studio, the Microsoft Office System, and a suite of new development tools, including the Business Intelligence Development Studio, sets SQL Server apart.
- *MySQL*: MySQL is an open-source, multi-threaded, multi-user SQL relational database management system. It is used in more than 11 million installations ranging from large corporations to specialized embedded applications. Not only is MySQL the

world's most popular open source database, it is a key part of LAMP (Linux, Apache, MySQL, PHP/Perl/Python), a fast growing open source enterprise software stack. More and more companies are using LAMP as an alternative to expensive proprietary software stacks because of its lower cost and freedom from lock-in. MySQL is flexible and runs on more than 20 platforms including Linux, Windows, OS/X, HP-UX, AIX, and Netware.

- *Oracle databases*, whose newest version is Oracle10g. The following list shows the Oracle database migration (Oracle, n.d.):
  - *Oracle7.2*, which is a client-server based relational database management system (RDBMS). The query language is based on SQL.
  - *Oracle8i*, which is an RDBMS with object capabilities included. Java has been added to the database capabilities.
  - *Oracle9i*, which features full XML database functionality with the new Oracle XML DB feature, and other improvements.
  - *Oracle 10g*, which is the first database designed for enterprise grid computing. Grid computing provides an environment in which individual users can access computers, databases, and experimental facilities simply and transparently, without having to consider where those facilities are located.

Other than the server-side database servers, a growing trend is to provide a client-side mobile database or an embedded database to a handheld device with a wide range of data-processing functionality. The functionality is frequently very sophisticated, and the flat file system that comes with these devices may not be able to adequately handle and manipulate data. Embedded databases have very small footprints, and must be able to run without the services of a database administrator and accommodate the low-bandwidth constraints of a wireless network. Some leading embedded-databases are Progress Software databases, Sybase's Anywhere products, and Ardent Software's DataStage (Ortiz, 2000).

Application Programs and Support Software

Application programs and support software are responsible for handling server-side processing. Three generations of programming languages and environments are used for server-side Web application development:

1. *1st generation*: Traditionally, conventional programming languages such as C/C++ and Java are used for Web development.
2. *2nd generation*: Dynamic programming languages such as Perl and PHP gradually replace conventional languages for Web development. A dynamic language basically enables programs that can change their code and logical structures at runtime, adding variable types, module names, classes, and functions as they are running. These languages frequently are interpreted and generally check typing at runtime.
3. *3rd generation*: Recently, a couple of IDEs (integrated development environments) are used for Web development:
   - *Adobe ColdFusion*, which is an application server and software development framework used for the development of computer software in general, and dynamic Web sites in particular.
   - *Microsoft ASP.NET*, which is part of Microsoft's .NET platform and is the successor to ASP technology. ASP.

NET is a free technology that allows programmers to create dynamic web applications.

- *Microsoft Visual Studio,* which is Microsoft's flagship software development product for computer programmers. It lets programmers create standalone applications, Web sites, Web applications, and Web services that run on any platforms supported by Microsoft's .NET Framework.
- *NetBeans IDE*, which is an open-source IDE for software developers. It is used to create professional cross-platform desktop, enterprise, Web, and mobile applications.
- *Ruby On Rails (ROR),* which is a full-stack framework for developing database-backed Web applications according to the model-view-control pattern.
- *Sun Java Studio IDE,* which is a development platform with features such as UML modeling, instant collaboration, and application profiling. It is used to develop, debug, tune, and deploy enterprise applications, Web services, and portal components based on the Java EE platform.
- *Zend Core*, which is the production PHP 5 stack that provides the certified, enhanced capabilities with support and services that professionals need for PHP development and production.

SUMMARY

The emerging wireless and mobile networks have extended electronic commerce to another research and application subject: mobile commerce. A mobile or an electronic commerce system involves a range of disciplines and technologies. This level of complexity makes understanding and constructing such a system an arduous task. To facilitate this process, this article divided a mobile or an electronic commerce system into six components, which can be summarized as follows:

1. *Applications*: Electronic commerce applications are already broad. Mobile commerce applications not only cover those applications, but also include new applications, which can be performed at any time and from anywhere by using mobile computing technology.
2. *Client computers or devices*: Desktop and notebook computers are for electronic commerce and mobile handheld devices, including smart cellular phones and PDAs, are used to perform mobile transactions. Handheld devices are convenient and have many advantages over desktop computers, but they are limited by their tiny screens, small memory, low processing power, and short battery life, and suffer from wireless network transmission problems. Numerous mobile devices are available in the market, but most use one of three major operating systems: Palm OS, Microsoft Windows Mobile, and Symbian OS. At this moment, Symbian OS leads the market, although it faces a serious challenge from Windows Mobile.
3. *Mobile middleware (mobile commerce systems only)*: Mobile middleware is used to facilitate mobile communication. It is not required for mobile commerce systems, but it can greatly reduce the complication of mobile communication. WAP and i-mode are the two major kinds of mobile middleware. WAP is widely adopted and flexible, while i-mode has the highest number of users and is easy to use. It is difficult to predict which middleware will be the eventual winner in the end; it is more likely that the two will

be blended somehow at some point in the future.

4. *Wireless networks (mobile commerce systems only)*: Wireless communication capability supports mobility for end users in mobile commerce systems. Wireless LAN, MAN, and WAN are major components used to provide radio communication channels so that mobile service is possible. In the WLAN category, the Wi-Fi standard with 11 Mbps throughput dominates the current market. It is expected that standards with much higher transmission speeds, such as IEEE 802.11a and 802.11g, will replace Wi-Fi in the near future. Compared to WLANs, cellular systems can provide longer transmission distances and greater radio coverage, but suffer from the drawback of much lower bandwidth (less than 1 Mbps). In the latest trend for cellular systems, 3G standards supporting wireless multimedia and high-bandwidth services are beginning to be deployed. WCDMA and CDMA2000 are likely to dominate the market in the future.
5. *Wired networks*: This component is a requirement for electronic commerce systems, but not necessary for mobile commerce systems, though mobile commerce systems will be greatly benefited by applying wired networks to its data communication because data transmission using wireless networks is more expensive than using wired networks. Among several types of wired networks, three major types are (i) LAN (local area network), (ii) MAN (metropolitan area network), and (iii) WAN (wide area network) based on the sizes of their covering areas.
6. *Host computers*: Host computers process and store all the information needed for mobile and electronic commerce applications, and most application programs can be found here. They include three major components: (i) Web servers, (ii) database servers, and (iii) application programs and support software.

Another important issue about mobile and electronic commerce systems is application programming. Electronic and mobile commerce programming, involving a wide variety of technologies and languages, consists of two kinds of programming:

- *Client-side programming*, which is to develop software running on client computers or devices. It is mostly related to Web interface construction. The popular languages for Web interface construction include CSS, DOM, (X)HTML, JavaScript, WML, WMLScript, XML, XSL(T), and so forth.
- *Server-side programming*, which is to develop software running on servers. The software normally receives requests from browsers and sends the results from databases/files/programs back to the browsers for display. The popular server-side languages include C/C++, Java, Perl, PHP, and so forth.

Chapter 3.39
E-Commerce Services Based on Mobile Agents

INTRODUCTION

The Internet offers a unique opportunity for e-commerce to take central stage in the rapidly growing online economy. With the advent of the Web, the first generation of business-to-consumer (B2C) applications was developed and deployed. Classical examples include virtual shops, on-demand delivery of contents, and e-travel agency. Another facet of e-commerce is represented by business-to-business (B2B), which can have even more dramatic economic implications since it far exceeds B2C in both the volume of transactions and rate of growth. Examples of B2B applications include procurement, customer relationship management (CRM), billing, accounting, human resources, supply chain, and manufacturing (Medjahed, Benatallah, Bouguettaya, Ngu, & Elmagarmid, 2003).

Although the currently available Web-based and object-oriented technologies are well-suited for developing and supporting e-commerce services, new infrastructures are needed to achieve a higher degree of intelligence and automation of e-commerce services. Such a new generation of e-commerce services can be effectively developed and provided by combining the emerging agent paradigm and technology with new Web-based standards such as ebXML (2005).

Agents have already been demonstrated to retain the potential for fully supporting the development lifecycle of large-scale software systems which require complex interactions between autonomous distributed components

(Luck, McBurney, & Preist, 2004). In particular, e-commerce has been one of the traditional arenas for agent technology (Sierra & Dignum, 2001). Agent-mediated e-commerce (AMEC) is concerned with providing agent-based solutions which support different stages of the trading processes in e-commerce, including needs identification, product brokering, merchant brokering, contract negotiation and agreement, payment and delivery, and service and evaluation. In addition, the mobility characteristic of peculiar agents (a.k.a. *mobile agents*), which allows them to move across the nodes of a networked environment, can further extend the support offered by the agents by featuring advanced e-commerce solutions such as location-aware shopping, mobile and networked comparison shopping, mobile auction bidding, and mobile contract negotiation (Kowalczyk, Ulieru, & Unland, 2003; Maes, Guttman, & Moukas, 1999).

To date, several agent- and mobile agent-based e-commerce applications and systems have been developed which allow for the creation of complex e-marketplaces—that is, e-commerce environments which offer buyers and sellers new channels and business models for trading goods and services over the Internet.

However, the growing complexity of agent-based marketplaces demands for proper methodologies and tools supporting the validation, evaluation, and comparison of: (1) models, mechanisms, policies, and protocols of the agents involved in such e-marketplaces; and (2) aspects concerned with the overall complex dynamics of the e-marketplaces.

The use of such methodologies and tools can actually provide the twofold advantage of:

1. analyzing existing e-marketplaces to identify the best reusable solutions and/or identify hidden pitfalls for reverse engineering purposes; and
2. analyzing new models of e-marketplaces before their actual implementation and deployment to identify, *a priori*, the best solutions, thus saving reverse engineering efforts.

This article presents an overview of an approach to the modeling and analysis of agent-based e-marketplaces (Fortino, Garro, & Russo, 2004a, 2005). The approach centers on a Statecharts-based development process for agent-based applications and systems (Fortino, Russo, & Zimeo, 2004b) and on a discrete event simulation framework for mobile and multi-agent systems (MAS) (Fortino et al, 2004a). A case study modeling and analyzing a real consumer-driven e-commerce service system based on mobile agents within an agent-based e-marketplace on the Internet (Bredin, Kotz, & Rus, 1998; Wang, Tan, & Ren, 2002) is also described to demonstrate the effectiveness of the proposed approach.

BACKGROUND

In a broad sense, an agent is any program that acts on behalf of a (human) user (Karnik & Triphati, 1998). An agent can just sit there and interact with its environment and with other agents through conventional means, such as local/remote procedure calls and asynchronous messaging, or through more advanced coordination infrastructures such as *tuple* spaces and *event*-based systems. Agents that do not or cannot move are called "stationary agents." Conversely, a mobile agent is a program that represents a user in a computer network and can migrate autonomously from node to node to perform some computation on behalf of the user. Thus mobility is an orthogonal property of agents—that is, not all agents are mobile. Also mobile agents can interact with their environment and, notably, with other agents through mobility-aware and mobility-unaware infrastructures (Fortino & Russo, 2005). Indeed, the emergence of mobile agents was motivated by the benefits they provide for creating distributed systems. In

fact, as Lange and Oshima (1999) pointed out in their seminal paper, there are at least seven good reasons to employ mobile agents: reduction of network load, overcoming of network latency, encapsulation of protocols, asynchronous and autonomous execution ("dispatch your agents, shut off your machine"), dynamic adaptation, seamless system integration, and robustness and fault-tolerance.

An agent-based e-marketplace (AEM) is a distributed multi-agent system formed by both stationary and mobile agents which provide e-commerce services to end-users within a business context. AEMs are, as previously pointed out, distributed large-scale complex systems which require tools which are able to analyze not only the AEM at the *micro* level (i.e., behaviors and interactions of their constituting agents), but also the AEM at the *macro* level (i.e., the overall AEM dynamics).

In Griss and Letsinger (2000), an agent-based framework for e-commerce simulation games has been developed by using *Zeus*, a Java-based multi-agent system developed at the British Telecom Lab. Its goal is to evaluate the potential consequences of novel combinations of market models, business strategies, and new e-services through multi-player shopping games, in which agents represent various typologies of sellers, buyers, brokers, and services.

In Wang et al. (2002), an infrastructure for Internet e-marketplaces based on the *Aglets* mobile agents that enables real commercial activities by consumers, agents, and merchants, has been proposed. Its goal is not only to provide an advanced e-commerce service, but also to evaluate several dispatching models for mobile agents.

Bredin et al. (1998) describe a simulated environment for mobile agents which allows analyzing the market-based resource control system of the *D'Agents* mobile agent system and, in particular, the resource allocation mechanism of its resource manager using a sealed-bid, second-price auction policy.

Although useful insights about AEM micro and macro levels can be acquired by playing e-commerce simulation games and, then, analyzing the obtained results, or by evaluating real e-commerce applications, discrete event simulators are essential for evaluating how AEMs work on scales much larger than that achievable in games or in applications which involve humans. In fact, discrete event simulation is currently extensively exploited as a strategic tool in most research and application areas which are directly or indirectly related to computer science. In this context, the article proposes an approach based on discrete event simulation and shows its application to the analysis of micro-level issues of a consumer-driven AEM: validation and evaluation of services based on mobile agents for product searching and buying.

MODELING AND ANALYSIS OF MOBILE AGENT-BASED SYSTEMS

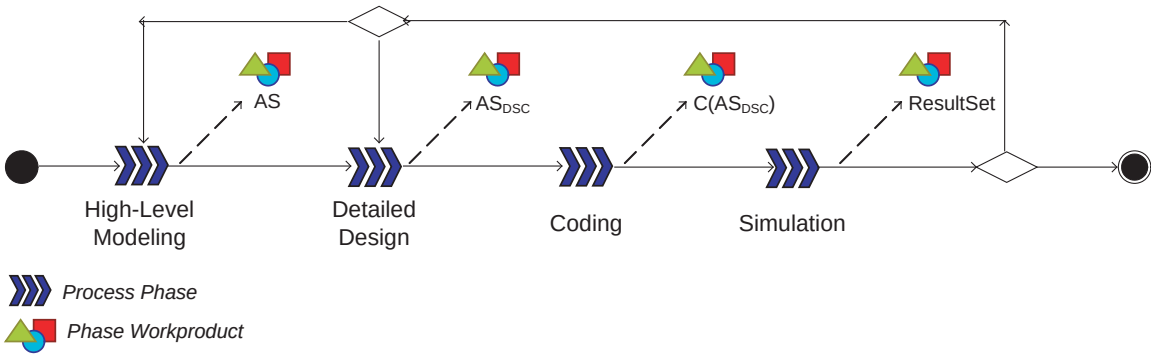
The StateCharts-Based Approach for Modeling and Analysis

The proposed approach (Fortino, Garro & Russo, 2005) consists of the following phases: high-level modeling, detailed design, and coding and simulation (see Figure 1).

The *High-Level Modeling* of an agent-based system can be supported through well-established agent-oriented methodologies (such as the Gaia methodology; Wooldridge, Jennings, & Kinny, 2000) which cover the phases of requirements capture, analysis, and high-level design. An agent-based system (AS) can be modeled as follows:

AS = <AT, LCL, act, ser, pro>,
where:
AT (Agent Types) is the set of types of agents embodying activity, offering services, and interacting with each other.

Figure 1. Phases and work products of the proposed approach



LCL (Logical CommunicationLinks) is the set of logical communication channels among agent types which embody interaction protocols.

act: $AT \rightarrow$ *activity description* is the activity relation which associates one or more activities to an agent type.

ser: $AT \rightarrow$ *service description* is the service relation which associates one or more services to an agent type.

pro: $LCL \rightarrow$ *interaction description* is the protocol relation which associates an interaction protocol to a logical communication channel.

The *Detailed Design* of an AS is achieved through a Statecharts-based formalism, namely Distilled StateCharts (DSC) (Fortino et al., 2004b), which allows for the specification of the behavior of the agent types and the interaction protocols among the agent types. In fact, a Statecharts-based specification of an entity describes both internal behavior and coordination through the reception and generation of events (Harel & Gery, 1997). DSC allow for the specification of the behavior of lightweight agents which have the following features: event-driven, single-threaded, capable of transparent migration, and executing chains of atomic actions. The DSC-based specification of an AS (AS_{DSC}) can be expressed as follows:

$AS_{DSC} = \{Beh(AT_1), \ldots, Beh(AT_n)\}$,
where:

$Beh(AT_i)$ is the DSC-based specification of the behavior of the i-th agent type.

$Beh(AT_i) = <S_{Beh}(AT_i), E_{Beh}(AT_i)>$, where $S_{Beh}(AT_i)$ is a hierarchical state machine incorporating the activity and interaction handling of the i-th agent type and $E_{Beh}(AT_i)$ is the related set of events to be handled triggering state transitions in $S_{Beh}(AT_i)$.

The *Coding* of an AS_{DSC}, $C(AS_{DSC})$, is carried out through the Java-based Mobile Active Object (MAO) Framework (Fortino et al., 2004b). In particular, $Beh(AT_i)$ can be seamlessly translated into a composite object (called MAOBehavior object), which is the object-based representation

of $S_{Beh}(AT_i)$, and into a set of related event objects representing $E_{Beh}(AT_i)$.

Finally, the *Simulation* phase of AS_{DSC} is supported by a Java-based discrete event simulation framework for distributed agent systems. The framework provides:

1. *Basic Simulation Objects*:
   - **Agent (Ag):** Represents a stationary or a mobile agent and includes a pair of objects: <MAOId, MAOBehavior>, where MAOId is the unique agent identifier and MAOBehavior is an agent behavior object.
   - **Event (Evt):** Represents the event for intra- and inter-Ags interactions.
   - **AgentServer (AgS):** Represents the agent server hosting **Ag**s.
   - **VirtualNetwork (VN):** Represents the logical network of hosts on which **AgS** are mapped.
   - **UserAgent (UA):** Represents a user, directly connected to an **AgS**, who can create, launch, and interact with **Ag**s.
2. A *Simulation Engine* Enabling:
   - execution of **Ag**s by interleaving their **Evt**s processing;
   - transmission of **Evts** among **Ag**s; and
   - migration of **Ag**s.

On the basis of the framework, a simulator program can be implemented and executed to obtain a ResultSet containing validation traces and performance parameter values. While the validation of agent behaviors and interactions is carried out on execution traces automatically generated, the performance evaluation relies on the specific agent-based system to be analyzed; the performance evaluation parameters are therefore set ad-hoc. The ResultSet can also be used to feed back the high-level modeling and detailed design phases.

A Consumer-Driven Agent-Based E-Marketplace

A consumer-driven e-marketplace is an e-marketplace in which the exchange of goods is driven by the consumers that wish to buy a product. The modeled AEM, inspired by the systems presented in Bredin et al. (1998) and Wang et al. (2002) consists of a set of stationary and mobile agents (see Figure 2) which provides basic services for the searching, buying, selling, and payment of goods.

The identified types of agents are:

- **User Assistant Agent (UAA):** Associated with users and assists them in: (1) looking for a specific product that meets their needs; and (2) buying the product according to a specific buying policy.
- **Access Point Agent (APA):** Represents the entry point of the e-marketplace. It accepts requests for buying a product from a registered UUA.
- **Mobile Consumer Agent (MCA):** Represents an autonomous mobile agent dealing with the searching, contracting, evaluation, and payment of goods.
- **Vendor Agent (VA):** Represents the vendor of specific goods.
- **Yellow Pages Agent (YPA):** Represents the contact point of the distributed Yellow Pages Service (YPS) providing the location of agents selling a given product. The organization of the YPS can be: (1) *Centralized* (C), where each YPA stores a complete list of Vendor Agents; (2) *One Neighbor Federated* (1NF), where each YPA stores a list of VAs and keeps a reference to only another YPA; or (3) *M-Neighbors Federated* (MNF), where each YPA stores a list of VAs and keeps a list of at most M YPAs.
- **Bank Agent (BA):** Represents a reference bank supervising money transactions between MCAs and VAs

The identified types of interactions between the agent types are described below by relating them to the system workflow triggered by a user's request (see Figure 2):

1. **Request Input (UAA → APA):** The UAA sends a request to the APA containing a set of parameters selected by the user for searching and buying the desired product—that is, the product description (*Prod_Desc*), the maximum product price (P_{MAX}) the user is willing to pay, and the type of buying policy (*BP*).
2. **Service Instantiation (APA→ MCA):** The APA creates a specific MCA and provides it with the set of user parameters, the type of searching policy (*SP*), and the location of the initial YPA to be contacted. Upon creation, the MCA moves to the initial YPA location.
3. **Searching (MCA→ YPA):** The MCA requests a list of locations of VAs selling the desired product to the YPA. The YPA replies with a list of VA locations and, possibly, with a list of linked YPA locations.
4. **Contracting & Evaluation (MCA → VA):** The MCA interacts with the found VAs to request an offer (P_{offer}) for the desired product, evaluates the received offers, and selects an offer, if any, for which the price is acceptable (i.e., $P_{offer} <= P_{MAX}$) according to the type of *BP*.
5. **Buying (MCA → VA → BA):** The MCA moves to the location of the selected VA and pays for the desired product using a given amount of e-cash (or bills) triggering the following money transaction: (a) the MCA gives the bills to the VA; (b) the VA sends the bills to a BA; (c) the BA validates the authenticity of the bills, disables them for re-use, and, finally, issues an amount of bills equal to that previously received to the VA; and (d) the VA notifies the MCA.
6. **Result Report (MCA → UAA):** The MCA reports the buying result to the UUA.

Analysis of Mobile Agent-Based Services

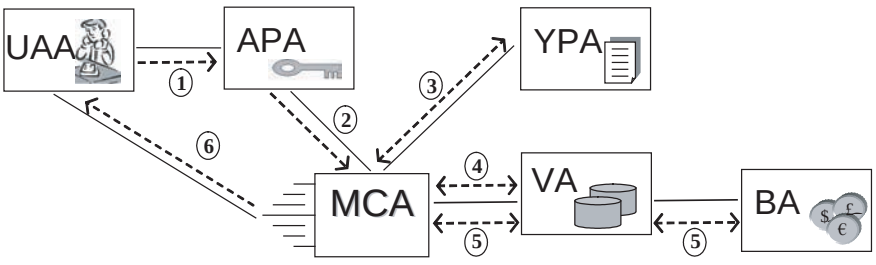
A model of MCA is defined on the basis of the tuple:

<SP, BP, TEM>,

where:

- *SP* is a searching policy in {ALL, PA, OS}:

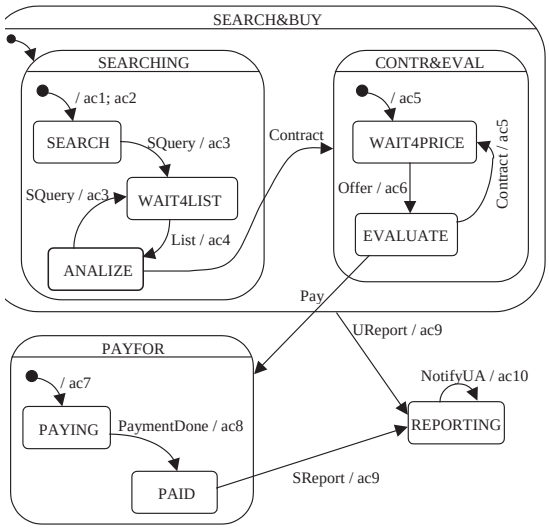
Figure 2. The reference consumer-driven agent-based e-marketplace model: the types of agents, the logical communication links among them, and the sequence of agent interactions



a. ALL: All YPAs are contacted.
b. *Partial* (PA): A subset of YPAs are contacted.
c. *One-Shot* (OS): Only one YPA is contacted.

- *BP* is a buying policy in {MP, FS, FT, RT}:
  a. *Minimum Price* (MP): The MCA first interacts with all the VAs to look for the best price of the desired product; then, it buys the product from the VA offering the best acceptable price.
  b. *First Shot* (FS): The MCA interacts with the VAs until it obtains an offer for the product at an acceptable price; then, it buys the product.
  c. *Fixed Trials* (FT): The MCA interacts with a given number of VAs and buys the product from the VA which offers the best acceptable price.
  d. *Random Trials* (RT): The MCA interacts with a random number of VAs and buys the product from the VA which offers the best acceptable price.
- *TEM* is a task execution model in {ITIN, PAR}:
  a. *Itinerary* (ITIN): The *Searching* and *Contracting & Evaluation* phases are performed by a single MCA which fulfils its task by sequentially moving from one location to another.
  b. *Parallel* (PAR): The *Searching* and *Contracting & Evaluation* phases are performed by a set of mobile agents in a parallel mode. In particular, the MCA is able to generate a set of children (generically called workers) and to dispatch them to different locations; the workers can, in turn, spawn other workers.

Figure 3. DSC-based behavior of the MCA models <,*,ITIN>*



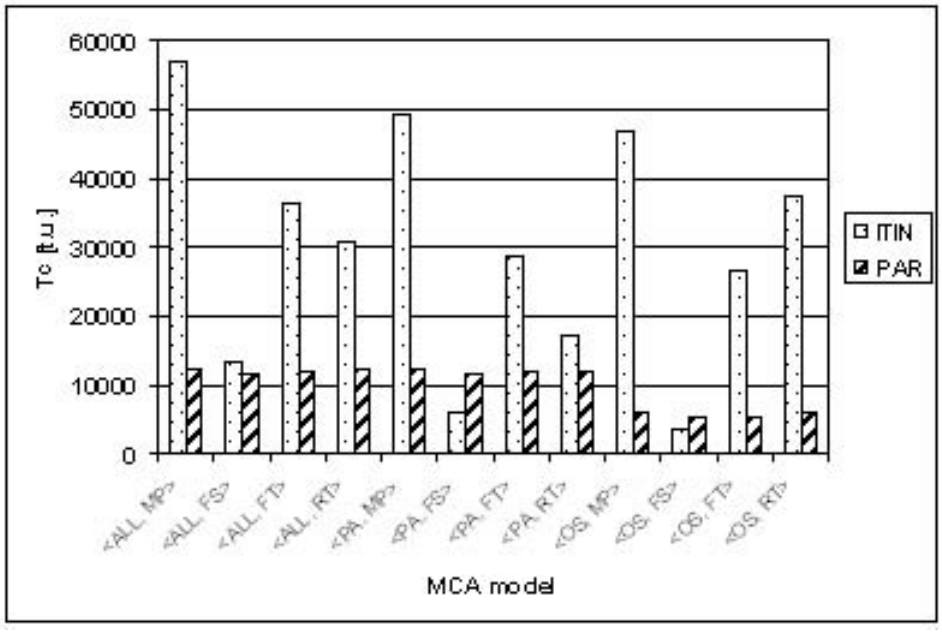
```
ac1 :nextYP=0;
ac2 :YPATarget=(MAOId)yp.elementAt(nextYP++);
     generate(new Move(self(), YPATarget.getCurrLocation()));
     generate(new SQuery(self()));
ac3 :generate(new VAListQuery(self(), YPATarget, vaListQuery));
ac4 :List reply = (List)mevent;
     Proc proc = processYPAReply(reply);
     if (proc.continueSearching()) ac2();
     else if (proc.noVendors()) sa2();
     else { nextVA=0; sa1(); }
sa1 :VATarget=(MAOId)va.elementAt(nextVA++);
     generate(new Move(self(), VATarget.getCurrLocation()));
     generate(new Contract(self()));
sa2 :generate(new UReport(self()));
ac5 :generate(new PriceQuery (self(), VATarget, priceQuery));
ac6 :Offer offer = (Offer)mevent;
     Eval eval = evaluateVAOffer(offer);
     if (eval.buySoon()) generate(new Pay(self()));
     else if (eval.moveAndBuy()){
      generate(new MAOMove(self(), VATarget.getCurrLocation()));
      generate(new Pay(self()));
     }
     else if (eval.noBuy()) sa2();
     else sa1();
ac7 :bills = prepareBills(price);
     generate(new PayFor(self(), VATarget, bills);
ac8 :nbills = nbills - eval.price();
     generate(new SReport(self()));
ac9 :generate(new Move(self(), self().getHomeLocation()));
     generate(new NotifyUA(self()));
ac10:reportTR();
```

Thus, each one of the defined models implements the product buying service differently. Figure 3 shows the generic DSC-based behavior of the MCA models <*,*,ITIN>. For the sake of brevity, the explanation is not given here, but readers unfamiliar with DSC-based programming can refer to Fortino et al. (2004b).

In order to analyze and compare the MCA models, the Task Completion Time (T_{TC}) parameter was defined as follows: $T_{TC}=T_{CREATION}-T_{REPORT}$ where, $T_{CREATION}$ is the creation time of the MCA and T_{REPORT} is the reception time of the MCA report. Accordingly, a simulator program was implemented which allows for computation of T_{TC} for each MCA model by varying the *Yellow Pages* organization, the number of YPAs (N_{YPA}), and the number of VAs (N_{VA}). In particular, the simulation scenario was set up as follows:

- Each stationary agent (UAA, APA, YPA, VA, BA) executes in a different agent server.
- Agent servers are mapped onto different network nodes which are completely connected through links having the same characteristics. The communication delay (δ) on a network link is modeled as a lognormally distributed random variable with a mean, μ, and a standard deviation, σ (Floyd & Paxson, 2001).
- Each UAA is connected to only one APA.
- The price of a product, which is uniformly distributed between a minimum (PP_{MIN}) and a maximum (PP_{MAX}) price, is set in each VA at initialization time and is never changed; thus the VAs adopt a fixed-pricing policy to sell products.

Figure 4. Task completion time of the MCA models in an e-marketplace with $N_{YPA}=10$, $N_{VA}=80$, and YPS=2NFBT



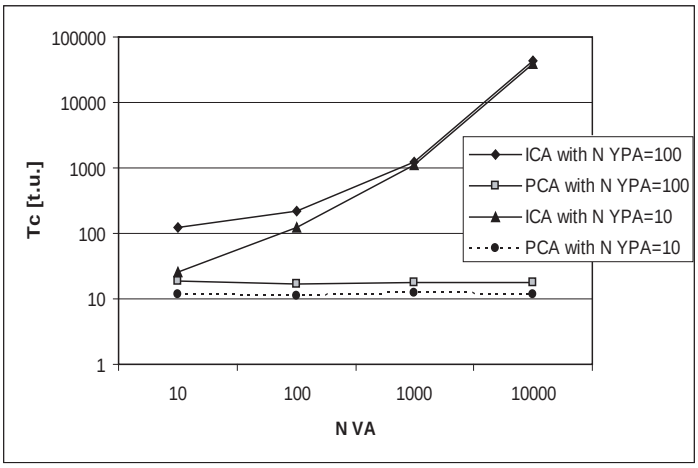
- Each YPA manages a list of locations of VAs selling available products.
- An UAA searches for a desired product, which always exists in the e-marketplace, and is willing to pay a price P_{MAX} for the desired product which can be any value uniformly distributed between PP_{MAX} and $(PP_{MAX}+PP_{MIN})/2$.

Simulations were run by varying (1) the organization of the Yellow Pages (C, 1NF and 2NF organized as a binary tree or 2NFBT), (2) the number of YPA agents in the range [10..1000], and (3) the number of VA agents in the range [10..10000]. These ranges were chosen for accommodating small as well as large e-marketplaces. The duration of the performed simulations were set so to allow for the completion of the buying task carried out by the MCA.

Figure 4 shows the T_{TC} of the <*,*,ITIN> and <*,*,PAR> models in a *medium-sized* e-marketplace with N_{YPA}=10, N_{VA}=80, and YPS=2NFBT. The lowest-performance model is the <ALL,MP,ITIN> model. The <ALL,MP,*> models are the only models guaranteeing both a successful purchase and the best purchase since they are able to find the VA offering the minimum price. The <*,*,PAR> models always outperform the <*,*,ITIN> models, but the <*,FS,*> models where the <*,FS,ITIN> models perform similarly or slightly better than the <*,FS,PAR> models. However, in the latter case, purchase of the desired product at the best price is not guaranteed.

In order to compare the performances of PCA (Parallel Consumer Agent) and ICA (Itinerary Consumer Agent) models, the results obtained for the <ALL, MP, *> MCA models adopting a YPA organization of the 2NFBT type are reported in Figure 5, where results were obtained setting N_{YPA} ={10, 100} and varying N_{VA}. In agreement with the analytical model reported in Wang et al. (2002), the PCA, due to its parallel dispatching mechanism, outperforms the ICA when N_{VA} and N_{YPA} are increased.

*Figure 5. Performance evaluation of the <ALL, MP, * > models for an e-marketplace with YPS=2NFBT, N_{YPA} ={10, 100}, and variable N_{VA}*



FUTURE TRENDS

To date, *Agents* have been employed primarily for product and merchant discovery and brokering (Sierra & Dignum, 2001). The next stage will involve moving into real trading, which will require considerable research and development efforts, including the definition, implementation, and notably, analysis of new products and services such as market-specific shells, payment and contracting methods, risk assessment and coverage, quality and performance certification, security, and trust management.

Moreover, in the very near future, a rapid growth in agent-mediated auctions is expected. Auction is a long-established and well-understood trading mechanism, and the agent technology can be used to develop and support agent-mediated auction houses (Luck et al., 2004).

In order to test these new trading and auction services within large-scale MAS, discrete-event simulation seems to be the most appropriate and reliable tool. Therefore, flexible and robust agent-oriented, discrete-event simulation frameworks must be carefully designed and developed to support analysis of MAS at different levels of granularity: from agent behaviors, protocols, and services (*micro-level*) to global MAS behavior (*macro-level*).

CONCLUSION

Using *agents* to support e-commerce (both B2C and B2B) is considered a key challenge for the agent community. This article has presented an integrated approach which effectively models and analyzes e-commerce services based on *agents*. In particular, a consumer-driven AEM was modeled, and the product searching and buying strategies carried out by the mobile consumer agents in this AEM were analyzed. The consumer-driven AEM model used here was derived from real systems using agent-based e-marketplaces on the Internet (Bredin et al., 1998; Wang et al., 2002). In line with the *future trends* which have been delineated, the proposed approach is being applied to the modeling and analysis of more complex AEMs and related services, and also enhanced by exploiting game theory and economics models.

KEY TERMS

AEM: An agent-based e-marketplace is a distributed multi-agent system formed by stationary and mobile agents which provide e-commerce services to end-users within a business context.

Agent: In a broad sense, any program that acts on behalf of a (human) user.

AMEC: Agent-mediated e-commerce is concerned with providing agent-based solutions which support different stages of the trading processes in e-commerce, including needs identification, product brokering, merchant brokering, contract negotiation and agreement, payment and delivery, and service and evaluation.

Distilled StateCharts: A statecharts-based formalism for lightweight mobile agents.

ebXML: Electronic business XML is an XML-based language and infrastructure which aims at enabling B2B interactions among companies of any size.

E-Marketplace: An electronic marketplace is an e-commerce environment which offers new channels and business models for buyers and sellers to trade goods and services over the Internet.

Mobile Agent: A program that represents a user in a computer network and can migrate autonomously from node to node, to perform a computation on behalf of the user.

INTRODUCTION

The B-POS (Bluetooth Point of Sale) is the prototype of a secure, mobile macropayment system. Since heterogeneous wireless network technologies such as PANs, LANs, and WANs have well-known security weaknesses, it is mandatory to enforce security services, such as authentication, confidentiality, integrity, and non-repudiation. This article describes a Java-based macropayment system prototype featuring security and independence from an e-money third party acting as an intermediary. This system can rely on the existing financial network infrastructure (e.g., credit card, ATM networks).

BACKGROUND

Currently, most of m-payment (payment performed with a mobile device) systems rely upon mobile WAN (wide area network, e.g., GSM/GPRS/UMTS), enabling the customer to buy contents (by mobile carrier) or goods billed to the mobile phone contract account or to a prepaid card (in a business model called "walled garden"). The widespread diffusion of Bluetooth-enabled mobile phones, however, can possibly boost the deployment of new application paradigms based on personal area networks (PANs) and NFC (near field communications), enlarging the payment paradigm to financial and banking systems and circuits (e.g., EFC —electronic financial circuits),

so achieving two major benefits: (1) to escape from the "walled garden," so acquiring the capability to buy every good and every service, not only those from the mobile carrier; and (2) collecting the payment capabilities in a personal trusted device (PTD, e.g., the smartphone) without dealing with the ATM/credit cards in the wallets, supporting both micropayments and macropayments (Me, 2003).

There has been a considerable amount of research focusing on the adoption of mobile payments using a POS (Me & Schuster, 2005). Most of the research effort on usability led to description of the adoption factors influencing the consumer in the adoption of the payment solution (Dahlberg, Mallat, & Oorni, 2003; Mallat, 2004; Pousttchi, 2003; Zmijewska, Lawrence, & Steele, 2004). Other research has focused on finding the most critical factor of success and the different requirements of mobile payment systems (Hort, Gross, & Fleisch, 2002; Muller, Lampe, & Fleisch, 2004). Many more studies focused on the adoption intentions of the consumers and the merchants toward a new electronic payment system (Plouffe & Vandenbosch, 2001). Early local mobile payment systems (cash like, micropayments) were pioneered by Chaum CAFÉ-IR (www.chaum.com/CAFE_Project.htm) based on public-key encryption and the blind signature scheme of Ecash: this system uses a smartcard and an electronic prepaid "wallet" to complete transactions via the InfraRed technology. The work of Blaze, Ioannidis, and Keromytis (2001) on microchecks (over the InfraRed links) is (somewhat) similar to ours, except for (at least) its minor concerns with fraudulent transactions (due to their small amount). Another important difference is that the payer is not required to authenticate the merchant during a transaction. Several other e-check systems have been implemented during recent years, but they were never customized for mobile/local transactions (e.g., SET, echeque, First Virtual). The foremost e-check system, Kerberos based, was NetCheque (http://gost.isi.edu/info/NetCheque/).

Currently, several countries have adopted mobile payments: in the Asian market, Singapore, South Korea, and Japan reached an advanced market stage, for example, the FeliCa contactless payment system, currently the de-facto standard method in Japan with over 20 million users, counts over six million FeliCa-enabled handsets and POS installed in all the major shop chains (www.sony.net/Products/felica). Europe is following close behind with successful m-payment services already launched in Austria, Croatia, and Norway, and in Italy, Telecom Italia Lab unveiled in December 2005 a contactless system called Z-SIM, where mobile phones can communicate with any terminal or object by very simple interaction. As a rule, a mobile payment system can be operator independent, where billing is based on an association between a credit card or bank account to the mobile phone (e.g., the Italian major credit card distributor CartaSi has recently launched its own mobile payment system).

MAIN FOCUS OF THE ARTICLE

B-POS aims to be a secure mobile macropayment system for local, contactless, and operator-independent payment systems, involving three different entities—bank, shop, and customer (smartphone)—communicating via secure channels, as shown in Figure 1. Due to well-known mobile vulnerabilities, especially regarding Bluetooth (Nichols & Lekkas, 2001, 402-415; Jacobson & Wetzel, 2001), it is mandatory to enforce security, firstly on wireless links. For this reason, the requirement of macropayment system security is met at the application layer, avoiding various communication layer vulnerabilities, (e.g. E3—electromagnetic environmental effects) or new, unpredictable vulnerabilities (e.g., wireless transport layer security (WTLS) gap in versions

prior to WAP 2.0). This task is performed using an asymmetric keys schema for the authentication with a derived symmetric session key. A mutual authentication is implemented among B-POS's communication parties, so the entities involved can trust each other.

The Bluetooth link connects the smartphone to the shop (1). Information exchanged between the shop and the bank happens on a secure channel. The customer refers to his own bank through a virtual private network (VPN), taking advantage of both these channels (3).

Since the end user trust should be placed into a customer-reliable authority, we centralized all the responsibilities into the bank, whose former task was to release and setup the BPOS mobile application on the customer device.

In order to achieve a widespread diffusion between customers, the prototype is suited for devices as PDAs and smartphones equipped with Kilo Virtual Machine (KVM). Former benefits in adoption of J2ME reside in advantages to use cross-platform code and embedded security mechanisms (safe box). Several further considerations suggest the J2ME platform as appropriate to support m-payments (Sun Microsystems, 2000a; Cervera, 2002):

- **Broad user experience:** The J2ME API provides enhanced possibilities to present GUI, for example, event handling and rich graphics.
- **Comprehensiveness:** The details of the machine architecture, operating system, and display environment are all handled transparently by the Java virtual machine (JVM). The same Mobile Information Device Profile (MIDP) m-payment client can run on all the MIDP-compliant devices (Sun Microsystems, 2000a, 2000b; Cervera, 2002). This allows the m-payment system providers to target a wider range of end-users.
- **Reduced network and server load:** The J2ME-based applications can operate when disconnected, and they only interact with a server when necessary. J2ME has its own runtime environment and the capability to store data in the mobile device.

The ease of use and the cheapness of further requirements led to a wireless point-to-point communication between the shop and the customer. For this reason, Bluetooth technology represents the most suitable alternative due to its limited range and the mobile phone market penetration (in Europe).

Money or virtual checks are not exchanged between entities, thus reducing fraud and stealing due to eavesdroppers. BPOS payments are performed in the bank context, where a customer authorizes the bank to commit a fund transfer from his or her personal bank account to the shop's.

Figure 1. BPOS architecture

Application's Schema Description

We divide the whole transaction in different phases (see Figure 2). Firstly, a former procedure is required, where the user physically interacts with the bank/CA, in order to install on his smartphone the BPOS application. He could request for this service from his trusted bank where he owns an account.

Setup Procedure

The BPOS Bank's portion code creates a symmetric key associated to a specific user that had requested the BPOS service. The key, stored into the BPOS application, will be installed on the user's personal device. The bank asks the user to turn on the application, forcing the user to select an application PIN, used to protect the system from unauthorized spawn of the application. Furthermore the customization of the application, needed for the individual payment, includes the storage of a specific certificate and an asymmetric key pair on the user device: this operation means that bank plays the role of CA. For further transactions, mutual authentication between the user personal device and the bank is no longer needed. Moreover the setup of the VPN guarantees the confidentiality of the exchanged information, avoiding spoofing attacks and repudiability, while a control acknowledge message prevents replay attacks.

Figure 2. BPOS application's schema

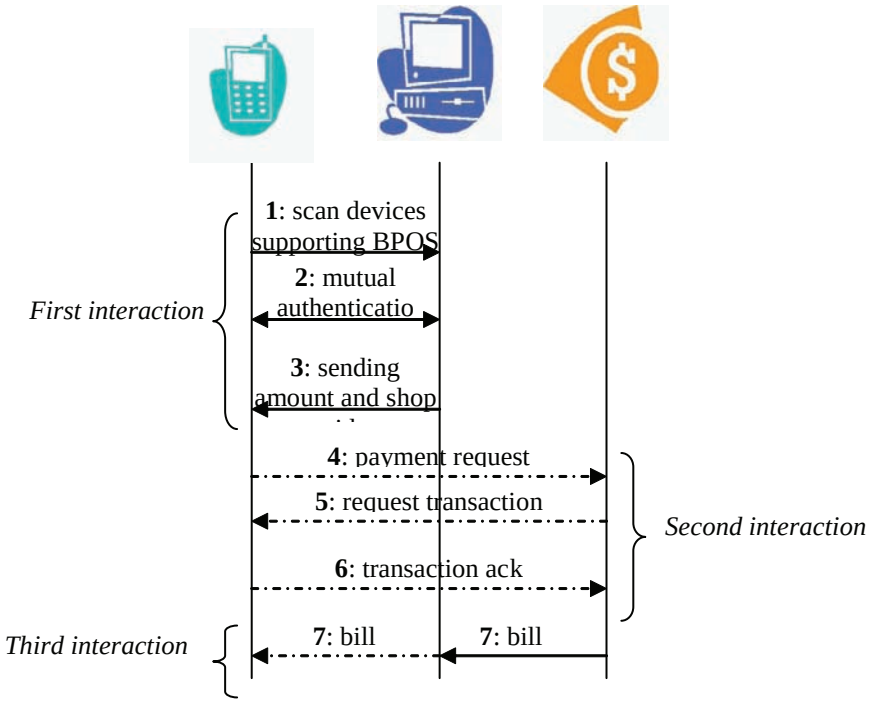

Figure 2 shows the application schema, enlightening three different interactions between the involved entities:

1. smartphone-shop (via Bluetooth),
2. smartphone-bank (via VPN), and
3. bank-shop-smartphone.

First interaction takes place on a Bluetooth connection and consists of three sub-steps: device discovery, (1) mutual authentication (2), and the payment amount dispatch (3). In the former phase, the user runs the BPOS application on his device, inserts his PIN, and starts the scan for devices. The scanning phase is filtered by the service presence in order to identify only the BPOS partner, then the user selects the shop where he is purchasing in a proposed list of shops.

The second sub-step of the user interaction with *shop* is the mutual authentication, achieving two different goals:

1. shop-customer, ensuring to the customer that the shop is the place where he is purchasing; and
2. customer-shop, ensuring to the shop that the ticket is addressed to the customer required to pay.

Table 1. Notation

Mutual Authentication Protocol:

i. $A \rightarrow B: Cert_A$
ii. $A \leftarrow B: Cert_B , PK_A(C_B , R_B)$
iii. $A \rightarrow B: SK_A(C_B) , PK_B(C_A , R_A)$
iv. $A \leftarrow B: SK_B(C_A)$
v. $A \rightarrow B: AS$

Symbol	**Description**
A	*Smartphone*
B	*Shop*
$Cert_A$	*Certificate of A*
$Cert_B$	*Certificate of B*
$PK_A(m)$	*Message "m" encrypted with the Public Key of A*
$PK_B(m)$	*Message "m" encrypted with the Public Key of B*
$SK_A(m)$	*Message "m" encrypted with the Private Key of A*
$SK_B(m)$	*Message "m" encrypted with the Private Key of B*
C_A	*Challenge of A for B*
C_B	*Challenge of B for A*
R_A	*Random number of A*
R_B	*Random number of B*
AS	*Arrangement of session key with HMAC-SHA256(R_A, R_B)*

The latter authentication side is important because the ticket is the only method to identify the current paying customer.

After the successful mutual authentication phase, the shop (payer) and the smartphone (payee) agree on a session key, used by the shop to send to the client:

- the amount to be paid, and
- its unique ID registered to the bank.

Second interaction involves the user and the bank over a VPN (see Figure 2), via a three-step communication: smartphone sending request for payment (4), bank sending request for the transaction confirm (5), and smartphone transaction acknowledge (6).

The smartphone needs to send a request to the bank for payment, so it creates a packet containing:

- customer identification number, registered to the bank (not encrypted); and
- an embedded packet encrypted with the symmetric key shared with the bank containing:
  - shop ID registered to the bank, received from the shop in the previous step (Figure 2, step 3);
  - amount to be paid received from the shop in the previous step (Figure 2, step 3);
  - a nonce X.

Moreover, the bank, after processing the information received, accesses its database in order to find information about the entities involved in the transaction, and consequently sends a request for transaction confirm to the smartphone via the established VPN. Hence, the bank translates information recovered in a new packet and sends it back to the smartphone. Finally, the smartphone/customer sends a transaction acknowledge to the bank. The customer views all the previous information on the device's display, so he can decide whether to confirm or not the requested transaction. This step is crucial to unmask a malicious subject pretending to be the genuine shop. In order to avoid replay attacks, the protocol uses a transaction Ack to keep the session state. Ack is computed using random X combined by cod.op to random Y (these are produced in steps 4 and 5).

Third interaction involved the bank sending the transaction status (a virtual ticket) to other entities, which protects the latter one by the use of the VPN.

Technical Features

Since B-POS fulfills the security as central requirement, the system is based on a large, careful use of cryptographic technique. Due to the hardware device restriction, the crypto-primitives implementation relied on the BouncyCastle APIs (http://www.bouncycastle.org, http://java.sun.com/products/javacomm/index.jsp). The Elliptic Curve Integrated Encryption Scheme (ECIES) algorithm, with a 192-bit elliptic curve (EC), provides support for asymmetric key needs and symmetric encryption/decryption, and ensures packet integrity between the shop and the customer. The ECIES combines the EC asymmetric encryption with the Advanced Encryption Standard (AES, 128-bit key) and adds a SHA-1 hash for message authentication. In comparison to a 1024-bit RSA key, the ECC (Elliptic Curve Cryptography) provides shorter keys, shorter encrypted messages, and faster private key operations. The system relies on the Elliptic Curve Digital Signature Algorithm (ECDSA) to sign the transmitted data with additional 48-byte signature value, thus avoiding its unnoticed modification. In this PKI, the bank entity produces the certificate and the asymmetric keys for other system entities. The X.509 certificate stored on the mobile devices and

shop is signed by a 1024-bit RSA public key of the bank, embedded in a PKCS12 envelop, which protects this information with a password. The mutual authentication phase between the shop and the smartphone could be performed in a secure way, exchanging the certificates guaranteed from the CA.

In a second phase of the application schema, the communications between the authenticated entities are protected by a session key. This key is derived from two random numbers R, derived from the challenge response authentication phase relying on a HMAC-SHA256(R1,R2) hash function. The message integrity is ensured via AES and a SHA-1 hash.

FUTURE TRENDS

The BPOS is suitable for the end user because of its ease of use, security, and independence from third parties; the overall time to complete the transaction is upper bounded at an acceptable two minutes. Further studies and field trials have to be carried on in environments with multiple Bluetooth devices running, since Bluetooth inquiry performances are currently not acceptable in terms of reliability of service.

CONCLUSION

In this article we proposed a local mobile payment system with respect to:

- **Security:** Communication sessions between principals are based on well-understood cryptographic techniques.
- **Traceability:** Transactions are not kept anonymous.
- **Usability and convenience:** Costs of deployment and management for all principals involved (consumers, merchants, and banks) are acceptable.
- **Portability and interoperability:** System design is based on "de facto" standards (hardware equipment and software modules).

In particular, the system does not rely on a third party because it makes use of the existing bank network infrastructure. This assumption, together with use of open software on smartphones, minimizes the impact (and costs) on merchants, customers, and banks.

Since current trends in mobile phone technology move towards a direction of miniaturization and higher computational and graphical performance, allowing the completion of the whole payment procedure in less than a minute, we believe that the BPOS prototype can help the development of new forms of payments, local payments, with very low impact on customers (payers), due to widespread diffusion of mobile phone and shops, allowing their reuse in the same financial network.

The final advantage consists of the avoidance of all the fraudulent activities dealing with ATM/credit cards.

KEY TERMS

Bluetooth: A standard for cable-free, short-range connectivity between mobile phones, mobile PCs, handheld computers, and other peripherals developed by Bluetooth Special Interest Group (Ericsson, IBM, Intel, Nokia, and Toshiba Consortium, http://www.bluetooth.com). It uses short-range, low-power radio links in the 2.4 GHz Instrumentation Scientific and Medical (ISM) band.

Elliptic Curve Integrated Encryption Scheme (ECIES): One of the most popular ECC (Elliptic Curve Cryptography) schemes, defined in *ANSI X9.63-2002, Public Key Cryptography for the Financial Services Industry: Key Agreement and Key Transport Using Elliptic Curve Cryptography* and *IEEE P1363a: Standard Specifications for Public Key Cryptography: Additional Techniques (draft).* ECC is based on arithmetic using elliptic curves, providing shorter key lengths, and under some conditions, improved performance over systems based on integer factorization and discrete logarithms.

Java2 Micro Edition (J2ME): A version of Java used to develop applications running on a consumer wireless device platform (like a smartphone or PDA). A MIDlet is a J2ME™ application, and the KVM Kilo Virtual Machine is the java virtual machine for mobile devices.

Macro/Micro-Payment: An electronic payment can be loosely categorized according to the amount of money conveyed from the payer (customer) to the payee (merchant): *macropayments* for transaction volumes exceeding $10 (10€) , *micropayments* for amounts less than $10 (10€).

Mobile Payment: An electronic payment can be defined as "the transfer of electronic means of payment from the payer to the payee through the use of an electronic payment instrument," where the electronic payment instrument is viewed as "a payment instrument where the forms are represented electronically and the processes to change the ownership of the means of payment are electronic" (Mobile Payment Forum, 2002). Mobile payments are a subset of electronic payments, where the payee device performs at least one payment step via a wireless link.

Point of Sale (POS): An electronic device used by a retail business (payer) to process credit/debit card transactions. The payee swipes or slides his credit/debit card through the machine, or in mobile POS, connects through radio network instead of swiping the card.

Public Key Cryptography Standards (PKCS12): A series of documents, published by RSA Data Security, defining standard protocols to enable compatibility among public key cryptography implementations. PKCS12 defines a file format commonly used to store private keys with accompanying public key certificates protected with a password-based symmetric key.

Smartphone: An electronic handheld device that integrates mobile phone capabilities, personal information management, short-medium range network capability (e.g., RFid, Bluetooth Wi-Fi), and resources to run ad-hoc application in the same device.

Virtual Private Network (VPN): A way to provide a confidential network through a public network. In IP-based networks, VPNs are defined by a network of secure links over a public IP infrastructure, for example, PPTP (Point-to-Point Tunneling Protocol), L2TP (Layer 2 tunneling protocol), and IP Security (IPSec).

X.509: An ITU-T standard for public key infrastructure (PKI). X.509 specifies standard formats for public key certificates and a certification path validation algorithm.

Chapter 3.41
Mobile Banking Systems and Technologies

Cheon-Pyo Lee
Mississippi State University, USA

Merrill Warkentin
Mississippi State University, USA

INTRODUCTION

The last decade has witnessed the rapid growth of mobile communication devices and wireless technologies across the globe. The convergence of mobile devices and wireless technologies has not only changed the way many activities are conducted, but has also provided a foundation for a new type of technology-aided commerce called mobile commerce (m-commerce). As e-commerce's next evolutionary stage, m-commerce opens up new business opportunities in business-to-consumer (B2C) markets in addition to extending current operations in e-commerce and traditional brick-and-mortar businesses (Varshney & Vetter, 2002). The significant power of m-commerce is primarily a result of the anytime-anywhere connectivity of wireless devices, which provides unique experiences and services (Figge, 2004; Zwass, 2003).

One of the most promising and value-added m-commerce services is mobile banking (Lee, McGoldrick, Keeling, & Doherty, 2003; Mallat, Rossi, & Tuunainen, 2004). Mobile banking is the newest electronic delivery channel to be offered by banks in which technology has become an increasingly vital element, and it provides convenience and enhanced value to both banks and customers. With its clear benefits, mobile banking is now gaining rapid popularity in European and Asian countries with the significant market penetration of mobile handsets and the optimally designed marketing tactics of service providers (Suoranta & Mattila, 2004). However, mobile banking is still marginally adopted across the globe, and especially in the U.S., the growth appears much slower than anticipated (Mallat et al., 2004). In the United States, there are only a small number of banks that have actually introduced mobile banking services, and most other

mobile banking efforts are in small-scale trials (Charny, 2001). Therefore, the technology which will be employed in the United States market has been of interest not only to financial institutions, but also to mobile technology developers and future users.

BACKGROUND

M-commerce is defined as any transaction with a monetary value—either direct or indirect—that is conducted over a wireless telecommunication network (Barnes, 2002). However, there is no clear definition for mobile banking services, so often the traditional banking services using mobile handsets (i.e., making transaction by calling a call center using a mobile phone) are considered as mobile banking services. Thus, it is very important to define a clear boundary of mobile banking service to avoid confusion. In this article, mobile banking refers to a client-server system that is specifically designed for mobile devices, allowing banking customers to use handheld devices to access their accounts, pay bills, authorize fund transfers, or perform other activities. Table 1 shows various mobile banking services currently provided.

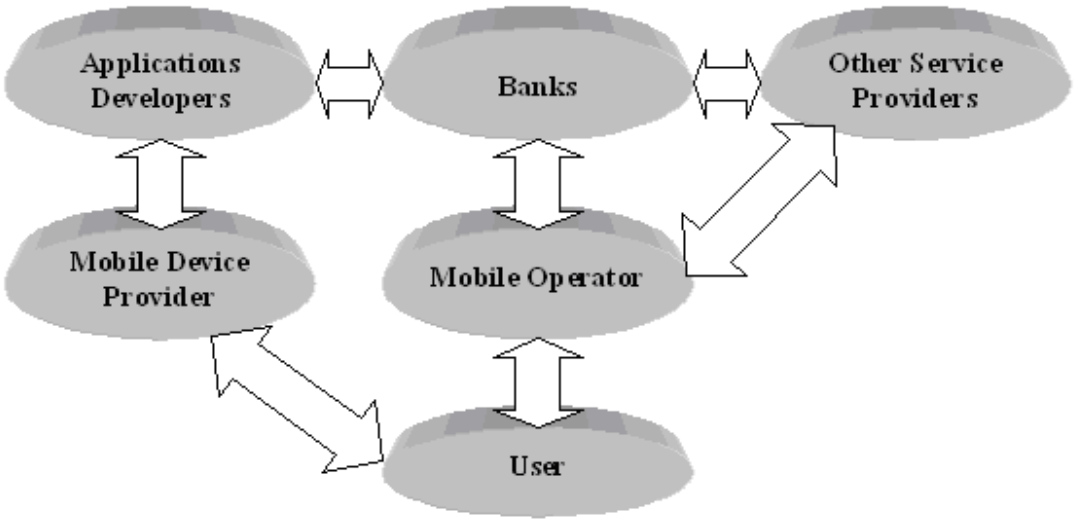
Mobile banking has two big advantages over the narrow sense of e-banking: security and convenience (Herzberg, 2003). E-banking is based on account-holder authentication by the payment system which can fail in multiple ways but do not distinguish the source of fraud. However, mobile devices, usually with a built-in display and keyboard, are well positioned to provide a technical solution for reducing fraud and allowing the fair allocation of responsibility for damages from fraud. In addition, unlike e-banking, the transactions through mobile banking can be made anywhere whether on foot or in cars, planes, or trains.

Mobile banking services began in 1999 in European and Asian countries, and have gained rapid popularity with the significant market penetration of mobile phones, the optimally designed marketing tactics of service providers, and the increased exposure to mobile technology (Suoranta & Mattila, 2004). Like many other mobile commerce services, mobile banking services are provided by several different entities, with which the customers of mobile banking services must interact to complete a successful mobile banking transaction, especially the mobile device provider, mobile operator, and content provider (Varshney & Vetter, 2002; see Figure 1). Thus, each entity in the mobile banking cycle must assist the others to attract more customers to mobile banking. The fastest way to promote the growth of mobile

Table 1. Mobile banking services

• Check the balances of checking and savings accounts, investment account, business banking accounts, lines of credit, credit card accounts, and loan and mortgage accounts
• Electronic funds transfer (EFT)
• Pay bills and taxes
• Request a check book
• Inquire about check status
• Customize the statements according to the user's specific needs and requirements

Figure 1. Mobile banking life cycle (Adapted from Varshney & Vetter, 2002)



banking services is mutual cooperation among the entities (Datta, Pasa, & Schnitker, 2001).

Mobile Devices

The significant potential of mobile banking derives mainly from the fact that the mobile device is a familiar device which is always with the user (Mattila, 2003). Thus, satisfaction with the mobile device is a very significant factor of the mobile banking adoption decision. Mobile device in this article refers to those devices that are used to connect to mobile services (Tarasewich, Nickerson, & Warkentin, 2002). Various mobile devices are available, including mobile phones, personal digital assistants (PDAs), wireless-enabled handheld computers, laptop computers, vehicle-mounted technologies, and personal message pager devices. Among them, wireless-enabled laptops, PDAs, and handsets are currently highly preferred mobile devices for mobile banking (M-Commerce Insider, 2001). Since the use of mobile banking depends on the capabilities of mobile devices, users' satisfaction with various factors of mobile devices significantly influences their adoption of mobile banking. Some of the features of mobile devices which prevent the adoption of mobile banking are small multifunction keypads, less computation power, and limited memory and disk capacity (Siau, Lim, & Shen, 2001).

Mobile Operator

Like many other m-commerce services, mobile banking services are so new that no single company has all the expertise required to develop and deliver compelling services on its own, but many studies point out that mobile operators play a significant role since customers access their networks to perform all transactions (Donegan,

2000; Varshney, 2003). Due to the significant power of mobile operators in mobile banking services, banks often see mobile operators trying to control the financial transaction, and the relationship between banks and the mobile operator is often described as one of mutual distrust (DeZoysa, 2001). The significant power of mobile operators in the m-commerce cycle also imposes important duties to perform in support of m-commerce, such as content provider relationship management, content billing, settlement, and customer care (Buellingen & Woerter, 2004). Thus, the m-commerce users utilize the service of the mobile operator more frequently than that of any other entity, and the service attributes of mobile operators, such as call quality and tariff level, not only influence the satisfaction with the mobile operator, but also influence the adoption of mobile banking services. For instance, current pricing strategies, mainly based on time-usage, of many mobile operators are considered to prevent the mobile users from adopting mobile banking (Yeo & Huang, 2003).

Banks as Content Provider

In mobile banking services, banks are the entity providing content, which is considered one of the most important factors regardless of whether a site is Web based or wireless. Poor quality of content is considered to be significant barrier to m-commerce (Venkatesh, Ramesh, & Massey, 2003). Therefore, users increasingly choose their mobile operators on the basis of the content available, and a majority of mobile network service subscribers are willing to switch mobile operators to get better mobile content (Barnett, Hodges, & Wilshire, 2000). However, the important feature of m-commerce content is that a successful Web interface does not simply translate into a successful mobile interface (Lee & Benbasat, 2004; Venkatesh et al., 2003). Therefore, in addition to accurate and stable content, proper fonts and colors that fit into mobile device screens are also considered significant factors to attract customers to mobile banking services.

MOBILE BANKING TECHNOLOGIES

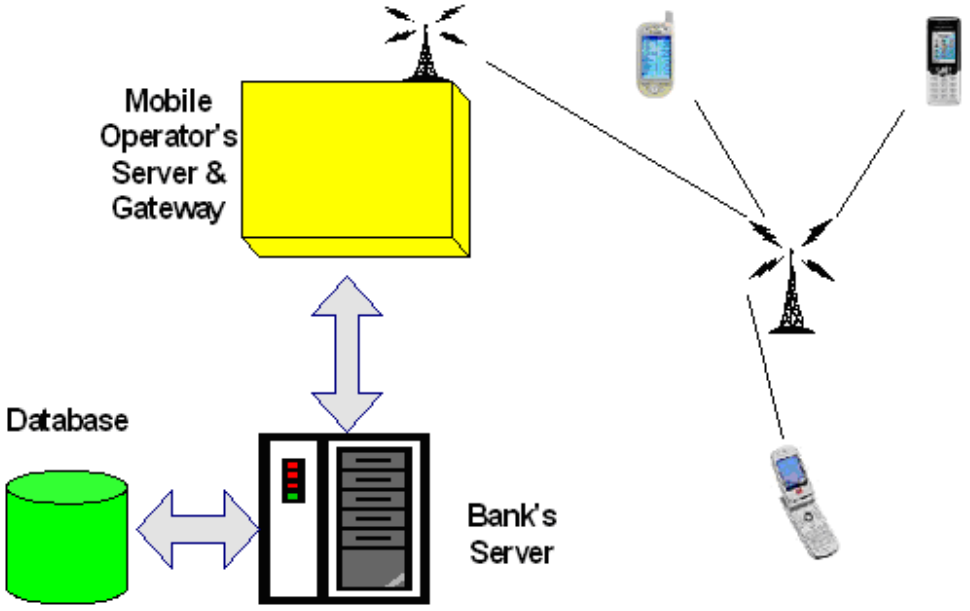
Mobile banking services are conducted by communication between the user's handset and the bank's server (see Figure 2). When the user requests a service, it is transmitted to mobile operator and forwarded to its gateway server. The server later interprets the request and forwards it to the bank's server. Then, the bank's server validates the customer for the mobile number and other information based on its database, and processes a valid request. The result is then passed on to the mobile operator's server which converts the format and transmits it to the user's mobile handset for display.

Like other entities in the mobile banking service cycle, the technologies employed for mobile banking services also play a significant role in mobile banking adoption. Various technologies have been tested and implemented in mobile banking systems, including short message service (SMS), Java, wireless application protocol (WAP), iMode, XHTML, and integrated-circuit (IC) chip. Among them, SMS and WAP have been the most popular technologies for mobile banking systems in Europe and some Asian countries (Marenzi, 2004).

Short Message Service (SMS)

An SMS mobile banking system uses the popular text-messaging service. When the customer requests information by sending an SMS containing a service command to a pre-specified number, the bank responds with a reply SMS containing the specific information. The most important feature of SMS mobile banking systems which attracts many customers is that it can be used conveniently with low cost. In addition, mobile banking with SMS enables every owner of a mobile phone to

Figure 2. How mobile banking services work



use mobile banking services. Therefore, in spite of its significant disadvantages, such as low data throughput, relatively long transaction time, limited service, and difficulty of use, SMS mobile banking services have been a dominant mobile banking technology (Kwon, 2004).

Wireless Application Protocol (WAP)

WAP has been implemented as a mobile banking technology to deliver fast and accurate banking services to customers (Lomax, 2002). WAP supports simple pages with 'menu' structures which are needed for most financial transactions (Economist, 2000). Therefore, it was popularly implemented as a major technology for mobile banking systems. However, even though WAP applications offer a greater graphical look and feel on current mobile phones, only a small percentage of the mobile users have WAP-enabled mobile devices, and only a small proportion of them actually have the knowledge of how to use them (Telephonyworld, 2004). In addition, WAP runs over circuit-switched networks in which the user is charged based on the time they spend online or how long they occupy the circuit (Yan, 2003). Since the initial connection takes a long time and there is a data call charge for browsing the service, WAP-based mobile banking service costs are usually high. Not surprisingly, WAP mobile banking service has proved too complex to use and has been replaced with less advanced technology, SMS, in many places (Zeddies, 2003).

iMode

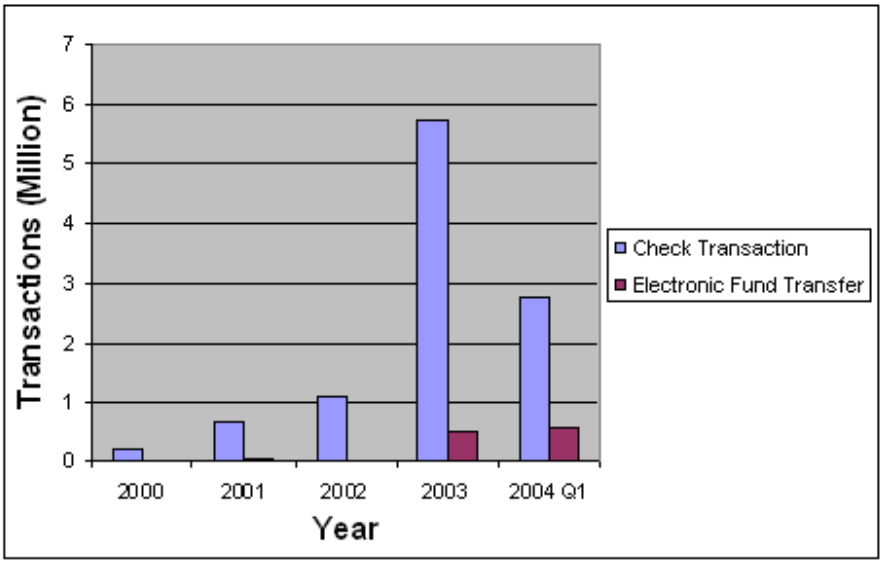
Recently some Western European banks started providing new mobile banking services using

the Japanese iMode technology in the hope of revolutionizing mobile banking (Marenzi, 2004). iMode created a successful business model and gained popularity in Japan. The packet-switching iMode uses the Packet Data Cellular Protocol to speed transmission, so users pay for each packet of data rather than their time (Yan, 2003). Therefore, the cost of using iMode banking is much cheaper than WAP-based mobile banking. However, this popular interactive service neither appeals to European customers nor changes the dominant trend of SMS in Europe and Asian mobile banking markets (Marenzi, 2004).

Integrated-Circuit (IC) Chip

Like in most other countries in Asia and Europe, SMS was also the first technology employed as a mobile banking technology in South Korea, where more than 70% of its 48 million citizens carry one or more mobile handsets and one-third of all mobile phone subscribers use their handsets for m-commerce activities (Kim, 2004). However, unlike most other countries, SMS mobile banking services in South Korea, where well-advanced e-banking services are available, did not attract customers at all and was considered as a failure since not much interest was shown (Kwon, 2004). Since then, various technologies including WAP and virtual machine (VM) have been tested and used to attract customers (Korea, 2004), but customers did not display much interest. However, a new integrated-circuit (IC) chip technology provided by the nation's smallest mobile operator changed the history of mobile banking in South Korea (Kim, 2004). The new chip-based offerings were a big hit, as a total 280,000 people signed up for the new services during the first four months after its introduction in September 2003. Since then, the number of mobile banking users has

Figure 3. The number of mobile banking transactions in South Korea (Source: www.bok.or.kr/contents_admin/info_admin/main/home/financial/payment/material/info/mobile.pdf



dramatically increased and reached 1.1 million as of September 2004 (Korea, 2004; see Figure 3).

The most important feature of IC chip-based mobile banking is that bank account data is encrypted on a smart-card chip, so it enables customers to connect to their account quickly and securely by pressing a single button on their mobile phone. In addition, to prevent someone else from using a mobile phone or IC chip, a special password or code given by banks is required for the user to make each transaction. Another important feature of IC chip-based mobile banking systems in South Korea is that they were introduced in cooperation between banks and mobile operators (Herald, 2004). Therefore, better services, such as relatively low-cost fixed data service (around $7 per month), are offered to users (Kim, 2004). Korea's mobile banking service history clearly shows the significant role of technology implemented in mobile banking services.

FUTURE TRENDS

In the United States, differing technical standards and the 'called-party-pays' system somewhat inhibit the use of mobile phones and mobile commerce (Economist, 2000). However, the market has been dramatically expanded over the last two-and-a-half years. The mobile data services market in the United States has grown from nothing to a market worth an estimated $1.5 billion, and various services have been added in the m-commerce marketplace (Media, 2004). However, the majority of mobile data usage in the United States to date revolves around text messaging and low-value downloads such as ringtones (Media, 2004).

In 2004, the first for individual subscribers in the country, AT&T Wireless Services Inc., an affiliate of Japan's NTT DoCoMo Inc., started offering a mobile phone-based fast data service in the United States, enabling users to browse the Web, e-mail, and share video clips (Wireless, 2005). Sprint, another mobile operator, introduced a new mobile banking service to small and independent business owners with spring mobile loan officer (Sprint, 2004). Thus, though mobile banking services have suffered from customer disinterest, many experts insist that mobile banking will eventually become a significant channel for personal banking. One Atlanta-based bank already reported recent success in mobile banking (RCR, 2004), and a major U.S. bank found that 93% of its customers are very interested in mobile banking services (O'Connell, 2004). All the evidence suggests that if mobile banking services are provided in the proper way, they will soon be a major transaction channel for personal banking.

CONCLUSION

There are three important factors which will decide the success of mobile banking services. First is the technology, *per se*, which when implemented for mobile banking systems will significantly influence the use of mobile banking. The success of South Korea's IC chip-based mobile banking service clearly shows that a good technology ultimately appeals to customers. Secondly, it is important that the technology should be approved before it is implemented by future users. The success of SMS and the failure of WAP demonstrates that the ability to offer simple services done well has proved far more attractive than sophisticated services done poorly (Lomax, 2002). Finally, the service of all entities in a mobile commerce cycle, especially mobile operators and mobile device providers, will significantly influence the mobile banking adoption. Therefore, all the entities in a mobile banking cycle should cooperate and assist each other in order to promote the rapid growth of mobile banking.

KEY TERMS

Circuit Switching: A type of communications in which a dedicated channel (or circuit) is established for the duration of a transmission.

Integrated Circuit (IC): A small electronic device made out of a semiconductor material. Integrated circuits are used for a variety of devices, including microprocessors, audio and video equipment, and automobiles.

Mobile Banking: A client-server system that enables banking customers to use handheld devices to access their accounts, pay bills, authorize funds transfers, or perform other activities.

Mobile Commerce: Any transaction with a monetary value—either direct or indirect—that

is conducted over a wireless telecommunication network.

Mobile Services: Services provided by a mobile operator that enable individual customers to access information and applications anytime-anywhere.

Packet Switching: A type of communication in which packets are individually routed between nodes, without a previously established communication path.

Wireless Application Protocol (WAP): A secure specification that allows users to access information instantly via handheld wireless devices such as mobile phones, pagers, two-way radios, smartphones, and communicators.

Chapter 3.42
Mobile Clinical Learning Tools Using Networked Personal Digital Assistants (PDAs)

Bernard Mark Garrett
University of British Columbia, Canada

INTRODUCTION

The School of Nursing at the University of British Columbia has more than 300 nursing students engaged in supervised clinical practice in hospital and community settings around Vancouver. Likewise, the Faculty of Medicine has more than 200 medical students undertaking supervised clinical experience locally and remotely in the Prince George and Vancouver Island regions. The management of these clinical experiences and the promotion of learning while in an active clinical setting is a complex process.

BACKGROUND

Supporting the students at a distance while undertaking their clinical experience is particularly resource-intensive. It requires the creation and maintenance of good communication links with the clinical and administrative staff, active management, clinical visits from faculty, and the provision and management of remotely based resources. However, there were few existing resources that helped to contextualize and embed clinical knowledge in the workplace in the practice setting (Landers, 2000). A technological solution was developed and implemented using several clinical applications designed for use on personal digital assistants (PDAs).

MOBILE CLINICAL LEARNING TOOLS

A suite of PDA-based tools were created for a pilot study with the involvement of nursing and medical students during the academic year of 2004-2005 to achieve the following objectives:

- To demonstrate the potential use of mobile networked technologies to support and improve clinical learning.

- To develop and evaluate a range of mobile PDA tools to promote reflective learning in practice and to engage students in the process of knowledge translation.
- To develop and evaluate a suite of pedagogic tools that help contextualize and embed clinical knowledge while in the workplace.
- To evaluate the value of networked PDA resources to help prevent the isolation of students while engaged in clinical practicum.

The tools developed provide a mobile clinical learning environment incorporating an e-portfolio interface for the Pocket PC/Windows Mobile (Microsoft, 2004) operating system. They were implemented on i-mate PDAs equipped with GSM/GPRS (Global System for Mobile Communications/General Packet Radio Service; GSM World, 2002). This platform offered considerable flexibility for the project. It supported the use of cellular telephone connectivity and Pocket Internet Explorer Web browser (which has a full Internet browser with support for HTML, XML/XSL, WML,cHTML, and SSL); the i-mate device had sufficient memory for the storage of text, audio, image, and video data, with a large screen and a user-friendly interface with an integrated digital camera.

The tools included a mobile e-portfolio (with a multimedia interface) designed to promote professional reflection (Chasin, 2001; Fischer et al., 2003; Hochschuler, 2001; Johns, 1995; Kolb, 1984). These mobile learning tools were designed to promote the skills of documentation of clinical learning, active reflection, and also to enable students to immediately access clinical expertise and resources remotely. Community clinical placements are being used for the testing domain, as there are currently no restrictions on using cellular network technology in these areas, whereas this is currently restricted in acute hospital settings in British Columbia and many other parts of the world.

THE PDA INTERFACE DESIGN

The main interface to the clinical tools was based on a clinical e-tools folder on the Pocket PC containing icon-based shortcuts to a number of specific applications (Figure 1).

The clinical e-portfolio tool represented the major focus for the project, allowing the student to access clinical placement information; log clinical hours; achieve clinical competencies; record portfolio entries in the form of text, pictures, or video clips; and record audio memos. This provides the user with a very adaptable interface, allowing them to choose how they input data. For example, a text-based entry describing a clinical procedure may be accompanied by a picture or audio memo.

The e-portfolio tool also incorporates a reflective practice wizard promoting the students to work through the stages of the Gibbs reflective

Figure 1. Screenshot of the clinical e-tools folder

cycle (Gibbs, 1988) when recording their experiences. This wizard also allows students to record their experiences with multimedia, including text, audio, digital images, or video input. Once the data have been recorded in the e-portfolio, they can be synchronized wirelessly (using the built-in GSM/GPRS or Bluetooth connectivity) with a Web-based portfolio. The data then can be reviewed and edited by the student or by clinical tutors.

The other icons represent the following applications:

- The synch portfolio icon initiates synchronization of the content of the student's e-portfolio on the PDA with that of a remote server.
- The University of British Columbia (UBC) library icon presents a shortcut to a Pocket Internet Explorer Web access to the UBC library bibliographic health care database search (CINAHL, Medline, etc.).
- The Pocket Explorer icon presents a shortcut to Pocket Internet Explorer for mobile Web access.
- The e-mail icon presents a shortcut to the Pocket PC mobile e-mail application.

The other icons on the screen (Diagnosaurus, ePocrates, etc.) represent third-party clinical software that was purchased and loaded onto the PDAs in order to support the students learning in the clinical area (e.g. a drug reference guide).

FUTURE TRENDS

In the future, the PDA will provide a one-stop resource to support clinical learning. Students also will be able to examine their learning objectives, record their achievements, and record notes/memos attached to specific clinical records for later review. Where students have particular concerns or questions that cannot be answered immediately in the clinical area, they will be able to contact their supervisors or faculty for support using e-mail, cell phone, or multimedia messaging service (MMS) communications.

The use of multimedia in PDA interfaces is likely to become much more widespread as the cost of these devices reduces and they become more accessible to a wider spectrum of the population. This already is occurring with the merging of cell phone and PDA technologies and the uptake of MMS and use of audio and video data entry on mobile devices (deHerra, 2003).

In the long term, multimedia mobile learning tools will encourage a more structured process of professional reflection among students in supervised clinical practice (Conway, 1994; Copa et al., 1999; Palmer et al., 1994; Reid, 1993; Sobral, 2000). When unexpected learning opportunities arise, students will be able to quickly review online materials in a variety of formats and prepare for their experience, record notes, record audio memos or images during their practice, and review materials following their experience.

An expansion in the use of such mobile clinical learning tools is envisaged, and there is considerable scope for the widespread application of such tools into areas where students are engaged in work-based learning. We are likely to see the integration of these technologies into mainstream educational practice in a wide variety of learning environments outside of the classroom.

CONCLUSION

The value of these new tools to students in clinical practice remains to be demonstrated, as the evaluation stage of the project has yet to be completed. The project also has highlighted the necessity of addressing some of the weaknesses of current PDA design, such as the small display screen and the need for more built-in data security. However, initial feedback appears promising, and the interface design appears to promote reflective

learning in practice and engage students in the process of knowledge translation.

KEY TERMS

Bluetooth: A short-range wireless radio standard aimed at enabling communications between digital devices. The technology supports data transfer at up to 2Mbps in the 2.45GHz band over a 10m range. It is used primarily for connecting PDAs, cell phones, PCs, and peripherals over short distances.

Digital Camera: A camera that stores images in a digital format rather than recording them on light-sensitive film. Pictures then may be downloaded to a computer system as digital files, where they can be stored, displayed, printed, or further manipulated.

e-Portfolio: An electronic (often Web-based) personal collection of selected evidence from coursework or work experience and reflective

commentary related to those experiences. The e-portfolio is focused on personal (and often professional) learning and development and may include artefacts from curricular and extra-curricular activities.

General Packet Radio Service (GPRS): A standard for wireless communications that operates at speeds up to 115 kilobits per second. It is designed for efficiently sending and receiving small packets of data. Therefore, it is suited for wireless Internet connectivity and such applications as e-mail and Web browsing.

Global System for Mobile Communications (GSM): A digital cellular telephone system introduced in 1991 that is the major system in Europe and Asia and is increasing in its use in North America. GSM uses Time Division Multiple Access (TDMA) technology, which allows up to eight simultaneous calls on the same radio frequency.

i-Mate: A PDA device manufactured by Carrier Devices with an integrated GSM cellular phone and digital camera**.** The device also incorporates a built-in microphone and speaker, a Secure Digital (SD) expansion card slot, and Bluetooth wireless connectivity.

Personal Digital Assistant (PDA): A small handheld computing device with data input and display facilities and a range of software applications. Small keyboards and pen-based input systems are commonly used for user input.

Pocket PC: A Microsoft Windows-based operating system (OS) for PDAs and handheld digital devices. Versions have included Windows CE, Pocket PC, Pocket PC Phone Edition, and Windows Mobile. The system itself is not a cut-down version of the Windows PC OS but is a separately coded product designed to give a similar interface.

Wizard: A program within an application that helps the user perform a particular task within the application. For example, a setup wizard helps guide the user through the steps of installing software on his or her PC.

Chapter 3.43
3G Mobile Medical Image Viewing

Eric T. T. Wong
The Hong Kong Polytechnic University, Hong Kong

Carrison K. S. Tong
Pamela Youde Nethersole Eastern Hospital, Hong Kong

ABSTRACT

Teleradiology is the technology of remote medical consultation using X-ray, Computed Tomographic or Magnetic Resonance images. It was commonly accepted by clinicians for its effectiveness of making diagnosis for patients at critical situations. Since the huge size of data volume involved in teleradiology [American College of Radiology et al., 2003], clinicians are not satisfied with the relatively slow data transfer rate. It limits the technology to fixed-line communication between the doctor's home and his office. In this project, a mobile high speed wireless medical image viewing system using 3G Wireless Network [Collins et al., 2001], Virtual Private Network and One-Time Two-Factor Authentication (OTTFA) technologies is presented. Using this system, teleradiology can be achieved by using a 3G PDA phone to query, retrieve and review the patient's record at anytime and anywhere in a secure environment. Using this technology, the patient-data availability can be improved significantly, which is crucial to timely diagnosis of patients at critical situations.

INTRODUCTION

Teleradiology is the technology of remote medical consultation using X-ray, Computed Tomographic (CT), or Magnetic Resonance (MR) images. This technique is commonly accepted by clinicians for its effectiveness of making diagnosis for patients at critical situations. For effective implementation of teleradiology, many technical problems including data integrity, accessibility, size of data volume, compression method and bandwidth of linkage should be considered. Hitherto, due to the huge size of data volume involved, clinicians are not satisfied with the slow data transfer rate. It limits the use of the technology to fixed line communication between a doctor's office and

his/her home. In this project, a mobile high speed wireless medical image viewing system using Third Generation (3G) mobile, Virtual Private Network (VPN), Common Gateway Interfacing (CGI), dynamic JPEG compression, WEB, Structural Query Language (SQL) [DuBois et al., 2002], Digital Imaging and Communication in Medicine (DICOM) [NEMA et al., 2004], and One-Time Two-Factors Authentication (OTTFA) technologies was developed. Using this system, teleradiology has been enhanced to a large extent – image data query and retrieval can be transferred from a hospital data centre to any notebook Personal Computer (PC), or to any 3G Personal Digital Assistant (PDA) phone at anytime and anywhere in a secure environment. Hence, the patient-data availability can be improved significantly, which is quite important for patients at critical situations.

BACKGROUND

Teleradiology involves the process of sending radiographic images from one point to another through digital, standard telephone lines, wide area network (WAN), or over a local area network (LAN). The radiographic images can be acquired either by a video capture board such as a frame grabber or the console of a medical imaging modality. After acquisition, the images were digitally stored in a teleradiology workstation in which the images were ready to be sent to a remote site over a network such as ethernet.

In the field of medical imaging, most of the images were stored in Digital Imaging and Communications in Medicine (DICOM) formation. DICOM is a standard that is a framework for medical-imaging communication. It was developed by the American College of Radiology (ACR) and the National Electrical Manufacturers Association (NEMA) [Bidgood et al., 1992] with input from various vendors, academia, and industry groups. It is referred to as "version 3.0" because it replaces versions 1.0 and 2.0 of the standard previously issued by ACR and NEMA, which was called the "ACR-NEMA" standard. It provides standardized formats for images, a common information model, application service definitions, and protocols for communication. Based upon the Open System Interconnect (OSI) reference model, which defines a 7-layer protocol, DICOM is an application-level standard, which means it exists inside layer 7 (the uppermost layer).

Today most teleradiology systems run over standard telephone [Oguchi et al., 2001] and ISDN (Integrated Services Digital Network) lines which are available in most parts of the world. Other high-speed lines, including T1 line and SMDS (Shared Multi-megabit Data Services) will also become more popular as their prices continue to drop. Over the next couple of years, we should see a substantial migration to wireless network such as IEEE 802.11x wireless and 3G (Third Generation) [Collins et al., 2001] networks, which offer higher flexibility than fixed line networks.

Digital images, whether viewed on a computer monitor, transmitted over a phone line [Reponen et al., 2000], or stored on a hard disk or archival medium, are pictures that have a certain spatial resolution. The spatial resolution, or size, of a digital image is defined as a matrix with a certain number of pixels (information dots) across the width of the image and down the length of the image. The more the number of pixels, the better is the image resolution. This matrix also has depth. This depth is usually measured in bits and is commonly known as shades of grey: a 6-bit image contains 64 shades of grey; 7-bit, 128 shades; 8-bit, 256 shades; and 12-bit, 4096 shades. The size of a particular image is referenced by the number of horizontal pixels "by" (or "times") the number of vertical pixels, and then by indicating the number of bits in the shades of grey as the depth. For example, an image might have a resolution of 640 x 480 and 256 shades of grey, or 8 bits deep. The number of bits in the data set can be calculated by the product of 640 x

480 and 8, which equals to 2,457,600 bits. Since there are 8 bits in a byte, the 640 x 480 image with 256 shades of grey is 307,200 bytes or .3072 megabytes of information.

Although images should be permanently archived as raw data or with only lossless data compression (i.e. no data is destroyed), hardware and software technology exists that allows teleradiology systems to compress digital images into smaller file sizes so that the images can be transmitted faster. Compression [Nelson et al., 1995] is usually expressed as a ratio: 3:1, 10:1, or 15:1. A 10:1 compression factor means that for each piece of information in the original image's matrix, ten are compressed. Certain images can withstand a substantial amount of compression without a visual difference: CT and MR images have large areas of black surrounding the actual patient image information in virtually every slice. The loss of some of those pixels has no impact on the perceived quality of the image nor does it significantly change reader-interpretive performance.

Transmission time has to follow the laws of size. The only way to reduce the transmission time is either to increase the speed of the modem or reduce the number of bits (compress the image) being sent.

The following formula is used to calculate the time to transmit an image:

(Matrix Size) x (Matrix Depth + X bits) x (Percentage of Compression) / (Network Speed)
= **Transmission Time (Seconds)**

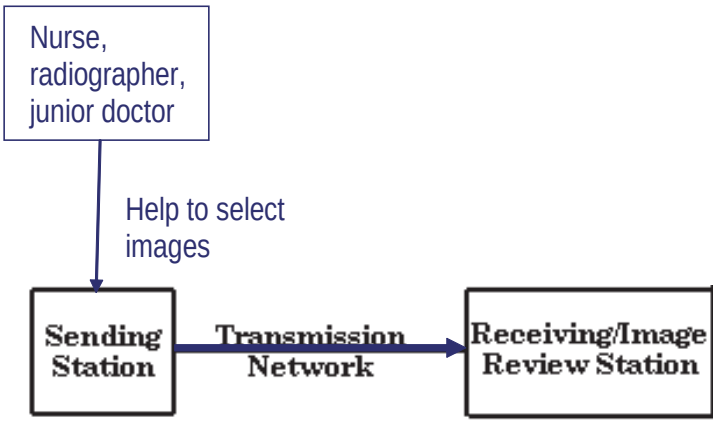
Where Matrix Depth is expressed as shades of grey: 256 shades of grey equal 8 bits; 128 shades of grey equal 7 bits; 64 shades of grey equal 6 bits. For transmission control, all devices add X bits as overhead when transmitting data.

Client/server computing developed from the need to move systems used for application development and operations from expensive mainframes to more efficient, less expensive--yet just as powerful--workstations. Client/server architecture involves the use of two types of computers: a client computer, which runs applications and makes requests for data and other resources, and a server, which processes the client's requests by distributing the requested resources. Client/server computing is known as a cooperative distribution system because both the client and the server cooperate in performing a task. For example, if a client requests a record from the server, the server uses its resources to process the entire file, while the client computer uses its resources to run an application that reads and writes individual records on the file. The server does not need to send the entire file to the client, thus diminishing network traffic or traffic over communication lines.

Client/server computing has numerous advantages for the medical world and for the field of radiology in particular. It permits workstations to achieve computing power previously only available from mainframes--at a fraction of the mainframe costs. By efficiently dividing resources, client/server computing reduces network traffic and improves response time. This efficiency offers a significant advantage to physicians who need to receive images quickly and who require real-time image navigation and manipulation to perform diagnostic tasks effectively. Client/server computing facilitates the use of graphical-user interfaces, making teleradiology and Picture Archiving and Communication System (PACS) applications [Tong & Wong, 2005] easier to use and more responsive. Additionally, clients and servers can be run on different platforms, allowing end users to free themselves from particular proprietary architectures. Software applications designed for client-server computing can interface seamlessly with most Hospital Information System (HIS) [RCR et al., 1999] or Radiology Information System (RIS) systems, while providing rapid soft-copy image distribution.

While most teleradiology systems used over the last decade were intended for on-call purposes,

Figure 1. Schematic diagram of traditional tele-radiology



the past two years have seen a rapid increase in the use of teleradiology to link hospitals and affiliated satellite facilities, other primary hospitals and imaging centres. As teleradiology allows radiologists using their time more efficiently, volume of images transmitted increases without substantially increasing the costs. Although a number of enabling technologies have developed for effective over-read networks, such as the more affordable high-speed telecommunications networks and improved data compression techniques [Nelson et al., 1995] in recent years, the traditional teleradiology technology is only available within fixed line communication system between the doctor's Home and his office and this requires manual image selection from the hospital-side. Both factors have limited the flexibility of the teleradiology technology.

SOLUTION

3G [Collins et al., 2001] is a generic name for a set of mobile technologies launched at the end of 2001 using a host of high-tech infrastructure networks, handsets, base stations, switches and other equipment to allow mobiles to offer high-speed Internet access, data, video and CD-quality music services. Data speeds in 3G networks, being up to 2 Megabits per second, show an improvement on the current technology. Today, various standards of 3G techniques are found in the commercial market including WCDMA, CDMA2000, UMTS and EDGE technologies.

Types of 3G

WCDMA – Wideband Code Division Multiple Access

A technology for wideband digital radio communications of Internet, multimedia, video and other capacity-demanding applications. WCDMA has been selected for the third generation of mobile telephone systems in Europe, Japan and the United States. Voice, images, data, and video are first converted to a narrowband digital radio signal. The signal is assigned a marker (spreading

code) to distinguish it from the signal of other users. WCDMA uses variable rate techniques in digital processing and it can achieve multi-rate transmissions. WCDMA has been adopted as a standard by the International Telecommunication Union (ITU) under the name International Mobile Telecommunications-2000 (IMT-2000) direct spread.

CDMA 2000 – Code Division Multiple Access 2000

Commercially introduced in 1995, CDMA quickly became one of the world's fastest-growing wireless technologies. In 1999, the International Telecommunications Union (ITU) selected CDMA as the industry standard for new "third-generation" (3G) wireless systems. Many leading wireless carriers are now building or upgrading to 3G CDMA networks in order to provide more capacity for voice traffic, along with high-speed data capabilities. Today, over 100 million consumers worldwide rely on CDMA for clear, reliable voice communications and leading-edge data services.

UMTS – Universal Mobile Telecommunication

The name for the third generation mobile telephone standard in Europe, standardized by European Telecommunications Standards Institute (ETSI). It uses WCDMA as the underlying standard. To differentiate UMTS from competing network technologies, UMTS is sometimes marketed as 3GSM, emphasizing the combination of the 3G nature of the technology and the GSM standard which it was designed to succeed. At the air interface level, UMTS itself is incompatible with GSM. UMTS phones sold in Europe(as of 2004) are UMTS/GSM dual-mode phones, hence they can also make and receive calls on regular GSM networks. If a UMTS customer travels to an area without UMTS coverage, a UMTS phone will automatically switch to GSM (roaming charges may apply). If the customer travels outside of UMTS coverage during a call, the call will be transparently handed off to available GSM coverage. However, regular GSM phones cannot be used on the UMTS networks.

EDGE – Enhanced Data for Global Evolution

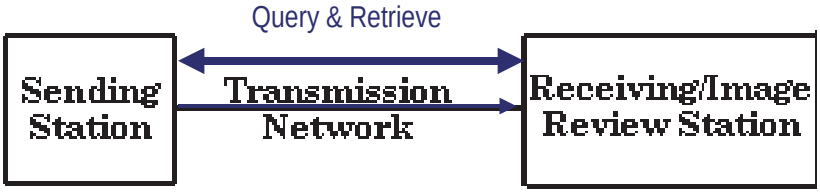
A technology that gives GSM the capacity to handle services for the third generation of mobile telephony. EDGE was developed to enable the transmission of large amounts of data at a high speed, 384 kilobits per second. EDGE uses the same TDMA (Time Division Multiple Access) frame structure, logic channel and 200 kHz carrier bandwidth as today's GSM networks, which allows existing cell plans to remain intact.

IMPLEMENTATION

The proposed system has been designed for image transfer using a UMTS type of 3G Wireless Network (Figure 2), which could provide a data transfer rate of at least 384 kbps, i.e. about 10 times the speed of a **Global System for Mobile Communications** (GSM) [Tong et al., 2003]. The security risk for this kind of connection to the hospital enterprise network is also ten times greater. One way to enhance the security is using One-time Two factors Authentication technologies for effective access control as shown in Figures 4, 5 and 6. The access right control and audit trail are based on the VPN technology. For management of terabytes of image data, a SQL-based database could be used. Users can search the database for any interested studies with the related images (Figures 7, 8, 9, 10, and 11). This design allows the clinician searching and retrieving the required studies without any help from the hospital side.

WEB technology, today, is the most robust client/server computing technology. WEB technology has been applied in many areas includ-

Figure 2. Schematic diagram of 3G medical image viewing system



ing desktop and mainframe computers. A WEB browser is also available in some mobile phones such as the PDA phone used in this project. In the proposed system, all CT and MR images were stored in a DICOM image archiving server. An Apache-based WEB server software [Kabir et al., 1999] was installed in an existing DICOM image server connected with a SQL server for image data management. The image data stored in the DICOM server would allow queries from the WEB browser through the 3G mobile PDA phone (Figure 3). The retrieved images were first converted from 16 bits into 8 bits and then JPEG-compressed before being sent to the remote client as a WEB page with configurable parameters such as image size, window level and width, rotation and flip using Common Gateway Interfacing (CGI) method [Tong et al., 2003]. CGI is one of the common techniques for the manipulation of data in WEB technology. The installed CGI software is an interface between the DICOM server and WEB client sides. It talks to the DICOM server using SQL and DICOM commands and communicates with the WEB clients using Hypertext Modelling Language (HTML). The clinical user can change the display parameters for image processing of the data dynamically in order to improve the viewability of the images.

RESULT

In the initial test of the system, transfer of 20 slices of CT images took about 45 seconds, which is much shorter than the travelling time required by the doctor driving from home to hospital. During a remote consultation, the clinician can also work independently to search for the target studies without any help from the hospital. Hence, unnecessary travelling of doctors to hospital can be minimized for non-urgent cases. For remote consultation using medical images, two major limitations have been identified: processing power of the portable image receivers and the speed of wireless network.

A typical 3G PDA phone was showed in Figure 3. In this phone, the display size is 2.9 inches with a resolution of 208 x 320. Comparing the resolutions of CT and MR images of resolutions of 256 x256 and 512 x 512 pixels, the PDA phone was sufficient or nearly sufficient to display those images. The one-time two-factor authentication token in which the displayed password was kept changing with an interval of one minute as shown in the Figure 4. The login page of the system was shown in Figure 5. The data entry was using a virtual keyboard, which was a basic function of the PDA phone as Figure 6. After login, user

might require the search of related studies. He could use the data management system for the search of interested examination using the patient identity number or study date as shown in Figure 7. For the patients with multiple studies or series of images, the thumbnail image of the first image of each series was displayed as the Figure 8. After the display, user could select the interested study by clicking the thumbnail image. A few minutes later, the user could see multiple CT or MR images as shown in Figure 9, 10, and 11.

FUTURE TRENDS

Today, teleradiology is mainly limited by the speed of the wireless network. With the next generation of wireless network such as IEEE 802.11 with a speed up to 108 mbps, it is anticipated that teleradiology can be performed more efficiently.

4G is the next generation of wireless networks that will replace 3G networks sometimes in future. In another context, 4G is simply an initiative by academic R&D labs to move beyond the limitations and problems of 3G which is having trouble getting deployed and meeting its promised performance and throughput. In reality, as of first half of 2002, 4G is a conceptual framework for or a discussion point to address future needs of a universal high speed wireless network that will interface with wireline backbone network seamlessly. 4G also represents the hope and ideas of a group of researchers in Motorola, Qualcomm, Nokia, Ericsson, Sun, HP, NTT DoCoMo and other infrastructure vendors who must respond to the needs of Multimedia Messaging Service (MMS), multimedia and video applications if 3G never materializes in its full glory.

CONCLUSION

It can be seen that with the proposed scheme involving the integration of WEB, SQL, DICOM, 3G, and JPEG technologies, a practical solution has been developed to tackle the commonly noted teleradiology implementation problems using high speed wireless networking technologies. In addition, data integrity and accessibility have been enhanced significantly. In conclusion, the proposed 3G mobile medical image viewing system can provide an efficient tool for clinicians' remote consultations, thus allowing timely diagnosis for patients at critical conditions at anytime and anywhere.

KEY TERMS

3G Technology: 3G (or 3-G) is an abbreviation for third-generation technology. It is usually used in the context of mobile phones. The services associated with 3G provide the ability to transfer both voice data (a telephone call) and non-voice data (such as downloading information from the internet, exchanging email, and mutlimedia messaging).

Common Gateway Interface(CGI): a standard protocol for interfacing external application software with an information server, commonly a web server. This allows the server to pass requests from a client web browser to the external application. The web server can then return the output from the application to the web browser.

Digital Imaging and Communications in Medicine (DICOM): is the industry standard for transferral of radiologic images and other medical information between computers. Patterned after the Open System Interconnection of the International Standards Organization, DICOM enables digital communication between diagnostic and therapeutic equipment and systems from various manufacturers.

Enhanced Data rates for Global Evolution (EDGE): An enhancement to the GSM and TDMA digital cellular phone systems that provides data transmission up to 384 Kbps. Like cellphones in general, the EDGE service is more ubiquitous for mobile users than searching for Wi-Fi hotspots; however, data rates are much lower than Wi-Fi.

Global System for Mobile Communications (GSM) A digital cellular phone technology based on TDMA(Time Division Multiple Access), which

is a satellite and cellular phone technology that interleaves multiple digital signals onto a single high-speed channel. Operating in the 900MHz and 1.8GHz bands in Europe and the 1.9GHz PCS band in the U.S., GSM defines the entire cellular system, not just the air interface (TDMA, CDMA, etc.).

One-Time Two-factor Authentication (OTTFA) is any authentication protocol that requires two independent ways to establish identity and privileges. This contrasts with traditional password authentication, which requires only one factor (knowledge of a password) in order to gain access to a system.

Teleradiology: is a means of electronically transmitting radiographic patient images and consultative text from one location to another.

Universal Mobile Telecommunications System (UMTS): The European implementation of the 3G wireless phone system. UMTS, which is part of IMT-2000, provides service in the 2GHz band and offers global roaming and personalized features.

Wideband Code Division Multiple Access (WCDMA): also known as Universal Mobile Telecommunications System(UMTS) in Europe, is 3G standard for Global System for Mobile Communications(GSM) in Europe, Japan and the United States. It supports very high-speed multimedia services such as full-motion video, Internet access and video conferencing. It uses one 5 MHz channel for both voice and data, offering data speeds up to 2 Mbps.

Section IV
Utilization and Application

This section introduces and discusses the ways in which information technology has been used to shape the realm of mobile computing and proposes new ways in which IT-related innovations can be implemented within organizations and in society as a whole. These particular selections highlight, among other topics, the implementation of mobile technology in healthcare settings, and the evolution of mobile commerce. Contributions included in this section provide excellent coverage of today's mobile environment and insight into how mobile computing impacts the fabric of our present-day global village.

Chapter 4.1
Dynamics of Mobile Service Adoption

Hannu Verkasalo
Helsinki University of Technology, Finland

ABSTRACT

This study utilized a newly developed handset-based mobile end-user research platform and obtained data from 548 Finnish smartphone users in 2006. In addition to descriptive adoption statistics, a path analysis model is developed that explains mobile service adoption contingent on a set of explanatory variables. The paper finds that user intentions have a strong impact on consequent adoption of the service. What is more, perceived hedonic benefits from the service are the strongest factor driving user intentions to use the service. The perceived technical capability to use the service and the role of the surrounding social network explain little why early-adopter users intend to use services. Interestingly multimedia services are strongly driven by newer more capable handsets and mobile Internet browsing benefits significantly from block or flat-rate (instead of usage-based) pricing plans for transmitted data. The paper develops several indices that measure time-varying characteristics of mobile services.

INTRODUCTION

Mobile services have evolved quite a lot from mere communication oriented services (circuit-switched voice, text messaging, voice mailbox) to today's multimedia, content retrieval, browsing and other advanced services. The mobile Internet (see Funk 2004) is emerging and the IP-based service delivery is likely to hit the mobile mass market domain very soon. Overlay networks existing already in the Internet (Clark et al. 2006) may have spill-over effects to the mobile industry. The mobile Internet scenario contrasts sharply with the dominant, vertically-oriented way of doing mobile business (see e.g. Karlson et al. 2003, Verkasalo 2007a and Vesa 2005). The emergence of the mobile Internet is driven by the wide-scale adoption of smartphones (i.e. converged devices) along with improvements in both cellular (GSM and 3G) and alternative (e.g. WiFi) radio networks. In terms of data services the same service evolution trends have been seen in the "wired" Internet earlier that can be seen in the mobile domain today. For example,

the movement from messaging data services to static content (Web) and further to multimedia streaming can already be seen in mobile service studies (Verkasalo 2007b).

Amidst the rapid evolution of the mobile industry many commercial service failures have taken place. It is difficult to pinpoint the reasons behind successes and failures. Typically not one but many issues affect the adoption of a particular mobile service. The reasons can be categorized into two main categories. First of all, a commercial/technical perspective includes issues that relate to marketing, positioning, developing, implementing, delivering and timing of the mobile service. These factors include e.g. demand forecasting, pricing, positioning of the service in the service provider's service portfolio, promotional activities, creation of end-user awareness, service quality management, and strategic push of the service in the value-chain (i.e. distribution management). These factors are called as t*echnological* or *business strategic* in Pedersen (2001). Second, the end-user perspective deals with end-user related factors driving or inhibiting service adoption. This perspective is called as *behavioral* in Pedersen (2001). Factors under this perspective include e.g. service usability, social pressure, network externalities, contextual environment, consumption choices, the user's motivation and technical capabilities. The first perspective deals more with the producer side of the market whereas the second perspective deals with the demand side of the market. Drivers and bottlenecks for service adoption might emerge in either domain.

Even though many potential factors explaining successes and failures of mobile services can be identified, it is often difficult to test hypotheses in practice. No suitable empirical research approaches have existed earlier to provide actual usage data to study the dynamics of mobile service adoption. Accurate data from end-users can be nowadays acquired with a handset-based mobile end-user research platform that was introduced in Verkasalo & Hämmäinen (2007). The new platform provides accurate usage statistics along with flexible tools to deploy questionnaire studies. The present paper attempts to provide descriptive results on mobile service adoption with data from Finland 2006. In addition, a path analysis model is built explaining the main drivers and bottlenecks of mobile service adoption based on empirical usage data and questionnaire studies.

EARLIER RESEARCH

Theoretical Models Explaining Technology Adoption

The adoption research can generally be divided into four categories:

- Diffusion research (market focus)
- Adoption approach (individual user focus)
- Gratification research (needs of users focus)
- Domestication research (consequence of adoption focus)

The diffusion research focuses on the market-level phenomena, and studies the diffusion of technology in the whole market. Adoption research, on the other hand, considers individual users as a focal research object. Gratification research contributes by analyzing the different kinds of benefits users seek from new technologies, and domestication research analyzes the role of new technologies in integrating to the every day life of people. Although this research paper mainly applies the statistical models introduced in the adoption research, elements from other research approaches are also applied in building the framework introduced in chapter 3.3. Therefore all these approaches are discussed now in detail.

First, Rogers (1962) introduced the idea of "***diffusion*** of innovations", and approached the adoption process in diffusion terms. In his research the adoption process follows a bell curve, suggesting that different kinds of people adopt new technologies at different pace. Only the most technology enthusiastic people adopt new products/services at first, the mass market being more cautious and thus adopting slower. The late-adopters are the most technology averse people, typically purchasing new technology only when it is inevitable. Rogers' research still serves as the general background for many kinds of adoption research. The diffusion research can be used in studying the emergence of new services. In Rogers (1995) it is argued that adoption is initiated by a new technology, after which the social setting and communication channels boost the diffusion. Rogers' theory has laid ground for many other research frameworks, for example Christensen's (1997) theory of "disruptive technologies" that take over dominant technologies by having a disruptive diffusion path. Time is the core factor in Rogers' idea of technology diffusion, as adoption (penetration of service) follows different patterns at different points of time after its introduction.

The second approach is the ***adoption perspective***, in which an individual user standpoint is taken. Each individual makes her own decisions in considering whether to try the service or not. A wide domain of research stems from adoption of information systems science, utilizing theoretical models developed a couple of decades ago. Earlier models attempting to explain adoption of technologies (particularly information system technologies and this is why the approach is sometimes called as IS adoption science) include the *theory of reasoned action, theory of planned behavior* and *technology acceptance model.*

A theory of reasoned action (Fishbein & Ajzen 1975) is based on the individual's attitude towards the action and subjective norm of the action (expected behavior of others in response to the individual's action). Together these determine the behavioral intention to use the technology. Ajzen later expanded the model; in a theory of planned behavior (Ajzen 1985; 1991 a third concept exists, namely the perceived behavioral control. This reflects the difficulty of performing the action. These models communicate that technology adoption depends both on the individual's own perceived benefit of performing the action and the social norm driven by people around the individual. All in all, these frameworks suggest that usage patterns not only depend on the individual's own capabilities and interests, but also on the sociological environment and norms in the culture.

Davis (1989) follows similar logic in his framework - a technology acceptance model (TAM). He distinguishes two concepts. First, the perceived usefulness reflects the expected benefits from using a certain technology. Second, the perceived ease of use reflects pretty much the same thing as the perceived behavioral control in the theory of planned behavior, i.e. how difficult it is to use the technology. In predicting information technology adoption the TAM model developed by Davis is the most used framework, and by 2000 more than 400 journal articles had cited the two original TAM articles (Venkatesh & Davis 2000). Almost all the information technology adoption articles that will be discussed later in this paper stem from the TAM model. Despite its popularity, further development of the model has taken place. For example, the original model as projected below suggested that perceived usefulness and perceived ease-of-use mediate all external factors (e.g. demographics), though this is not always the case (see e.g. Burton-Jones & Hubona 2005). The original model typically explains 40% of usage intentions and 30% of actual use (see e.g. Venkatesh & Davis 2000 and Meister & Compeau 2002). Applications of the framework might in the best case achieve better explanatory power.

Holistic adoption models (see e.g. Pedersen and Thorbjørnsen 2003) deployed earlier in the mobile context and stemming from the TAM model are close to the research approach applied

in developing the theoretical framework for this research paper. Holistic behavioral models typically utilize statistical methods such as structural equation modeling (SEM), and they derive from theoretical models illustrated above (particularly Davis' research). In Nysveen et al. (2005a) the adoption approach utilizing variations of the TAM model with SEM analysis is called as information systems research, as most studies utilizing structural equation models from the adoption perspective deal with the adoption of ICT services and systems. The research done by e.g. Pedersen and Thorbjørnsen (2003) is used as a basis for the model of this paper. The next section will discuss the theoretical approaches to study mobile services in detail. Because of e.g. increasing context-specific nature and various ubiquitous characteristics (Heinonen and Pura 2006; Rask and Dholakia 2001) mobile services should be considered carefully when applying earlier information systems adoption models.

The other approaches to study the adoption of technology include a uses and gratifications research approach (see e.g. Leung and Wei 2000; Höflich and Rössler 2001) and domestication perspective (Haddon 2001; Ling 2001; Skog 2002). The former approach (***gratification research***) deals with the gratifications that users look for when using mobile services. These gratifications can be either utilitarian (business value or direct utility) or hedonic (entertainment oriented) (Flanagin and Metzger 2001). The latter approach (***domestication research***) has close linkage to sociology, anthropology and ethnology. Sometimes domestication research does not focus on individual adoption only, but extends to the adoption from the cultural or societal point of view (see e.g. Ling and Yttri 2002). Domestication research attempts to tackle the consequences of service usage and the integration of the technology/services in the customer's every day life (Pedersen 2005). These two frameworks reflect softer scientific disciplines in studying mobile services than the diffusion or adoption perspectives. All approaches share same concepts and ideas, and they are thus not totally separate from each other.

Emergence of Mobile Services

Little research on the emergence of mobile services exists. This section briefly describes some of the main outcomes of earlier research, particularly in light of this paper. Many of the focal services studied in this paper have just been introduced to the market, and no research on them is available. However, this section attempts to emphasize generic observations in the adoption of mobile services that have relevance also with new emerging services.

The mobile Internet is defined in this paper to consist of new packet-switched mobile data services. The first mobile data services were hyped quite a lot in the public in the late 90s, but in practice the mobile Internet has not kicked off yet (Saarikoski 2006). Particularly the WAP technology and mobile email can be considered failures (Sigurdson 2001). Many reasons are suggested as possible bottlenecks, from pricing (see e.g. Gao et al. 2002) to general difficulties in terminal configuration (Verkasalo 2007b). These reasons were found as bottlenecks in mobile payment adoption, too (Mallat 2006b). MMS messaging experienced similar disappointing customer adoption rates at first to WAP, email and electronic payments are experiencing right now. In Japan NTT DoCoMo has achieved satisfactory demand for mobile Internet services, and Japan can be considered as the world's leading mobile market in many other dimensions, too (Saarikoski 2006; Minges 2005). The key difference to Western operators is that NTT DoCoMo has bundled service interfaces directly to the handset and actively pushed new value-added services. Consequently both the customer awareness has been increased and ease of adoption significantly improved.

The Internet service expansion to the mobile domain could serve as a prospective spark that could significantly push the extent of mobile data

service usage. The reasons for the potential impact of Internet services can be divided into two. First of all, the pricing/commercial models of Internet services are different from operator-based mobile services (in terms of pricing, for example, Internet services are free of charge, or sold in flat-rate bundles). Second, the spill-over effects and value already embedded in Internet services (e.g. instant messaging communities, the variety of WWW-based content services, webmail) serve as a strong force if suitable mobile access technologies (e.g. the network access and adequate terminals for the usability's sake) can be deployed with low price. Earlier research has pinpointed the need for alternative radio access methods to fixed Internet service access, the key alternative being mobile cellular connectivity (Kearney 2001). These two factors (commercial/pricing models and mobile extension of the Internet) are evident in the final conclusions of Aarnio et al. (2002), as they state on the future prospects of mobile services that "*…prices must come down to overcome the critical mass threshold and in most cases the services should be integrated to the Internet...*".

Niina Mallat (2006a) illustrates some interesting characteristics of mobile services in her dissertation. According to her studies, several successes and failures could be identified in the mobile payment service sector. Mallat concludes her dissertation with the note that usage situation and context are important in explaining the adoption of mobile electronic payments. The same can be generalized to the wider mobile domain. In studying mobile service adoption the special characteristics of mobile services – the freedom of context and location – should be internalized in the framework is possible. Mallat criticizes earlier mobile service adoption research for not taking contextual factors that well into account. Also Hejden et al. (2005) emphasized the importance of context in influencing the perceived value of services.

In tackling the drivers and bottlenecks of mobile services, Aarnio et al. (2002) studied 1 553 Finnish respondents and found five user segments from the sample that resembled classical adoption categories. Their paper studied both traditional Internet and new mobile services. The authors emphasize the important role of prices in mobile service adoption. Furthermore, they suggest that social norm should not be overlooked in mobile services. However, Nysveen et al. (2005a) suggest that different mobile services depend on explanatory factors differently. For example, some services are more dependent on social pressure/norms than others. For example in the research of Pedersen and Thorbjørnsen (2003) the social norm did not explain that much of the variance.

Pedersen and Thorbjørnsen (2003) developed a structural equation model incorporating motivational, attitudinal, social and resource-related influences on the intention to use mobile services. Their model explained about 62-75% of the variance in the dependent variable (intention to use). In all of their case studies (focusing on different services) they found that both extrinsic (utilitarian) and derived (i.e. expressiveness) motivations have an important role to play, whereas intrinsic (entertainment-oriented) motivations are less explanatory. Pedersen (2005) continues by suggesting that many of the factors suggested in earlier ICT adoption research work fine in the context of mobile services, but also many new dimensions should be taken into account (such as expectations and subjective norm). Pedersen (2005) argues that by extending the decomposed theory of planned behavior (Taylor & Todd 1995) with elements from domestication research the explanatory power of the models in mobile services can be increased. To criticize existing statistics models Nysveen et al. (2005b) argue that gender could have moderating effects in the adoption of mobile services, though the original TAM model suggests that all background variables should be fully mediated by the included explanatory factors. All in all, in statistically evaluating the determinants of usage, different services should

be treated individually and one should be careful with cross-service generalizations.

Some mobile services are more goal-directed (utilitarian) instead of experimental (hedonic) (Nysveen et al. 2005a). Pedersen and Thorbjørnsen (2003) acknowledge the same. Also Wong and Hiew (2005) argue for the emphasis on the expected benefits from mobile services. Hejden et al. (2005) comply by concluding that utilitarian and hedonic values have some correlation but it is particularly utilitarian value that has a significant impact on the intention to use the services whereas hedonic values relate to more ad-hoc use cases. The utilitarian importance might have, however, derived from the market context at the time of the study in Hejden et al (2005), as many new mobile services emerging today are actually quite entertainment instead of business-oriented. Most new mobile services are therefore targeted at consumers instead of business customers. Hejden et al. (2005) nevertheless found that perceived risks from the service negatively drive the service's utilitarian value, whereas hedonic value is not affected by the perceived risks (e.g. the service is justified to be more difficult to use if it relates to "killing time"). Some papers (e.g. Tseng et al. 2007) emphasize that in addition to direct value also network externalities matter in analyzing the benefits of electronic services. In mobile instant messaging, for example, the value embedded in the buddy network affects the utility from using mobile instant messaging.

Pedersen (2005) notes that adoption studies in the mobile domain might have differing objects of research. He distinguishes between users (Green et al. 2001; Bakalis et al. 1997), services (see Verkasalo & Hämmäinen 2007; Kim 2001; Pedersen et al. 2001) and terminals (see Chuang et al. 2001; Skog 2000). In this paper the approach is mainly from the user point of view, and the process through which end-users adopt services is the focal research objective.

EMPIRICAL ANALYSIS

Research Method and Dataset

A pioneering mobile end-user research platform was utilized in acquiring data for this research paper. The new mobile end-user research platform is based on a developed Symbian/S60 smartphone client that observes all kinds of usage actions taking place in the handset. Usage-levels stamps on any application, network or user interface level action is logged with accurate context-specific information (e.g. time). This data is sent to centralized servers every night for analysis purposes. Research is conducted in panels lasting typically 2-3 months, and a typical panel includes hundreds of interested customers which in the panel become panelists. All panelists participating in these study panels sign a contract and they are aware of the research process. Usage data is complemented with various WWW-based questionnaires through which to acquire data on issues that are not usage-related (e.g. motivations and attitudes). Though the accuracy and scope of acquired data is a clear contribution in the world of end-user research, the challenges include e.g. biased end-user domain (early-adopter users) and sample size (being still in the range of 400-1000 panelists). The research method has been used already in various papers, such as (Verkasalo 2006a, Verkasalo 2006b, Verkasalo & Hämmäinen 2006, Verkasalo 2007a, Verkasalo 2007b, Verkasalo 2007c and Verkasalo 2007d). For more information on the research method, see Verkasalo & Hämmäinen (2007).

In acquiring data for this research paper SMS recruitment messages were sent to 28 000 Finnish consumer subscribers who owned a Nokia S60 device. 1 071 (3.8%) customers visited the recruitment site and answered the beginning questionnaire. Out of the registered panelists 695 (65%) managed to generate at least three active weeks of smartphone usage data. The rest either did not manage to install the research client or then quit the panel study earlier than was supposed.

Some people might have used the smartphone with the research client installed as a secondary phone, and thus they were excluded, too. Out of the active panelists 548 (79%) answered the final questionnaire, which was more comprehensive than the beginning questionnaire. In addition to demographics, the beginning and final questionnaires covered various background questions related to user motivation, usage patterns and opinions on usability and performance of mobile services.

The details of the panel are introduced in Verkasalo (2007b). In brief, most panelists were young male consumer customers. The panel consisted of early-adopter customers, as in earlier handset-based service studies (see Verkasalo 2005). 37% of panelists considered themselves either experienced or very experienced smartphone users, whereas only 19% considered themselves as beginners. 56% considered themselves as normal in terms of smartphone usage patterns.

The questions asked from the panelists in background questionnaires are listed in Appendix A. The whole dataset used in this paper consists of a questionnaire that was filled in by the panelists, together with a comprehensive set of aggregated usage-level measurements that reflect objectively panelists' actual behavior during the panel. The background questionnaire was used in obtaining data on the factors that have been found important earlier in studying technology adoption (see particularly Pedersen's research). Because of respondents' limited time, only one question was asked for each of the identified factors. Earlier statistical adoption studies have had more comprehensive questionnaires, and therefore they have the possibility to use both the measurement and structural parts of structural equation modeling. In this paper only the path model is estimated. Data is collected for the services that were identified as being of great interest at that point of time (in 2006).

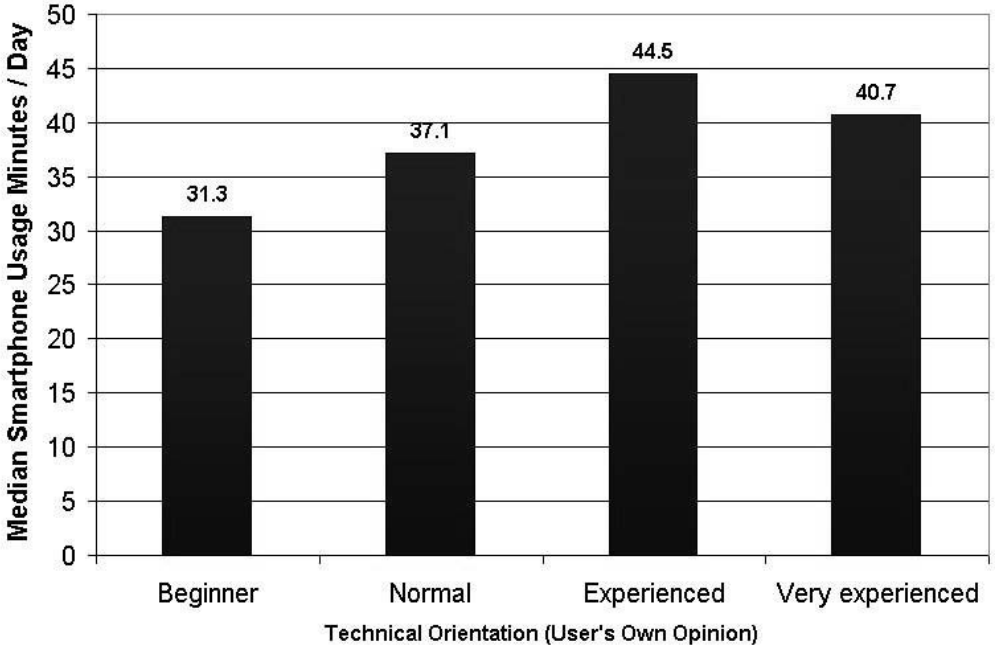
For each of these services a usage frequency variable was calculated measuring the share of days when a particular service was used out all active days spent in the panel. If a service is in constant use, this variable ranges from 50% (meaning usage every second day) to 100% (usage every day). If usage is less frequent, the usage frequency variable takes lower values. This variable well reflects the extent of use, and it is restricted to take values in the range of 0% to 100%. This variable is used as an indicator of usage in the estimated path model later in this paper.

Descriptive Statistics

Figure one depicts the user's own opinion about himself/herself in terms of technical experience with smartphones and estimated average minutes of smartphone service usage per day. More experienced users spend time with smartphone devices more than less experienced users by observation. People with stronger technical interests and capabilities should be more likely to explore new services on the one hand and more likely to learn using them and adopting the service into every day use, on the other hand. Therefore the observed results on total smartphone usage time are quite expected. Because no data on user experience was available for all of the panelists, the total smartphone usage minutes per day is used a proxy for user experience in path modeling later in this paper.

Next the focus is on particular services for which a comprehensive dataset was collected combining both questionnaires and actual usage data. Figure below projects the identified key smartphone services in two dimensions: the share of panelists who intended to use the service before the panel (*intention index*), and the share of panelists who actually used them (*usage index*). The projected diagonal line depicts the points in which the service's all users who have intentions to use the service actually used the service during the panel. In some cases it, however, might be that some users who did not intend to use the service actually used it anyways. The services that fall off the line have some bottlenecks in the

Figure 1. Correlation of technical orientation and extent of handset use



adoption process because not all of the interested panelists used them. Conversely, those services that are above the line have been adopted by more panelists than who actually intended to do so.

WEB/WAP browsing, MMS, offline multimedia and gaming have experienced usage approximately according to intentions. In other words, approximately those who intended to use the services also were able to do so. Therefore these services can be considered as sort of successes in this study. More interestingly, there are many services that lie relatively far away from the diagonal line. These include e.g. instant messaging, mobile email (both embedded email clients and webmail included) and streaming multimedia. People had intentions to use these services, but for a reason or another usage did not realize. Some bottlenecks for adoption remain for some services, whereas for some services bottlenecks are significantly lower. All services that received high usage indices (located in the upper right hand corner) have been available in the market for longer than those that received low usage indices. Clearly service maturity reflects in the results.

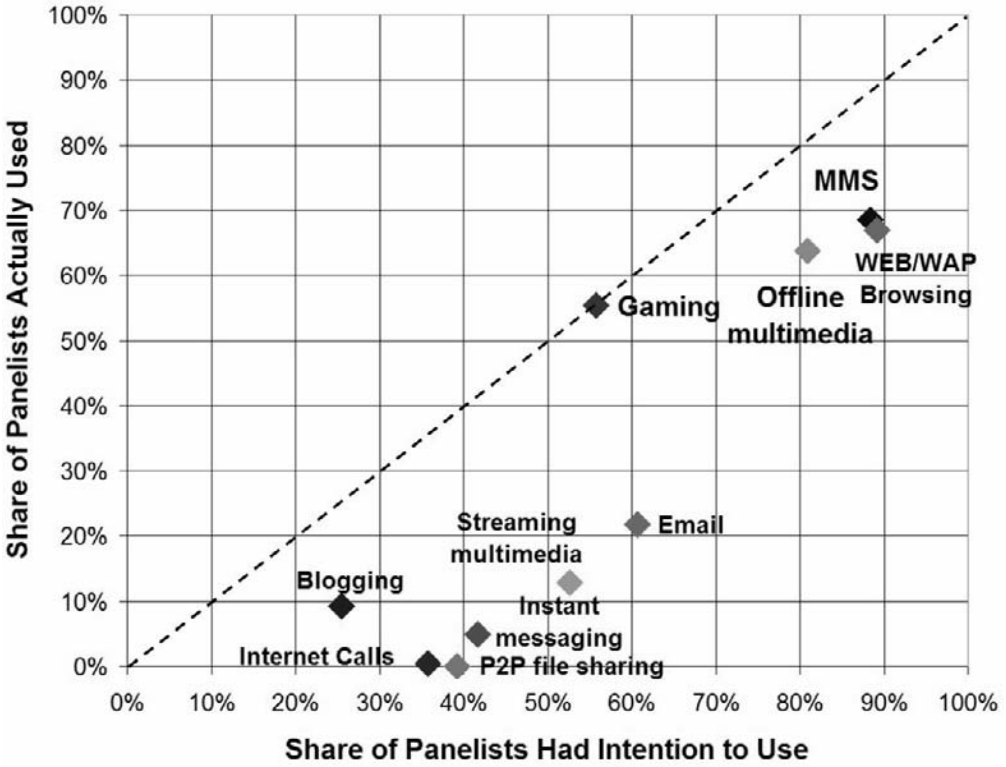
Figure two demonstrates how intentions correlate with service adoption. Those who stated they have strong interest towards the service had significantly higher adoption rates. Strong correlation between intentions and the consequent adoption process exists. As was found above, WEB/WAP browsing, MMS, gaming and offline multimedia playback catch a wide domain of those users who originally had intentions towards the particular service. On the other hand, only 60% of those who had a very strong interest to use mobile email and 33% of those who had a very strong interest to use various streaming multimedia services actually did use these services. There are many arguments to explain why certain services experience good adoption whereas some others do not. Some of these reasons include the technical difficulty to configure/use the service, immaturity of the service, unavailability of necessarily technical

help, problems in the marketing / communication functions and suboptimal pricing.

Figure three demonstrated that there exists a gap between user intention and actual usage. This is called here as the "adoption gap", as it reflects the problems in moving from intentions to actual usage. This paper develops a service *adoption index* measuring the extent of this gap. The index can be calculated by measuring the share of panelists who actually used the service out of those who intended to use it. For services that experience little bottlenecks in adoption, this should be close to 100%, whereas for services with significant bottlenecks this should be closer to 0%. Graphically all services located close to the diagonal line have high service adoption indices. The advantage of this index is that it can be used when comparing services with different customer awareness (e.g. different diffusion levels of original intention to use), as effectively the measure is normalized based to the number of people who intended to use the service (instead of all panelists).

In addition, there exists a gap between intended usage (reflecting current short term interest to explore the service) and expected future service diffusion (reflecting future expectations for the service, i.e. is the service going to succeed in the mobile market by extending the "wired" version of the service). A background question was asked with regards to users' expectations of different mobile services succeeding in the mobile market by replacing their use of the service in other platforms (e.g. desktop computers or MP3 players). This is called as an attitude towards the service variable in this research paper as it reflects positive expectations for the mobile version of the service. Rather than reflecting general attitude it reflects positive

Figure 2. User intentions and actual use of services



long-term perception of the service eventually being used by the panelist herself. *Attitude index* measures the share of panelists having a positive attitude towards the service. Further, *timing index* measures the share of panelists having positive intentions to use the service during the panel (in the short term) out of those panelists having a positive (long-term) attitude towards the service. This variable is very useful, as it normalizes the number of people intending to use the service by the number of people having long-term interest (i.e. attitude) towards the service. Therefore the timing index can be used in evaluating whether the market is ready to adopt a particular service right now, given that positive attitudes and therefore eventual latent demand for the service exist. The timing index is high if a relatively high share of interested panelists are likely to adopt a given service in the short-term, and low if service adoption is for a reason or another (e.g. unavailability of the service) not acute right now.

The table above summarizes the calculated indices for the identified services. By looking at the attitude index, it can be said that people have positive attitudes (future expectations for mobile services replacing their use of corresponding services with other devices) towards most services, the most so with regards to offline multimedia playback, MMS (replacing corresponding multimedia messaging clients in desktop computers, such as some IM clients) and mobile email. The second column (intention index), however, tells that most people have short-term interest to use only browsing, MMS, games and offline multimedia services. Indeed, the timing index is higher than 50% for these services. They are likely to generate usage right now. Some other services (having high attitude indices) might be successes further in the future according to the panelists, an example being e.g. mobile blogging which has a rather positive attitude index but low intention and consequently timing index. Also mobile VoIP (Internet calls) have promising prospects, as many people have positive long-term attitudes towards the service though no short-term interest (intention) to use the service exists. The timing index therefore reflects current propensity of taking service into use, given that there is a positive attitude towards the service. The fourth column projects the actual share of panelists having used the service during the panel, and finally adoption index in the fifth column states that only offline multimedia, browsing, MMS and gaming have been adopted without significant bottlenecks. All of these five indices can be measured over time. Longitudinal comparisons would provide visualizations on the development of services over their individual adoption curves.

The panelists themselves have opinions with regards to the key bottlenecks for new mobile services not to actually succeed in the market. All together 71 panelists were asked randomly (utilizing the pop-up questionnaire functionality in the research platform) why they think new mobile services do not survive in the market. Each respondent could pick only one answer, and the results are projected in figure four.

According to the panelists it is still pricing that has the most influence on actual usage. In other words, even though people have interests, too high a price level or suboptimal pricing structure might prevent them from using a particular service. The second most important thing the respondents identified as a bottleneck is technical implementation. Many services (according to the panelists particularly handset-embedded mobile email) are simply too difficult to use or configure, and this serves as a bottleneck. The research paper now turns to studying the adoption process in a more detailed manner by utilizing path modeling and comprehensive background data.

Path Analysis Model

Path analysis is used as a tool in verifying the theoretical hypotheses of this paper. Path analysis is an extension of multiple regression. Wright (1921; 1934; 1960) was first to utilize path analysis

in empirically studying direct and indirect effects of theoretical models. In essence, path analysis extends multiple regression by including a number of equations instead of only one (Schumacker & Lomax 2004).

Pedersen and Thorbjørnsen (2003) is used as a basis for the theoretical model developed here. Therefore factors perceived enjoyment, perceived usefulness, social push (called in other contexts as subjective norm) and behavioral control (i.e. perceived ease of use) are included to have either direct or indirect (mediated by attitude) effect on intention to use. The perceived expressiveness variable is not included in this model to keep it simpler. After all, it has not been included in all of the earlier TAM models. For the attitude variable a question was asked with regards to a particular service having already replaced or replacing potentially in the future the existing use of the service with e.g. computers or MP3 players. If people have a positive attitude towards the service, they answer positively to this question. Each factor is measured by a single question, listed in Appendix A. Due to limited data (and consequent unobserved uncertainty) the developed path model does not work that well by itself. However, the path models estimated for each of the services can still be compared against each other in analyzing the role of each factor in the context of a cross-service study. The original TAM model assumes that demographics (such as gender and age) and many other background variables are totally mediated out by the included independent factors in the extended TAM model. This simplifies the analysis.

Because of the variety of data available not only related to background variables but also on actual usage, the theoretical model is extended to include a factor reflecting actual usage (usage frequency of the service). Actual use is depicted to depend on intention to use, technical capability of the phone (the handset features serve either as a bottleneck or enabler), data pricing (lower marginal data prices should push services that generate data charging records), monetary pool available for smartphone usage (more monetary resources should have a positive impact on service usage that generate charging records) and user experience

Figure 4. Reasons for the failure of new mobile services

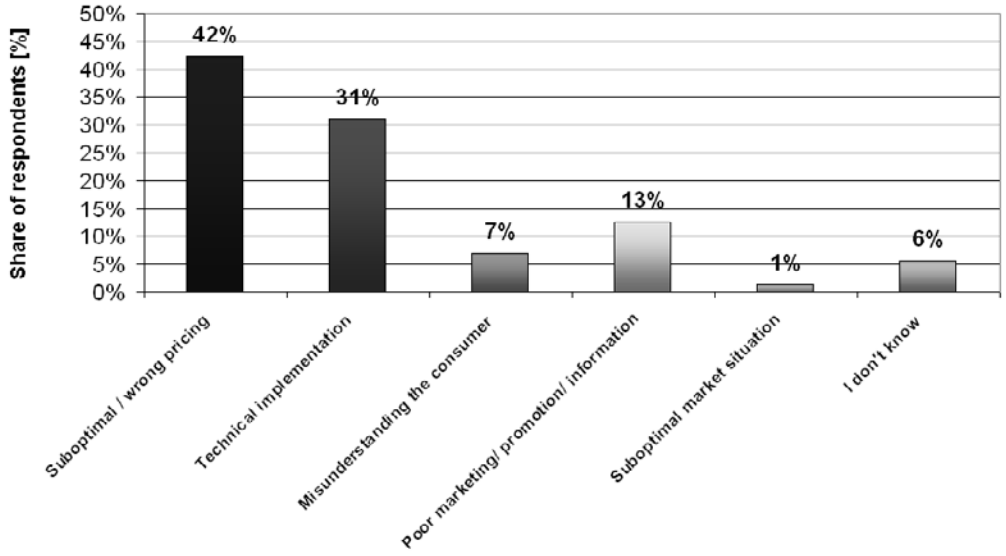


Figure 5. Developed theoretical path model of mobile service adoption

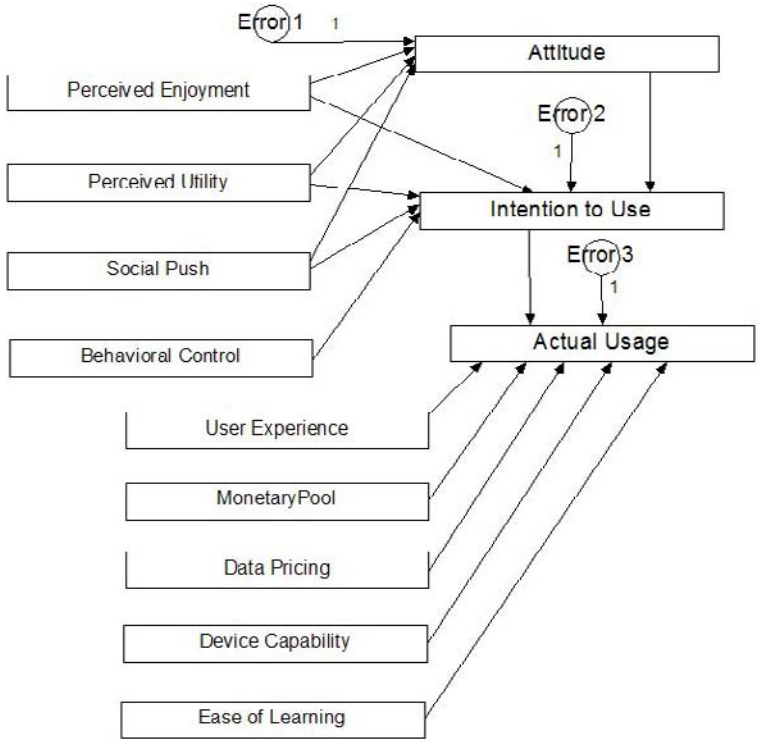

(more experienced users should be more likely to be capable of using the service). The technical capability of the phone is a boolean variable taking value 1 if the handset is based on Nokia S60 3rd edition platform (all new Nokia smartphones) and 0 otherwise (older Nokia S60 handset). Data pricing takes values 0 (no data plan, expensive usage-based charging), 1 (block-priced data plan, relatively cheaper to use data services) and 2 (flat-rate, unlimited usage with zero marginal cost). Monetary pool is proxied through ABPU (average billing per user) rates of subscribers, hypothesizing that high average bills of the past reflect the user's mobile service budget. User experience is here communicated through estimated average minutes of smartphone usage per day (that has strong correlation to user's experience according to a smaller sample of data).

One more variable is included to reflect a positive perceived easiness of learning and ease of getting help (i.e. facilitating conditions in actually using the service) for the service. This is projected to have a direct impact on actual use. The behavioral control variable introduced earlier better reflects the expected difficulty of use thus having implications in the initial intention to use, whereas the ease of learning component is hypothesized to be relevant if the initial interest towards the service exists and the problem is how to actually use the service given positive intentions.

The models are estimated with AMOS (add-on package for SEM in SPSS), using the maximum likelihood approach. Because there are missing data points (not all people answered the questionnaires), only panelists with full data are included.

All in all, 426 panelists are included in the path estimation.

Results of Path Analysis

The estimated path analysis diagrams for the chosen services are depicted in Appendix B. The figures include path coefficients (above the paths) and for dependent variables the share of variance explained by the model (above the box representing the variable). Some model fit indices are reported, too. First, a fit index CMIN/DF is included - the relative chi-square that represents how much the fit of data has been reduced because one or more paths have been dropped from the full model. Generally if this index is more than 3, too many paths have been dropped. The second included fit index is GFI (goodness of fit index). This tells how much of the variance in the sample variance-covariance matrix is accounted for by the model. Generally this should be above 0.9. Finally RMSEA (root mean square error of approximation) estimates lack of fit if compared to the full model. 0.08 or below is considered generally as adequate fit.

By looking at the results in Appendix B, the first observation is that the fit indices are quite poor. In other words, the developed model is perhaps not the best one to explain the involved complex relationships. GFI indices range from 0.82 (IM and email) to 0.86 (browsing). The second observation is that the model quite poorly explains the dependent variables under interest. The variance explained for the intention to use variable range from 0.05 (blogging) to 0.24 (gaming and MMS). The variance explained for the actual usage variable range from 0.01 (blogging) to 0.27 (gaming). Lots of uncertainty (e.g. non-internalized variables) exists that would explain intentions and actual usage, and the model therefore cannot depict all of the variance in the dependent variables. Almost all of the variables included in the framework model the demand-side, and therefore the missing (explanatory) variables are probably related to supply-side factors (e.g. service push, pricing and availability).

Without going into the details of each service (the estimated path models can be found from Appendix B), the table below summarizes the statistically significant path coefficients for each service.

It is surprising that perceived enjoyment has very strong impact on attitude for all services. People who think the enjoyment value is high (for any service) have high expectations that they are going to replace existing use of the service with the mobile version of the service (this is here called considered positive attitude). Perceived enjoyment positively (and statistically significantly) drives intentions directly, too. It can be generalized that the advanced mobile service market in Finland is building on expected hedonic benefits even in services which have been generally considered business-oriented (email).

Further, utilitarian benefits are important, too. The impact towards attitude is positive for all services expect for streaming multimedia, though the relationships are not as strong as with hedonic benefits. Interestingly the positive forward-looking attitude towards mobile instant messaging is strongly pushed by perceived utilitarian benefits. This confirms that instant messaging is a viable communication channel rather than a service meant for entertainment purposes solely. The direct impact of perceived utility on intentions is not that strong as the impact of perceived enjoyment (hedonic benefits), but the model nevertheless confirms that the intentions to use browsing, MMS, email (strong effect), blogging and IM are at least partly driven by utility-related expectations. Expectedly perceived utility does not drive offline multimedia playback, gaming or streaming multimedia usage intentions, because they are quite entertainment-oriented by nature.

Social push is all about the impact of supportive/driving social context with regards to usage attitude and/or intentions. Social push has positive impacts particularly on email and instant messag-

Table 2. Statistical significance of estimated paths

ing. This can be explained by the fact that these services are currently available, and the marginal impact of somebody in the close social neighborhood helping or recommending the service might be significant to drive attitude towards possible future use. The direct effect of the social push on intention to use is not very strong for any of the other services, communicating the fact that these early-adopter users are quite independent.

Behavioral control measures the user perception of herself being capable of using the service and to overcome technical challenges. Particularly for browsing and gaming this factor is a significant driver of intentions, whereas for most other services it has a positive though less significant effect. The statistical significance for the path originating from behavior control is generally not that strong. This might be due to the fact that Hejden et al. (2005) hypothesized that for hedonic services behavioral control does not have that strong an impact. For MMS there is no relation at all, as MMS is already well integrated into smartphones and thus there is little variance in end-user behavioral control.

The TAM model suggests that attitude towards the service should drive intentions. The attitude variable included in this research is geared towards current or future role of the mobile service possibly replacing existing use of the service with other devices (e.g. laptops or MP3 players). Therefore this variable is not reflecting general attitude in the purest sense. There is a statistically significant relation between attitude and intention only for mobile email. Positive mobile email attitude levels correlate strongly with positive intentions. People who think mobile email is or will be an important part of their smartphone usage in the future also have strong short-term intentions of using the service. For many other services the effect of attitude on intention is statistically insignificant. This can be explained by the fact that people generally perceive that these new advanced services are unavailable / technically poor, and therefore they lack short-term intentions of use though there is a positive general attitude. Another argument is relatively stronger effects of direct effects of background variables. In other words, rather than for many background factors having an indirect impact via positive attitude that the service would replace something (having a flavor that something else is sacrificed), for example perceived enjoyment or utility directly drive intentions and these relations are very strong.

When moving to actual use of services, it becomes clear that the variables hypothesized to have direct effect on realized usage are important. User experience (proxy through average usage minutes per day) has statistically significant relationships with actual usage of browsing, MMS, offline multimedia playback and gaming. These are services users have probably used already earlier with their smartphones, and therefore experience variable strongly drives usage. For some very new services such as email, IM or streaming the experience variable does not have a statistically significant effect. This might be because earlier experience relates to services that have been in the market already for some time (on which experience can accumulate), whereas experience does not help with regards to services that are just about to hit the market or are available later in the future.

Monetary pool has a strong effect on MMS usage, which has strong correlation with other mature service (such as voice and SMS) usage. In other words, higher consumption levels on mobile telephony do not drive any of the truly new service categories. First, some services are simply free and they do not depend on consumption levels or available monetary pool but on e.g. perceived enjoyment instead. Second, still most of the ABPU (average billing per user) rate consists of voice and SMS service charging, and therefore it does not reflect data service prices/consumption that well. All of the services that require network connectivity in this research are based on IP connectivity and are therefore independent of circuit-switched service pricing.

Data pricing (the lower marginal cost of using data services) has the most significant relationship expectedly with browsing usage. Browsing is currently the most important data (Internet) service. There is also weaker (but still statistically significant) effect on email usage. However, for other data services data pricing does not have an effect. This is partly due to little actual usage realized for other than browsing data service.

Interestingly device capability has the biggest influence on email and multimedia functionalities. The impact on multimedia is not a surprise, as if nothing else, new handsets include at least better multimedia functionalities (camera chips, memory capacity, MP3 player functionalities, better displays for movie/video playback) than older ones. The marginal email usage is coming from webmail oriented email usage. This is partly driven by better browsers included in newer handsets together with new high-resolution displays. This explains the path from device capability to email usage.

Ease of learning variable does not have an impact on actual usage at all. These early-adopter users, after all, all know that there is help available

for example in the Internet. On the other hand, they also tend to play around with the handset by themselves rather than think that they need somebody else for help, not to talk about manuals that are shipped with new handsets.

Finally, the most important variable in the model (intention to use) has statistically significant effects on all service usage expect for blogging. As concluded already earlier with descriptive statistics, people who have strong intentions to use the service tend to adopt the service (use it in practice) with a higher probability than those who do not have intentions. Blogging has not been used by that many, and therefore intentions cannot correlate with usage. Most blogging usage comes actually from Nokia's preinstalled Lifeblog application. Because of this it can be that those who explored blogging merely randomly launched Lifeblog, even though they did not have clear intentions. All in all, usage intentions are still the most important driver of advanced mobile service usage, therefore suggesting that the needs of end-users are the key issue in bringing new mobile services to the market instead of push-centric service introduction strategies.

A couple of reasons exist for the general poor fit of the estimated models. First, these are advanced services, and there are probably many random factors that lead into a usage event. The service must be in the market available for panelists and the technical performance/accessibility has to be in order. These are some of the variables the model cannot internalize, and this explains the poor share of variance explained for usage-level variables. Similarly intentions originate from many other factors (in advanced services) than those included in the model. For example, promotional events and availability of the service certainly do affect the short-term intention to use a service. These variables are not included in the model. In many cases these reasons explain the poor fit of the model. Indicative results suggest that the depicted theoretical model is not the optimal one. For example mobile blogging is a rather new service on which customers have very little or limited knowledge on. For this service most paths are insignificant and model fit is very poor. In addition, it is difficult to explain the variance of dependent variables if these variables have no or very little variance. Gaming is a well-known service and the market-level factors (e.g. operator competition, network performance, pricing, promotional events) have less impact. Therefore the theoretical adoption model receives much better results for gaming than for blogging, for example.

CONCLUSION

The paper utilized a newly developed handset-based mobile service research platform in deploying questionnaires and measuring actual usage of mobile services. This study differs from other handset-based research in its specific focus on the adoption process and associated measurements, utilizing also questionnaires. Descriptive statistics reveal that for most services not all mobile service demand (i.e. usage intentions) is fulfilled, i.e. not all panelists interested in services are actually using them. However, those strongly intending to use the service, ceteris paribus, expectedly have higher probabilities of adopting the service in practice.

The paper developed five indices that can be measured over time and therefore utilized in longitudinal analysis. These indices communicate the general attitude towards mobile services (attitude index), short-term intentions of usage (intention index), the current propensity of taking services into use (timing index), the extent of service usage (usage index) and the probability of using the service given intentions exist (adoption index). These indices communicate that panelists on average have positive attitudes towards mobile versions of the services included in the study, but only matured mobile services (introduction more than a year ago) experience positive short-term

intentions of usage and consequent adoption. Different services are clearly experiencing different phases of their life-cycle at this point of time. The developed indices can be utilized in projecting the phase of diffusion for each service emerging in the market.

The estimated path models reveal that perceived hedonic (enjoyment) benefit is the strongest driver of both attitude and intention towards the service. This is in contrast to Pedersen and Thorbjørnsen (2003) who found that utility-centric benefits drive intention to use mobile services. In the estimated models of this paper perceived utility drives intention to use only in the case of mobile email. In general, many of the newly developed mobile services should be considered as generating hedonic rather than business/utilitarian value to end-users. The social setting around panelists or expected technical difficulties do not explain intentions to use. This is most likely due to panelists in the dataset being early-adopters (quite independent and technically advanced users). User experience with smartphones explains actual use of services that have already been in the market for some time, but experience of the user does not explain the adoption of the most recent services. Pricing of data traffic has a strong effect only on browsing and email as they are the most visible mobile Internet services currently. Multimedia services, on the other hand, benefit from higher capability of handsets. The most important thing driving actual use of services, however, is the intention of end-users to use the service, and therefore user needs should be looked upon in the future instead of technology push strategies.

The estimated path models do not have very good fit. Instead of using standardized sets of questions and structural equation modeling in verifying the theoretical model, a more simplified path modeling exercise was chosen due to limitations in the panel study implementation. Improvement of the theoretical model remains as a future work task in addition to the acquisition of more comprehensive dataset supporting not only path but also measurement part of the SEM analysis. One of the key conclusions of this paper is, however, that the internalized variables of the estimated adoption model poorly explain the variance observed in intention and usage-level variables. Therefore most advanced mobile services have special characteristics and external sources of variance that were not observed in this analysis. These likely originate from the supply side of the market. Nevertheless, the demonstrated fitting of empirical data with path analysis was found to be an efficient method to compare the role of different variables in explaining the adoption of emerging mobile services.

Some mobile services are truly successful in the market, whereas some others are hyped quite a lot but few people actually adopt them. A need exists to acquire data on user opinions and service usage in order to understand the actual dynamics of mobile service adoption. This understanding is valuable in e.g. better commercializing mobile services and in improving mobile customer relationship management processes (for mobile CRM see Liljander et al. 2007). This paper showed that new handset-based data can help in better understanding the mobile service adoption process. The research differed from other handset-based research in focusing on the modeling of the adoption process, and combining efficiently questionnaire data with usage data. The paper introduced many new indices that reflect the different sides of the adoption process, and additionally demonstrated that different services can be compared against each other with the handset-based research approach. Future handset-based research should deploy wider questionnaires to make the statistical procedure of path modeling more reliable. In particular, the measurement part of the analysis should be deployed before estimating the structural part of the path model. In addition, a wider perspective towards the adoption process should be taken. For example, potential long-term usage should be better modeled against potential

short-term usage, and reasons why explorative usage sometimes does not lead to sustainable and repetitive usage should be looked upon.

APPENDIX A: QUESTIONS ASKED IN THE BACKGROUND QUESTIONNAIRE

Background factors are recoded into the following scale:

- ABPU... 1 (small) - 5 (big) (asked before the panel)
- Work... 0 (not) - 1 (yes) (asked before the panel)
- Age... 0 (young) - 1 (old) (asked before the panel)
- Gender... 0 (women) - 1 (men) (asked before the panel)
- Device_Capability... 0 (old device = lower capability) - 1 (new device = higher capability) (asked before the panel)
- Data_Pricing... 0 (usage-based), 1 (block-priced), 2(flat) (asked before the panel)
- Experience (of smartphone usage in the user's own opinion)... 1 = Beginner, 2 = Normal, 3 = Experienced, 4 = Very experienced (asked before the panel)
- Panel_Days... Number of days observed active in the panel (derived from usage data)
- Handset_Usage_Activity... Number of application activations during an average day (derived from usage data)
- Smartphone_Usage_Day... Minutes of smartphone usage on an average day (derived from usage data)

Questions are asked in relation to the following mobile services:

- WEB/WAP services, Internet browsing
- Email
- Instant messaging / chat
- MMS messaging
- Gaming
- Internet telephony
- P2P file sharing
- User-created content creation, blogging
- Streaming/Internet multimedia
- Offline multimedia

1. I intend to use the following services during the next couple of months… (intention to use) (asked before the panel)
2. Mobile versions of the following services are going to replace / have already replaced the use of those services with other devices (such as PCs, MP3 players, Radio)... (attitude) (asked after the panel)
3. The use of the following services generates enjoyment, pleasure and entertainment to me... (enjoyment value) (asked after the panel)
4. The use of the following services increases my work or study related productivity and performance... (utilitarian value) (asked after the panel)
5. I do not have / would not have significant technical difficulties in using the following services... (behavioral control) (asked after the panel)
6. It is easy for me to learn and develop my skills in using the following services... (ease of learning) (asked after the panel)
7. People around me (e.g. friends or family) have recommended the use or have helped me in using the following services... (social push) (asked after the panel)

Likert scale answers:

1 = Strongly disagree, 2 = Disagree, 3 = Slightly disagree, 4 = Neutral, 5 = Slightly agree, 6 = Agree, 7 = Strongly agree
